BACKGROUND
Cortical-bone fragility is a common feature in osteoporosis that is linked to non-vertebral fractures. Regulation of cortical-bone homeostasis has proved elusive. The study of genetic disorders of the skeleton can yield insights that fuel experimental therapeutic approaches to the treatment of rare disorders and common skeletal ailments.

METHODS
We evaluated four patients with Pyle’s disease, a genetic disorder that is characterized by cortical-bone thinning, limb deformity, and fractures; two patients were examined by means of exome sequencing, and two were examined by means of Sanger sequencing. After a candidate gene was identified, we generated a knockout mouse model that manifested the phenotype and studied the mechanisms responsible for altered bone architecture.

RESULTS
In all affected patients, we found biallelic truncating mutations in SFRP4, the gene encoding secreted frizzled-related protein 4, a soluble Wnt inhibitor. Mice deficient in Sfrp4, like persons with Pyle’s disease, have increased amounts of trabecular bone and unusually thin cortical bone, as a result of differential regulation of Wnt and bone morphogenetic protein (BMP) signaling in these two bone compartments. Treatment of Sfrp4-deficient mice with a soluble Bmp2 receptor (RAP-661) or with antibodies to sclerostin corrected the cortical-bone defect.

CONCLUSIONS
Our study showed that Pyle’s disease was caused by a deficiency of sFRP4, that cortical-bone and trabecular-bone homeostasis were governed by different mechanisms, and that sFRP4-mediated cross-regulation between Wnt and BMP signaling was critical for achieving proper cortical-bone thickness and stability. (Funded by the Swiss National Foundation and the National Institutes of Health.)
OSTEOPOROSIS IS A SKELETAL DISEASE that is characterized by low bone mass, defective bone structure, and a high risk of fracture. Cortical-bone mass is a major determinant of bone strength and therefore of susceptibility to fractures. With aging, the mass of cortical bone may decrease more than the mass of trabecular bone, and fractures occurring in older persons result mostly from cortical-bone fragility. Although progress has been made in therapeutic approaches to reducing the risk of vertebral fracture (which occurs at sites rich in trabecular bone), currently available treatments do little to reduce the risk of nonvertebral fracture, which results mostly from cortical-bone fragility.\textsuperscript{1,3}

Pyle's disease (Online Mendelian Inheritance in Man [OMIM] number, 265900) was described in 1931 by Edwin Pyle, an orthopedic surgeon in Connecticut, as a “case of unusual bone development”; it was described again in 1933, by the German radiologist Max Cohn, as “spongious hypertrophy of bone.” Pyle's disease is characterized by long bones with wide and expanded trabecular metaphyses, thin cortical bone, and bone fragility.\textsuperscript{4,7} Fractures are common in Pyle’s disease, and fracture lines usually go through the abnormally wide metaphyses, revealing their fragility. We considered that unlike other mendelian disorders that affect overall bone density,\textsuperscript{8} Pyle's disease seems to be a disorder of bone architecture, and an understanding of its pathogenesis might offer insights into cortical-bone homeostasis.

We evaluated four patients with Pyle's disease, by means of exome sequencing or Sanger sequencing, to identify the genetic basis for the disorder. After a candidate causal gene was identified, we studied a knockout mouse model to determine the role of the gene in the pathogenesis of Pyle’s disease, in skeletal development and homeostasis, and in determining the strength of trabecular and cortical bone, as well as to test methods of treatment.

