Solvent responsive catalyst improves NMR sensitivity via efficient magnetisation transfer

Amy J. Ruddlesden and Simon B. Duckett*

A bidentate iridium carbene complex, $\text{Ir(C,O-L)}_2$(COD), has been synthesised which contains a strongly electron donating carbene ligand that is functionalised by a cis-spanning phenolate group. This complex acts as a precursor to effective magnetisation transfer catalysts which form after reaction with $\text{H}_2$ and a suitable two electron donor. In solvents such as benzene, containing pyridine, they are exemplified by neutral, chiral $\text{Ir(H)}_2([\text{C,O-L}](\text{py}))$, with inequivalent hydride ligands and Ir-O bond retention, whilst in methanol, Ir-O bond cleavage leads to zwitennionic $[\text{Ir(H)}_2([\text{C,O-L}'](\text{py}))]\text{Cl}$, with chemically equivalent hydride ligands. The active catalyst’s form is therefore solvent dependent. Both these complexes break the magnetic symmetry of the hydride ligands and are active in the catalytic transfer of polarisation from $\text{parahydrogen}$ to a loosely bound ligand. Test results on pyridine, nicotinaldehyde and nicotine reveal up to ≈ 1.2% single spin proton polarisation levels in their $^1\text{H}$ signals which compare to the normal 0.003% level at 9.4 Tesla. These results exemplify how rational catalyst design yields a solvent dependent catalyst with good SABRE activity.

The use of hyperpolarisation methods to overcome the inherent insensitivity of NMR spectroscopy reflects an area of research where $\text{Para}$hydrogen Induced Polarisation ($\text{PHIP}$) features heavily. The incorporation of $\text{parahydrogen}$ ($\text{p-H}_2$), a nuclear singlet, into a molecule was first shown to produce an enhanced NMR signal in 1987. The increase in signal intensity for resonances arising from, or coupled to, p-H$_2$ derived protons, has since been the subject of intense investigation. Recently a p-H$_2$ technique that does not chemically change a molecule, called Signal Amplification By Reversible Exchange (SABRE), has been developed. Polarisation is transferred through J-coupling between the p-H$_2$ derived hydride ligands and the substrate ligands. Exchange with free substrate and fresh p-H$_2$ enables the build-up of polarisation in the substrate pool through multiple visits to the catalyst. The most commonly used catalysts are cationic species which contain either phosphine or N-heterocyclic carbene (NHC) ligands.

In fact, one of the most effective magnetisation transfer catalysts is $\text{Ir(COD)(IMes)}\text{Cl}$ [where IMes = 1,3-bis(2,4,6-trimethylphenyl)imidazole-2-ylidene, COD = cyclooctadiene] which forms the charged complex, $[\text{Ir(H)}_2(\text{IMes})(\text{substrate})]\text{Cl}$ once activated with H$_2$ and a substrate. This SABRE catalyst contains chemically equivalent but magnetically inequivalent hydride ligands and polarisation transfer has proven particularly efficient in polar protic solvents such as methanol. Furthermore, using this catalyst a wide range of substrates including nicotinamide, isoniazid and pyrazole have been shown to become hyperpolarised. This type of approach has been exemplified for $^1\text{H}$, $^{13}\text{C}$, $^{31}\text{P}$, $^{19}\text{F}$ and $^{15}\text{N}$ nuclei. However, due to the charged nature of such a species, it has proven less efficient in the range of low polarity solvents commonly used in NMR analysis.

It has also been shown that species with chemically inequivalent hydride ligands can act as SABRE catalysts. One reported example of this class of catalyst is given by $[\text{Ir(H)}_2(\text{CH}_3\text{CN})(\text{IMes})(\text{PCy}_3)(\text{pyridine})]\text{Cl}$. Recently, a system that exhibits a wider solvent tolerance has been developed. It contains a bidentate ligand which binds through carbene and phenolate centres, resulting in a neutral catalyst in all solvents tested. While it was found to exhibit greater activity in non-polar solvents such as benzene, it was not efficient in methanol due to much slower ligand exchange.

