Abstract
The absence of specific guidance on how to use US to diagnose and manage patients with inflammatory arthritis, especially with rheumatoid arthritis (RA) has hindered the optimal utilisation of ultrasound (US) in clinical practice, potentially limiting its benefits for patient outcomes. In view of this, a group of musculoskeletal US experts formed a working group to consider how this unmet need could be satisfied and to produce guidance (additional to EULAR imaging recommendations) to support clinicians in their daily clinical work. This paper describes this process and its outcome, namely six novel algorithms, which identify when US could be used. They are designed to aid diagnosis, inform assessment of treatment response/disease monitoring and to evaluate stable disease state or remission in patients with suspected or established RA, by providing a pragmatic template for using US at certain time points of the RA management. A research agenda has also been defined for answering unmet clinical needs.
Recently, the European League Against Rheumatism (EULAR) has produced recommendations for using imaging in rheumatoid arthritis (RA) management to aid diagnosis, assessment of prognosis, assessment of treatment response/disease activity and to support remission surveillance.\(^1\) How these recommendations should be applied, however, is open to interpretation.

Among the different imaging techniques, ultrasound (US) has shown to be of particular help in the diagnostic work-up of RA, in guiding treatment decisions and in monitoring disease activity and remission. Despite the difference in the quality of the US machines\(^2-4\) and the possible different level of experience of the operators, published data supports the value of using US in the management of patients with inflammatory arthritis.\(^1\)\(^5\) This evidence has encouraged many rheumatologists to embrace US in their clinical practice.\(^6\) The expansion of US in rheumatology has occurred alongside, and is complementary to, the acceptance of the treat-to-target model, in which disease activity and response to treatment must be closely monitored.\(^7\)

The prompt diagnosis of RA and early initiation of disease-modifying anti-rheumatic drugs (DMARDs) reduce inflammation, limit disease progression, control symptoms and minimise functional loss.\(^8-10\) According to the American College of Rheumatology (ACR)/EULAR classification criteria,\(^11\) a patient with synovitis can be classified as having RA if a certain number of joints with synovitis are detected or if bone erosions are present. However, clinical examination and conventional radiography (CR) are neither sensitive nor accurate enough to detect disease activity and structural damage in early disease.\(^12-15\)

In contrast, US is able to detect synovitis at presentation and differentiate between intra-joint synovial inflammation and other causes of symptoms/swelling, such as tenosynovitis, bursitis and other soft tissue lesions.\(^16-20\) This is also reflected in the ACR/EULAR classification criteria, in which US-detected synovitis in clinically unaffected joints may be used to increase the number of involved joints to satisfy the fulfilment of the classification criteria.\(^21\) Moreover, the earlier patients are diagnosed and treated, the more likely they are to achieve remission and subsequently not flare if treatment is reduced.\(^22\)

Once the presence of RA is confirmed, the optimal management requires tight therapeutic control for setting remission as primary treatment goal as stated by the EULAR recommendations for the management of RA.\(^23\) These recommendations underline that even patients with longstanding disease should be able to achieve stability with low disease activity (LDA). Therefore, an early, accurate assessment of
treatment response/level of inflammation is essential. US offers objective information on how synovitis is responding to treatment which can be either the first DMARD in early RA or a change of therapy in more established disease.\textsuperscript{24, 25} It can confirm a good response, identify a poor response and detect a loss of response.

The use of US to monitor patients considered to be in remission can help predict those likely to suffer subsequent joint damage and flare-up of disease.\textsuperscript{26} It has been shown that between 15 and 62 per cent of patients considered to be in remission based on clinical examination have synovial hypertrophy on US.\textsuperscript{27-29}

Between 19 and 30 per cent also have radiographic progression on further evaluation.\textsuperscript{30} It has also been suggested that remission should only be defined in the absence of synovitis as shown by US.\textsuperscript{31}

Although EULAR recommendations and published data support the use of US in several areas of RA management, they do not provide specific guidance on how to use US, which may result in an inconsistent or sub-optimal utilisation of US and, potentially the sub-optimal treatment of patients. Therefore, there is a clear need for pragmatic, expert guidance for clinicians wishing to use US in their daily practice.