METHODS

PATIENTS

Patients 1 and 2 were a brother and sister who were referred for skeletal deformity at 16 and 14 years of age, respectively. The parents were first-degree cousins originating from Turkey; they were healthy and of normal height. The motor and mental development of Patient 1 were normal, and his height was in the upper range of normal. Tooth eruption was delayed, starting at the age of 1 year and finishing only at 7 years of age. The deciduous teeth failed to shed. Genu valgum was noted when the patient was 7 years of age and was progressive. No pain or muscular weakness was reported. He had two fractures after minimal trauma: the left radius at 7 years of age and the right femur at 17 years of age after orthopedic surgery for valgus correction. At 16 years of age, his height was 177 cm (75th percentile), his weight 60 kg (25th to 50th percentile), his head circumference 52 cm (>2 SD below the mean for his age), and his arm span 181 cm. A radiographic survey showed disturbed modeling of the long bones, with wide metaphyses and thin cortices, and an absence of paranasal sinuses — findings consistent with Pyle's disease (Fig. 1A and 1B).\textsuperscript{4,6} Bone mineral densitometry (conducted by means of fan beam dual-energy x-ray absorptiometry [DXA] on a GE Lunar Prodigy machine) of the lumbar spine (L1 to L4) and proximal femur revealed z scores of −2.7 and −1.1, respectively. The levels of calcium, phosphate, alkaline phosphatase, vitamin D, and parathyroid hormone in plasma or serum were normal (Table S1 in the Supplementary Appendix, available with the full text of this article at NEJM.org).

Patient 2, the younger sister of Patient 1, had dental findings similar to those of her brother. She did not have bone fractures, walking difficulty, joint pain, or muscular weakness. At 14 years of age, her height was 172 cm (>97th percentile), her weight 51 kg (50th percentile), her head circumference 50 cm (>2 SD below the mean for her age), and her arm span 172 cm. She had genu valgum, bilateral cubitus valgus, and limitation of extension in proximal interphalangeal joints of the second, third, fourth, and fifth fingers. The radiographic findings were similar to those in her elder brother and were consistent with Pyle’s disease (Fig. S1 in the Supplementary Appendix).\textsuperscript{4,6} Bone mineral densitometry of the lumbar spine (L1 to L4) and proximal femur revealed z scores of −2.1 and −1.4, respectively. The serum levels of calcium, phosphate, alkaline phosphatase, vitamin D, and parathyroid hormone were normal; levels of bone metabolism markers are shown in Table S1 in the Supplementary Appendix.

The unaffected parents of Patients 1 and 2 and an unaffected younger brother consented to undergo a clinical and radiographic workup. The re-
Figure 1. Clinical, Radiographic, and Molecular Findings.

Panel A shows Patient 1 at 16 years of age; he had deformation of the lower limbs with marked varus of both legs. The expanded distal femora could be easily palpated above the knees. The appearance of the bone at the tibial midshaft, with thicker cortex, is relatively normal. Panel C is an anteroposterior skull radiograph of Patient 2, showing expansion of the diploe. Panel D is an anteroposterior and lateral projection of the distal right tibia in Patient 3, showing changes similar to those in Panel B. In addition, two fractures run through the abnormal metaphysis, and a third fracture runs through the distal fibula. Panel E is a hand radiograph of Patient 2 at 14 years of age, showing expanded metaphyses and thin cortices at the distal radius, as well as expansion of the distal metacarpals and (to a lesser degree) of the phalanges. Panels F, G, and H show the nucleotide sequences of SFRP4 in controls, affected patients, and heterozygous family members. Patients 1 and 2 are homozygous for a nucleotide insertion in exon 2 (Panel F); as a result, amino acid residues 167 and 168 are replaced, and a stop codon is generated at position 169, leading to a truncated protein. Both parents and the brother are heterozygous for the insertion. Circles denote female family members, squares male family members, open symbols unaffected family members, and black symbols affected family members. Patient 3 is homozygous for a C-to-T transition that transforms codon 232 from arginine to a stop codon (Panel G). Patient 4 is homozygous for the deletion of 7 nucleotides; as a consequence, there is a stretch of 10 missense amino acids (codons 161–170), followed by a premature termination at codon 171 (Panel H). Panel I is a diagram of the sFRP4 protein, illustrating the two main domains as well as the positions of the three mutations found in the patients.
results of routine blood chemical tests were normal; levels of bone metabolism markers were also within age-specific reference ranges (Table S1 in the Supplementary Appendix). Skeletal radiographs showed a mild tubulation defect of the long bones, as has been observed previously in obligate heterozygotes for Pyle’s disease (Fig. S2 in the Supplementary Appendix).