In this study, the related neutral iridium complex, $\text{Ir(C,O-L)}_2$(COD), 1, [where L$_1$ = 3-(2-methylene-phenolate)-1-(2,4,6-trimethylphenyl)imidazolylidene], has been synthesised starting from salicylaldehyde. It contains a cis-spanning phenolate-substituted bidentate NHC (see Scheme 1). Benzyl protection of the phenol allowed conversion of the aldehyde to the bromide via the alcohol. Addition of 1-(2,4,6-trimethylphenyl)-1H-imidazole then formed the imidazolium bromide salt. Deprotection followed by silver carbene formation and subsequent transmetallation afforded the product, the phenoxide iridium carbene complex, 1. Key experimental details, synthesis and characterisation of compounds, SABRE experiments, kinetic data, activation parameters, UV-vis data. See DOI: 10.1039/x0xx00000x
In solution, complex 1 appears yellow/orange in colour. UV-Vis analysis in DCM showed it exhibits three absorption bands in the visible region of the spectrum (373, 425 and 490 nm) with absorption coefficients in the range of charge transfer transitions (1017, 1326 and 249 dm$^3$ mol$^{-1}$ cm$^{-1}$). Work by Perutz et al. has assigned similar bands in related square planar metal complexes to metal d-p transitions although earlier assignments suggested they were metal-to-ligand charge transfer bands.

At room temperature, the $^1$H NMR spectrum of complex 1 in CD$_2$Cl$_2$ yields well resolved resonances (see Figure 1). Two doublets at δ 6.53 and 5.17 are observed for the CH$_2$ linker protons which have a common $^3$$J$(HH) coupling of 14.9 Hz. These two protons are diastereotopic due to the seven-membered metallocycle which is indicative of the retention of the Ir-O bond. Complex 1 is air/moisture sensitive but stable as a solid and in solution under N$_2$. It also forms stable complexes once fully reacted with substrate and hydrogen as detailed in the following reactions.

Upon cooling a CD$_2$Cl$_2$ solution of complex 1 to 243 K all of its NMR signals become broad and undefined due to fluxional behaviour and when pyridine is added to this solution no reaction is evident. If, however, H$_2$ gas is added at 255 K, a limited reaction occurs as two pairs of hydride signals are now seen at δ −12.35 and −18.25 (1.7 % conversion) and at δ −12.39 and −17.64 (0.6 %). These minor hydride containing products are conformational isomers of compound 2 (see Scheme 3) which arise due to differing metallocycle orientations, analogous behaviour has been reported.

When p-H$_2$ is used in this reaction, these hydride ligand signals do not show any significant $^1$H NMR signal enhancement. However, the free H$_2$ signal in these spectra is substantial which suggests that 1 undergoes rapid and reversible oxidative addition of H$_2$ to form 2 which consumes the p-H$_2$. There is no indication of the hydrogenation of COD at 255 K and upon warming to 298 K, these hydride signals broaden into the baseline of the corresponding NMR spectra and strong signals for 1 are always visible.

When a CD$_2$Cl$_2$ solution of 1 reacts with both pyridine and H$_2$ at 298 K a new neutral iridium species, Ir(H$_2$)(xpy)(py)$_2$, is observed to slowly form containing two bound pyridine environments in a ratio of 1:1 (see ESI for details). This species is also formed in C$_6$D$_6$. The mutually coupled inequivalent hydride signals appear in CD$_2$Cl$_2$ at δ −22.55 and −25.49 ($^3$$J$(HH) = 8.1 Hz) and in C$_6$D$_6$ at δ −21.94 and −24.52 ($^3$$J$(HH) = 7.7 Hz). Their inequivalence suggests Ir-O bond retention, a fact which is further supported by the diastereotopic nature of the CH$_2$ linker protons which appear as doublets in both CD$_2$Cl$_2$ and C$_6$D$_6$. Both complexes undergo pyridine and H$_2$ exchange as highlighted in Scheme 2, although only the pyridine ligand trans to hydride dissociates. The use of EKSY NMR experiments enabled determination of experimental rate constants for pyridine loss in 3 at 294 K of 3.74 ± 0.06 s$^{-1}$ in CD$_2$Cl$_2$ and 13.5 ± 0.6 s$^{-1}$ in C$_6$D$_6$. The corresponding H$_2$ loss rates were 0.80 ± 0.01 s$^{-1}$ and 3.02 ± 0.07 s$^{-1}$ respectively and are therefore much slower than those of pyridine loss.