To address this need, a group of musculoskeletal US experts reviewed the available literature and discussed the best approach to developing pragmatic suggestions for the use of US in the daily management of patients with suspected or established RA.

The authors also reflected on the areas for which there is a paucity of evidence, by producing a research agenda for optimising the application of US in clinical practice.

**Methods**

A two-step procedure was followed. The expert group, composed of 10 rheumatologists experienced in musculoskeletal US representing seven European countries (Denmark, England, France, Germany, Hungary, Italy and Spain), met twice in September 2014 and January 2015. The objectives of these meetings were: i) to formulate key clinical questions related to the use of US in RA, ii) to identify and critically appraise the available evidence, and iii) to generate pragmatic algorithms on the application of US in suspected or established RA based on both evidence and expert opinion. To meet the first and second objectives, the group was divided into three task forces: a) diagnosis, b) assessment of treatment response and c) assessment of disease state. Each task force utilized the search terms of the SLR used for producing the EULAR imaging recommendations,\textsuperscript{1} which was proposed as supplementary material for the published article. They, therefore, updated the
literature search to January 2015 using the same MESH terms. Any paper published after this date was incorporated if relevant for the purpose of the project (narrative literature search). The articles were analysed from the perspective of three key questions: i) the role of US for improving the diagnosis of RA, ii) the role of US for monitoring response to treatment, iii) the role of US in evaluating sub-clinical disease activity in stable disease. It was decided not to create a separate research question for addressing the specific role of US as a predictive tool for diagnosis, severity or response to treatment, as few data are available for supporting a separate question. However, prediction aspects have been investigated in each of the three above mentioned research questions.

The results of the literature review were detailed and considered by the group to establish what is known (evidence) and what is unknown or uncertain (more evidence needed). In cases of uncertainty or lack of evidence, it was agreed that consensus expert opinion should guide the best use of US in these particular circumstances and future research questions should be developed to reduce uncertainty. A hundred percent agreement (i.e. unanimous) was required in case of lack of literature evidence. Five algorithms were finalised according to this process (Figures 1-5).

Results and Discussion

a) Using US to establish or confirm a diagnosis of RA

Since 2010, new classification criteria, the ACR/EULAR 2010 criteria, are proposed for helping to classify patients suffering from RA at an earlier stage of disease than by using the modified ACR 1987 criteria. This means that patients can benefit from an appropriate treatment before the structural damage lesions detected by CR appear. However, some studies have supported the fact that even these new criteria can lack both sensitivity (i.e. delaying diagnosis) and specificity (i.e. overestimating the presence of true RA). There is substantial evidence to show that US supports a more accurate and sensitive diagnosis of RA than both clinical assessment and CR. According to EULAR imaging recommendations, the detection rate of synovitis at the hand and wrist using US was double that obtained with clinical examination. Patients assessed by US are likely to fulfil the ACR/EULAR criteria for RA at an earlier stage of their disease than those assessed using conventional assessment. In addition, US may be particularly useful for the differential diagnosis of RA, as it can differentiate between joint inflammation and tenosynovitis, bursitis and other soft tissue lesions that can mimic clinical synovitis.
Recent data suggest that Doppler US can detect sub-clinical RA in at-risk patients who are seropositive (for rheumatoid factor (RF) or anti-citrullinated peptide antibodies (ACPA) but who have not yet developed clinical signs of inflammation.\textsuperscript{40, 41} Both the qualitative and quantitative features of this sub-clinical inflammation have, in seronegative patients, been shown to predict future clinical progression to RA.\textsuperscript{42} The value of adding US to routine assessment seems to be greatest in ACPA negative patients.\textsuperscript{42}

The experts, therefore, proposed three potential uses of US during the diagnostic work-up, and in the absence of definite erosions at CR: i) to determine whether sub-clinical synovitis is present in at-risk patients with no sign of inflammation on clinical examination; ii) to re-assess patients whose clinical synovitis does not fulfil ACR/EULAR criteria; and iii) to confirm the diagnosis in patients who fulfil the ACR/EULAR criteria on clinical examination, but for whom there is a doubt to be considered as “false positive” or where synovitis is the outcome (for example, on entry to a study).