Patient 3 was a 58-year-old man who was evaluated for a possible fracture after a workplace accident. His height was 173 cm, and his weight was 72 kg; both measures were between the 50th and the 75th percentile for Japanese men. He was from Kyushu island, a region with a relatively high level of consanguinity. No details of his early medical history are known. Fractures were noted in the tibia, but the tibia also had a highly abnormal shape and structure that prompted additional radiographic evaluation. The findings were considered typical for Pyle’s disease (Fig. 1D, and Fig. S1 in the Supplementary Appendix).

Patient 4 was a boy from India. His biologic parents were unknown. He was examined at the age of 3 years 6 months because of progressive genu valgus deformity that had developed after he started walking. Apart from the leg deformity, he was in good health; his height was in the 10th percentile, and there was no history of fractures. His primary dentition looked normal. Radiographs showed the metaphyseal tubulation defect, chalk-like appearance of the bone, and lack of cortical bone that are typical of Pyle’s disease (Fig. S1 in the Supplementary Appendix).

OVERSIGHT AND LABORATORY STUDIES

Informed consent was obtained from the patients, their parents, or both with the use of consents forms of the Hacettepe University Hospital (Ankara, Turkey), the Manipal University Hospital (Manipal, India), or the Lausanne University Hospital (Lausanne, Switzerland). The genetic study was conducted with the approval of the ethics commission of the Lausanne University Hospital. In brief, we sequenced the exomes of Patients 1 and 2; in addition, the exons of SFRP4 in Patients 3 and 4 were sequenced by means of Sanger sequencing. Details of the laboratory procedures, bioinformatics filtering, and prioritization of variants are provided in the Supplementary Appendix. We did not include any other patients with Pyle’s disease in the analysis.

We obtained two independent lines of knock-out mice, one from Procter & Gamble and one from Lexicon; both lines had disruption of the first exon of Sfrp4 and had the same phenotype. Full details regarding the generation of mouse models, skeletal phenotyping, ex vivo and in vitro studies, and in vivo treatment with the bone morphogenetic protein (BMP) inhibitor, RAP-661, and sclerostin antibodies are provided in the Supplementary Appendix.

RESULTS

IDENTIFICATION OF SFRP4 MUTATIONS

Filtering of the exome-sequencing data from Patients 1 and 2 (Table S2 in the Supplementary Appendix) resulted in the retention of three homozygous variants: one in the complement component 9 gene (C9), one in DAB2, and a single-nucleotide insertion predicted to result in a frameshift with a premature stop codon (c.498_499insG; p.Asp167Glyfs*3) in SFRP4, the gene encoding secreted frizzled-related protein 4 (sFRP4) (Fig. 1F and 1I). The SFRP4 variant stood out because it affects a protein involved in a pathway that is highly relevant to bone homeostasis — that is, the Wnt-signaling pathway. SFRP4 polymorphisms had been linked to bone mineral density in genome-wide association studies, and SFRP4 had been suggested as a candidate gene for craniofacial disorders, although no pathogenic mutation had been identified. Segregation analysis confirmed heterozygosity in both parents and in the unaffected brother.