This behaviour changes significantly upon moving to protic methanol. Now, the addition of H$_2$ to a CD$_3$OD solution of complex 1 at 250 K, results in a very limited reaction to form a dihydride (< 1 %, with resonances at δ −12.65 and −18.27 and the low concentration presumably prevents observation of its conformational isomer) but upon warming further, rapid and total decomposition of 1 follows. In contrast, the addition of pyridine to a CD$_3$OD solution of complex 1 at 243 K forms the phenolate dissociation product, square planar 4 quantitatively (see Scheme 3 and ESI) where the COD ligand yields four inequivalent alkene proton resonances.

Upon the addition of p-H$_2$ and pyridine to 4 at 243 K, two PHIP enhanced hydride signals become immediately visible at...
δ ~ 12.34 and ~17.50 that are shown to couple via COSY. They arise from H₂ addition to 4 which initially forms the alkene dihydride complex, 5. The CH₂ linker protons of 5 remain diastereotopic on phenolene rotation due to the absence of a mirror plane. Upon warming to 265 K, this system evolves further and a single hydride signal becomes visible at δ ~ 22.18 due to the formation of [Ir(H₃)(tacn)O⁻₂⁻][py]₃]⁺, 6; the COD is converted to cyclooctene. Further NMR analysis, confirms that 6 contains two bound pyridine ligand environments, in a 2:1 ratio, two hydride ligands and an iridium-carbene bond. Its CH₂ linker protons are now equivalent, appearing as a singlet at δ 4.83 due to the existence of a mirror plane as detailed in Scheme 3.

Scheme 3. Species formed during the reaction of 1 with H₂ and pyridine in CD₃OD (4, 5 and 6) and CD₂Cl₂ or CD₂OD (2 and 3) solution.

Complex 6 is zwitterionic, and its cationic Ir(III) centre is balanced by phenoxide ion formation. Hence the final reaction product formed from 1 with pyridine and H₂ is solvent dependent. The two pyridine ligands of 6 that lie trans to hydride are shown to dissociate with an experimental rate constant of 1.35 ± 0.03 s⁻¹ at 294 K, although no exchange of the pyridine trans to the carbene is observed. In CD₂OD, rapid H/D exchange, accompanied by HD formation, is observed which prevents the quantification of the H₂ loss rate in this solvent. At 294 K, the ligand exchange rates of species 3 in CD₂OD are therefore much faster than those in CD₂Cl₂, but both are faster than those of 6 in CD₂OD as shown in the ESI.

The ligand exchange rates of 6 in CD₂OH were examined as a function of temperature and activation parameters for these processes were calculated (see ESI). The activation enthalpy values for both pyridine and hydride loss are very similar to each other (90.7 ± 1.6 kJ mol⁻¹ and 88.3 ± 9.1 kJ mol⁻¹ respectively). The entropy of activation values of 71.3 ± 5.3 J K⁻¹ and 56.1 ± 30.6 J K⁻¹ for pyridine and hydride loss respectively are also similar and positive thereby confirming the dissociative character of these steps. Similar ligand exchange processes, in a series of related complexes, yield values of similar size. A ligand exchange mechanism featuring reversible pyridine dissociation with H₂ loss via [Ir(tacn)O⁻₂⁻][H₂][H₂][py]₃]⁺ is therefore indicated.