Figures 1 and 2 summarize these proposals. In Figure 1 it is suggested that patients considered at risk of RA due to symptoms and/or sero-positivity or with clinically suspected RA, should undergo an US evaluation along with a full clinical examination, including CR. This additional evaluation could improve patient outcome by facilitating the application of ACR/EULAR criteria, either by increasing the number of inflamed joints or, in absence of clinically-detected inflammation, by confirming the presence of sub-clinical synovitis, allowing, therefore, a diagnosis at an earlier stage. US may also be helpful for excluding the presence of RA in case of normality of the US evaluation. In the latter cases, therapeutic management will be adapted according to the presence of concomitant prognostic factors.

Additionally, it is proposed to perform an US examination even in patients fulfilling ACR/EULAR criteria (Figure 2) at baseline evaluation. The use of US in those patients may help to detect false-positive patients by excluding other causes of joint pathology such as inflammatory flare of osteoarthritis or crystal-related diseases, based on the ultrasound appearance of typical findings (i.e. osteophytes, crystals, presence of double contour...). It is still a matter of debate as to how to determine the true ability of US to exclude diseases other than RA. There is some evidence to recommend specific cut-off values for Grey Scale (GS) and Doppler ultrasound to confirm the presence of inflammation at joint level for the diagnosis of RA.\textsuperscript{38, 43} Increasing cut-off thresholds has been shown to increase the specificity for RA but at the expense of decreased sensitivity.\textsuperscript{32}
Research Agenda:
- Threshold of normality of US findings
- Minimal number of joints to scan for diagnostic purposes
- Predictive validity of sub-clinical, US-detected synovitis in terms of “window of opportunity”

b) Using US in assessing response to treatment

Published data have consistently shown that US can detect a response in US-detected joint inflammation after treatment (for between one week and one year) in patients treated with either conventional synthetic DMARDs (csDMARDs) or biological DMARDs (bDMARDs). Both GS and Doppler are at least as sensitive as clinical examination and laboratory markers in detecting changes in RA patients who have initiated effective therapy. The more comprehensive the US examination, the more sensitive it is in detecting change. However, reduced-joint US assessments have also shown a good sensitivity focusing on either a few target joints such as the wrist, metacarpophalangeal and metatarsophalangeal joints, or on a few small joints plus one or two large joints.

Based on the literature review and experts’ opinion, it is proposed that RA patients on either csDMARDs or bDMARDs should undergo assessment with US at baseline treatment and after three to six months of treatment to assess initial response, in order to help clinicians tailor therapy (maintaining, changing or tapering). Figures 3 and 4 summarise the pragmatic algorithms for using US in assessing treatment response either under cs or bDMARDs.

Figure 3 shows the proposed use of US in RA patients under csDMARDs or bDMARDs to i) re-evaluate non-inflammatory causes of poor clinical response in patients without US synovitis (A) ii) support change of treatment (i.e. escalation) in patients with poor clinical response and confirmed US synovitis (B), iii) maintenance or tapering in patients with good clinical response and absence of US synovitis (C); and finally, iv) assess change of therapy (i.e. escalation) in patients with csDMARDs with good clinical response but significant US synovitis (D), or in case of patients under bDMARDs, to possibly maintain the therapy, as the importance of synovitis in patients on a bDMARD is less certain.

Finally, Figure 4 shows the suggested use of US to support change of treatment versus investigation of non-inflammatory causes in patients with loss of clinical response with US synovitis or without US synovitis, respectively, independently of the treatment
(csDMARDs and/or bDMARDs). In particular, in such patients with a good clinical response, the presence of US synovitis would make tapering of treatment inadvisable.63

Detection of synovitis is important since Doppler, as well as GS, US-detected synovitis are able to predict structural damage in both early RA,31 41 64–68 and in established disease.69 70 The importance of synovitis in patients on a bDMARD needs further investigation.