In Patient 3, Sanger sequencing of SFRP4 in genomic DNA revealed homozygosity for a different point mutation (c.694C→T; p.Arg232*) that was predicted to result in a premature stop codon with truncation of the protein (Fig. 1G and 1I). In Patient 4, we found a homozygous deletion of seven nucleotides (c.481_487delGTACAGG; p.Val161Lysfs*11) that was predicted to result in a short stretch of 10 missense amino acids followed by a premature stop codon (Fig. 1H); the predicted effect of this mutation at the messenger RNA (mRNA) level was remarkably similar to that of the mutation that was found in Patients 1 and 2. Thus, the observed mutations in all four patients were predicted to result in premature stop codons with truncation of the sFRP4 protein. These mutations could result in either nonsense-mediated mRNA decay or, if the mRNA were translated, the synthesis of a pro-
tein lacking a large portion of the netrin-like domain, which is necessary for positioning of sFRP4\textsuperscript{15} and for Wnt inhibition.\textsuperscript{16} Quantitative polymerase-chain-reaction analysis of fibroblast mRNA from Patient 2 revealed a severe reduction in SFRP4 mRNA (Fig. S3 in the Supplementary Appendix), which suggests that the c.498_499insG mutation results in nonsense-mediated mRNA decay.

**MARKERS OF BONE TURNOVER**

We assayed plasma levels of osteocalcin, procollagen type 1 N-terminal propeptide (P1NP), and bone-specific alkaline phosphatase as markers of bone formation, carboxy-terminal collagen cross-links as a marker of bone resorption, and osteoprotegerin and sclerostin in all members of Family 1 (Table S1 in the Supplementary Appendix). The P1NP levels exceeded those of age-related and puberty-related control values in both affected family members, possibly resulting from an increased rate of type I collagen synthesis and deposition. Osteocalcin levels were also higher than reference values. The levels of bone-specific alkaline phosphatase were elevated in both affected family members and in the heterozygous brother. Together, the three osteoblast-derived metabolites seem to indicate a particularly active bone deposition. The findings are similar to those in Pyle’s disease and confirm a pathophysiological mechanism involving vigorous formation of trabecular bone but an impairment in the formation of cortical bone. The findings are similar to those in Pyle’s disease and confirm a pathophysiological mechanism involving vigorous formation of trabecular bone but an impairment in the formation of cortical bone. Additional radiographs of humans and mice and other details on the bone findings are provided in Figures S1, S2, S4, and S5 and Table S3 in the Supplementary Appendix.

**OSTEOBLAST, OSTEOCLASTS, AND SFRP4 DEFICIENCY**

The protein Sfrp4 is a soluble Wnt decoy receptor that binds Wnt ligands and thus modulates both canonical (i.e., β-catenin–dependent) and noncanonical (i.e., β-catenin–independent) Wnt signaling.\textsuperscript{15,19} To understand the effects of Sfrp4 deficiency on cortical and trabecular bone, we first sought to determine whether the activation state of the Wnt-signaling pathway differs between these two compartments. Given that Sfrp4-null long-bone cortex and calvariae have the same phenotype (decreased thickness), we used primary calvarial osteoblasts to investigate the molecular mechanisms by which Sfrp4 modulates cortical bone. Similarly, because trabecular bone is intimately associated with the bone marrow compartment, we used bone marrow–derived osteoblasts to assess the effect of Sfrp4 deficiency on trabecular bone. Sfrp4-null calvarial osteoblasts had activation of both canonical and noncanonical Wnt signaling, as indicated by an increase in active β-catenin and phosphorylated Jnk levels and by an increase in the expression of the ca-
Figure 2 (facing page). Functional Consequences of Sfrp4 Deletion and Correction of the Cortical Phenotype in Sfrp4-Null Mice.