Both catalysts 3 and 6 therefore exhibit the substrate and H₂ exchange characteristics required for them to act as SABRE catalysts. To test their substrate signal enhancing performance, samples were prepared containing catalyst 1 and a chosen substrate in the desired NMR solvent. These were rigorously degassed before the addition of 3 bars of H₂.

Samples were tested by reintroducing p-H₂ into the headspace of the NMR tube, shaking the sample in the low field outside of the spectrometer and then rapidly transferring the sample into the spectrometer for examination. This resulted in the observation of enhanced signals in the corresponding single scan ¹H NMR spectra for the hydride ligands, bound substrate and free substrate in solution as exemplified by Figure 2. The total enhancement value seen for the five protons of pyridine in C₆D₆ proved to be 1850-fold under the conditions detailed.

For CD₂Cl₂ this enhancement level was reduced to ca. 1660-fold whilst for CD₂OD solution it became 710-fold. Given the corresponding gain in signal-to-noise levels that these enhancements provide, the resulting time savings are substantial in all solvents. For comparison purposes, the site specific enhancement values for the substrates pyridine, nicotinaldehyde and nicotine are summarised in Table 1. The performance of 1 as a SABRE catalyst for pyridine like substrates has therefore been established.

![Figure 2. Thermally polarised and hyperpolarised ¹H NMR spectra of a CD₂Cl₂ solution containing 0.06 M pyridine, 11 mol% 1 and 3 bars p-H₂. The enhanced signals for free and bound pyridine (in 3) and the corresponding hydride ligands are indicated.](image)

It is known that the amount of signal enhancement observed in the ¹H NMR spectrum of a substrate under SABRE is significantly affected by the ligand exchange rates, as previously explained by Green et al. For comparison, [Ir(H₂)(1-IMes)(py)]Cl, is commonly used as the catalyst benchmark for SABRE and its pyridine dissociation rate was
found to be 23 s⁻¹. While the ligand dissociation rates for 3 and 6 are much lower, they still achieve good hyperpolarisation levels. In fact, these data show that one pyridine substrate trans to hydride in CD₂Cl₂ or CD₆D₂ is more efficient at receiving SABRE than the two equivalent pyridine ligands of 6 in CD₂OD. Furthermore, the concept of an active solvent responsive catalyst is illustrated.

In summary, the iridium precatalyst Ir\((\text{C}_{6}\text{H}_{5})_{\text{Cl}}\)(COD), 1 containing a phenol substituted NHCH has been synthesised and shown to act as an efficient SABRE catalyst precursor. The active catalytic species is solvent dependent. Complex 1 contains an Ir-O bond which is affected by solvent polarity and proton availability; in non-polar CD₂Cl₂ and polar aprotic CD₆Cl₂, this bond is strong and substitution resistant with 1 forming \(\text{Ir}\{\text{C}_{6}\text{H}_{5})_{\text{Cl}}\}(\text{H})\)py)₃ (3) on reaction with H₂ and pyridine. In contrast, on changing to polar protic methanol, the Ir-O bond becomes labile and the phenolate easily dissociates from the iridium centre, such that zwitterionic \(\text{Ir}\{\text{C}_{6}\text{H}_{5})_{\text{Cl}}\}(\text{H})\)py)₃] (6) forms. 6 is directly analogous to the efficient SABRE catalyst \(\text{Ir}\{\text{H})\text{(Mes)}\text{py})\text{Cl}\) which performs well in CD₂OD but has lower activity in non-polar CD₂Cl₂ and CD₆D₂. Both 3 and 6 undergo pyridine and H₂ exchange thereby enabling them to act as SABRE catalysts, whilst 6 works well in CD₂OD, catalyst neutrality in the non-polar solvents CD₂Cl₂ and CD₆D₂ results in the formation of 3 which is highly active for SABRE catalysis. This study therefore shows that catalyst design and control can lead to improved magnetisation transfer in a range of solvents, a requirement for future studies that seek to identify low concentration analytes and to produce hyperpolarised MRI contrast agents.