Panel A shows representative radiographic images of wild-type and Sfrp4-null female littermates at 10 weeks of age. The arrowhead indicates the expanded metaphyses in the Sfrp4-null mice (four mice were analyzed in each genotype). Panel B shows microcomputed tomography (microCT) analysis of cortical thickness in femur midshaft of wild-type (black bars) and Sfrp4-null (open bars) mice at 4, 7, 17, 24, 60, and 68 weeks of age. The bars show mean values; T bars indicate standard errors. P<0.05 for the comparison with wild-type at each time point (five mice were analyzed in each genotype). Panel C shows representative histologic features of von Kossa-stained trabecular bone in proximal tibiae (top row; scale bar, 1 mm) and cortical bone in the tibial midshaft region (bottom two rows; scale bars, 300 μm) of wild-type, heterozygous, and Sfrp4-null mice at 10 weeks of age (five mice were analyzed in each genotype). Sfrp4 deletion leads to increased trabecular bone, decreased cortical thickness, and increased width. Panel D shows the differential effects of Sfrp4 deletion on canonical and noncanonical Wnt signaling in calvarial osteoblasts and bone marrow–derived osteoblasts. The total amount of active β-catenin, phosphorylated Jnk (p-Jnk), and total Jnk was assessed in calvarial osteoblasts and bone marrow–derived osteoblasts isolated from Sfrp4-null and wild-type littermates. Actin was used as a loading control. Fold differences in protein levels were measured by normalizing to actin and to total Jnk and dividing the normalized protein level by the mean normalized level in wild-type cells; values are expressed as means ±SD. An asterisk indicates P<0.05 for the comparison with wild type (three to five independent experiments were performed). Panel E shows the analysis of Sost mRNA expression in wild-type and Sfrp4-null calvarial osteoblasts and bone marrow–derived osteoblasts after 0, 14, and 28 days of osteogenic differentiation. Sfrp4 deletion affects Sost expression only in calvarial osteoblasts. The bars show mean values; T bars indicate standard deviations. An asterisk indicates P<0.05, and a double asterisk P<0.01 for the comparison with wild type at each time point (three independent experiments were performed). Panel F shows the regulation of bone morphogenetic protein (BMP) signaling by sFrp4. Wnt5a stimulates Bmp2 mRNA expression, which was blunted by sFrp4 in MC3T3-E1 cells. The bars show mean values; T bars indicate standard deviations. An asterisk indicates P<0.05 for the comparison with control, and a dagger P<0.05 for the comparison with Wnt5a-treated cells (three independent experiments were performed). Panel G shows the quantification of Bmp2 mRNA expression in wild-type and Sfrp4-null calvarial osteoblasts and bone marrow–derived osteoblasts. Sfrp4 deletion affects BMP signaling only in calvarial osteoblasts. The bars show mean values; T bars indicate standard deviations. An asterisk indicates P<0.05 for the comparison with wild-type calvarial osteoblasts (three independent experiments were performed). In Panels E, F, and G, fold differences in mRNA expression relative to that in wild-type cells were calculated as described by Livak and Schmittgen.14 Panel H shows the effects of Sfrp4 deletion on Smad1, Smad5, and Smad8 phosphorylation, which occurs only in calvarial osteoblasts. We measured fold differences in protein levels by normalizing to Smad1 and dividing the normalized protein level by the mean normalized level in wild-type cells; values are expressed as means ±SD. An asterisk indicates P<0.05 for the comparison with wild type (three to five independent experiments were performed). Actin was used as a loading control. Panel I shows representative histologic features of von Kossa-stained tibiae of 3-week-old wild-type and heterozygous mice after vehicle (phosphate-buffered saline) or RAP-661 treatment. Blocking BMP signaling through RAP-661 treatment increases cortical thickness in heterozygous mice (five mice were analyzed in each group). Panel J shows representative images of von Kossa–stained tibiae of wild-type and Sfrp4-null female littermates at 10 weeks of age. The arrowhead indicates the expanded metaphyses in the Sfrp4-null mice (four mice were analyzed in each genotype). Sfrp4 deletion leads to increased trabecular bone, decreased cortical thickness, and increased width.

Noncanonical Wnt target gene Axin2; in contrast, Sfrp4 deficiency led to activation of canonical Wnt signaling but not of noncanonical Wnt signaling in bone marrow–derived osteoblasts (Fig. 2D, and Fig. S6A in the Supplementary Appendix). This difference suggested that the reduced cortical bone thickness might result from activation of noncanonical Wnt signaling.

Expression of sclerostin, an osteocyte-derived potent Wnt inhibitor,20-23 was markedly increased in Sfrp4-null calvarial osteoblasts but only mildly increased in bone marrow–derived osteoblasts (Fig. 2E), which suggests a possible explanation for this differential effect. The sclerostin gene, Sost, is a known target of the BMP signaling pathway,24 and activation of BMP signaling has been shown to lead to thin bone cortex.25 Therefore, we sought to determine whether changes in BMP expression, BMP signaling, or both in response to activated noncanonical Wnt signaling might be contributing to the cortical phenotype in Sfrp4-null mice. Activation of noncanonical signaling by Wnt5a in the osteoblast cell line MC3T3-E1 increased Bmp2 mRNA expression (Fig. 2F); this effect was blocked by the addition of sFrp4 (Fig. 2F) and enhanced in the absence of Sfrp4 (Fig. 2G). In addition, sFrp4 inhibited the Wnt5a-dependent activation of the BMP-responsive Id–luc reporter gene, as did Noggin and RAP-661, both of which are inhibitors of BMP signaling (Fig. S6B in the Sup-
REVERSING THE EFFECTS OF SFRP4 DEFICIENCY

We therefore used RAP-661 to inhibit the BMP pathway in vivo. Pharmacologic inhibition of the BMP pathway increased cortical-bone thickness in wild-type mice and, in mice that were heterozygous for an Sfrp4 mutation, restored the cortical-bone mass to the level found in vehicle-treated wild-type mice (Fig. 2I), while further increasing the mass of trabecular bone. In addition, RAP-661 treatment significantly improved the thickness and bone mineral density of calvarial bones of heterozygous mice. When administered from an early age, this treatment led to an improved bone shape, partially reversing the bone-modeling defect (Fig. 2I). We observed a similar effect on the bone mineral density of the tibia mid-shaft cortical region. The finding that treatment with RAP-661 reduced the endogenous expression of sclerostin both in wild-type mice and in heterozygous mice suggested the possibility of using a sclerostin-neutralizing antibody to block the effects of sclerostin directly. Inactivation of sclerostin in vivo restored the cortical bone thickness in Sfrp4-null mice and significantly reduced bone diameter (Fig. 2I). Additional pharmacologic data are available in Figure S8 and Tables S4 and S5 in the Supplementary Appendix.

DISCUSSION

Although cortical-bone fragility is a major contributor to osteoporotic nonvertebral fractures, little is known about the specific regulation of cortical-bone thickness and density. Moreover, current antosteoporosis therapies have a greater effect on trabecular bone than on cortical bone; relative changes in trabecular-bone mass in response to treatment and as measured by DXA, and thereby the reduction of the risk of vertebral fractures, are of greater magnitude than are those of cortical-bone and nonvertebral fractures. We explored the mechanisms that cause Pyle’s disease, a genetic disorder that is characterized by cortical-bone fragility, limb deformity, and fractures, in an effort to understand the mechanisms by which cortical-bone homeostasis is regulated. In previous studies, genetic bone disorders have provided insights into the mechanisms by which bone is formed and maintained. On radiographs of patients with Pyle’s disease, the meta-

plementary Appendix). This effect of sFrp4 was blocked by Jnk inhibitors, whereas Wnt3a, a classic canonical Wnt ligand, did not alter the activation of the ld–luc reporter gene; this confirms that activation of BMP signaling depends on the noncanonical branch of Wnt signaling. Thus, noncanonical Wnt signaling activates the BMP pathway, and sFrp4 inhibits this activation. Sfrp4 deficiency is thus expected to result in enhanced BMP signaling. Accordingly, expression of Smad1, Smad5, and Smad8, as well as phosphorylation of Smad1, Smad5, and Smad8, were increased in calvarial osteoblasts derived from Sfrp4-null mice but not in bone marrow–derived osteoblasts derived from Sfrp4-null mice (Fig. 2H, and Fig. S6C and S6D in the Supplementary Appendix), a finding that supports the hypothesis of compartment-specific effects.

Both canonical and noncanonical Wnt signaling cascades also affect osteoclastogenesis and bone resorption. In Sfrp4-null mice, the number of osteoclasts was normal in trabecular bone (Table S3 in the Supplementary Appendix) but significantly increased along the diaphyseal endocortical surface (Fig. S7A in the Supplementary Appendix). In growing (8-day-old) Sfrp4-null mice, the number of osteoclasts along the periosteum was reduced, although not significantly (mean ±SE, 2.0±0.3 osteoclasts per periosteal perimeter in Sfrp4-null mice vs. 2.4±0.3 osteoclasts per periosteal perimeter in wild-type mice; six mice per genotype were analyzed), and was consistently increased along the endosteum (6.3±0.8 osteoclasts per endosteal perimeter in Sfrp4-null mice vs. 4.7±0.7 osteoclasts per endosteal perimeter in wild-type mice; six mice per genotype were analyzed), which may explain the abnormal shape and metaphyseal expansion. Together with the decreased cortical-bone formation (Fig. S5 in the Supplementary Appendix), the increase in endocortical bone resorption would be expected to contribute to the thinning of cortical bone in Sfrp4-null adult mice. Increased osteoclastogenesis is consistent with an increase in the ratio of Rankl expression to Opg expression (Fig. S7B in the Supplementary Appendix). These findings show that sFrp4 acts on osteoblasts to suppress endocortical osteoclastogenesis by binding to noncanonical Wnts (such as Wnt5a) and preventing activation of BMP signaling in the cortex.
physis of tubular bones are widened (their shape is similar to that of an oar), the bone cortex is either reduced to a barely visible line or absent altogether, and the central rarefaction of trabecular bone tissue is lacking; instead, the metaphyses seem to be composed of homogeneous trabecular bone. The radiographic findings in our study suggested a vigorous formation of trabecular bone and an impairment in the formation or homeostasis of cortical bone, and the abnormal shape suggested a failure of the remodeling process that occurs in cortical bone during growth.

The genetic studies provided evidence that recessive mutations in Sfrp4 are a cause of Pyle’s disease. We therefore explored the cellular mechanisms of the abnormal bone architecture in Sfrp4-null mice. The mouse model reproduced the human phenotype to a remarkable degree. We showed that the phenotype was due to the differential regulation of Wnt signaling and BMP signaling (Fig. S9 in the Supplementary Appendix). Whereas deletion of Sfrp4 activated predominantly canonical Wnt signaling in trabecular bone, leading to increased trabecular bone mass, both canonical and noncanonical Wnt signaling were increased in cortical bone. We went on to show that both noncanonical Wnt and BMP signaling in cortical bone prevented cortical-bone formation and had to be down-regulated by sFRP4 to allow for proper cortex thickness and strength.

Our results also highlight critical limitations of the most commonly used tools for the diagnosis and evaluation of skeletal diseases. For example, DXA measurements that are widely used to predict fractures are often discordant between cortical (femur) and trabecular (spine) bone sites, leaving clinicians in a quandary about whether to treat. This is further illustrated in our study, in which, despite the presence of profoundly altered bone structure involving increased trabecular bone and extremely thin cortexes, neither classic measurements of bone mineral density nor biochemical markers were reliable indicators of risk. The decreased bone mineral density must reflect the very thin cortex, but it fails to indicate whether the density of trabecular bone is normal or increased. Similarly, markers of bone formation are systemically increased, whereas markers of bone resorption are unchanged in these patients, which reflects the status of the trabecular bone but not of cortical bone. In the future, high-resolution quantitative computed tomography and the development of cortical-bone markers, such as peristin, may allow an assessment of these two bone compartments, as well as stratification of the two bone compartments with respect to risk prediction.

In summary, we showed that Pyle’s disease was caused by a genetic deficiency in sFRP4, that there were differences in the homeostasis of cortical bone versus trabecular bone, and that these processes might be specifically modulated by pharmacologic interventions.