Some data suggest that US-detected bone erosions may also be sensitive to change.59 71

By evaluating the real presence of inflammation, and by excluding other causes of joint pain (such as deformity, peri-articular lesions and OA flare) the use of US in assessing response to therapy can be of a great help in clinical practice. The same consideration expressed in the previous section on diagnosis and the capability of US to discriminate different diseases, is also of debate in this context. In addition, recent studies question the benefit of US for managing early RA patients for reaching a therapeutic target (such as low disease activity) according to DAS values.24 25 33 In fact, in these two randomized, controlled studies, the “target control”, based on US data, did not do better than the target control based on DAS 28, nor for DAS response over time, neither for radiographic progression. However, it is worth noting that in both studies the achievement of a DAS remission was higher in the US group. Further studies, with a higher number of patients, in an international multi-centre setting, in RA patients with different disease duration and different disease activity (and with different endpoints/outcomes), are needed for confirming or refuting these results.

**Research agenda**

- Is Doppler alone sufficient to monitor response to therapy?
- Should the same US mode (GS vs Doppler, or both combined) be applied in early and established disease?
- Which reduced joint assessments are most sensitive to change in early and established RA?
- Should tenosynovitis be included in the US evaluation of RA?
- How often should US be used to monitor therapeutic response?
- What is the long-term impact on RA outcomes of US evaluation?
- Should a strategy trial be performed only in international multicenter settings?
c) **US in assessing remission/low disease activity state**

Sustained remission is important as flares predict erosive progression over time and functional disability.\(^2^2\)–\(^2^4\) Studies have shown that in patients in remission determined either by physician or by use of various remission criteria, sub-clinical synovitis is present in both GS and Doppler\(^2^7\)–\(^2^9\) and that the amount of synovitis detected by US is independent of whether the patient is receiving csDMARDs or bDMARDs.\(^7^5\) Studies of patients on csDMARD therapy have shown that a Doppler signal of >1 is associated with erosive progression on X-ray over time\(^7^6\) and synovitis shown by GS US indicate the occurrence or worsening of bone erosions.\(^3^0\)

The presence of sub-clinical synovitis with a Doppler signal >1 increases the risk of flare in the disease in RA patients in remission\(^2^6\)\(^,\)\(^3^1\)\(^,\)\(^7^7\) whereas having Doppler negative joints is the best predictor for not experiencing a flare.\(^3^1\) The need to taper or stop bDMARD treatment should also be carried out so flares are avoided. Patients with a high US score on GS and Doppler are more likely to relapse when stopping or tapering biological therapy that patients with a low score.\(^6^3\)\(^,\)\(^7^8\)

Based on the literature review and experts’ opinion, RA patients on both csDMARDs and bDMARDs should undergo assessment with US. The best time decided by the expert is at least after six months of clinical stable disease state to determine possible need for treatment alterations.

**Figure 5** shows the proposed algorithm for using US in patients on both csDMARDs and bDMARDs who are in stable clinical state. The experts agree that in these cases every patient should undergo US assessment at least after 6 months of a stable state in order to determine the potential need for treatment alteration (increased or tapered).

If the US examination does not reveal signs of synovitis, then either continue the current treatment or consider tapering the treatment. If the US examination reveals synovitis, then consider changing or optimizing the current treatment.

**Research agenda**

- Defining the threshold of US remission according to the duration of the disease
- Explore if all treated RA patients achieve US-defined remission
- Does achieving US-defined remission improve patient outcomes?
- How frequently should US be used to confirm absence of disease activity in patients in US-defined remission?
Conclusions

Developments in the management of RA in recent years have produced remarkable improvements in patient outcomes to the point where almost every patient now has a realistic chance of achieving either remission or low disease activity. It is important that imaging techniques keep pace with this advancement. While clinical assessment and CR have shown considerable value in the diagnosis and monitoring of RA, used alone they do not have sufficient sensitivity to support the current treat-to-target approach. The addition of targeted US assessment will help improve diagnosis and treatment of RA patients in daily clinical practice and the algorithmic approach presented in this paper might help to achieve this goal. In this context, the availability of high-quality machines with a Doppler setting adapted to the study of slow flow as observed in inflammatory tissues, will permit greater homogeneity of US reports, and an easier and wider utilization of US in clinical daily management. In this context, educational and training tools play a key role in improving the skills of rheumatologists in US as well as in teaching its pragmatic use in clinical practice.\textsuperscript{79}

The optimal dissemination and application of the proposed algorithmic approaches for using US in the management of new and established RA patients will require the support of educational initiatives and training activities. Further multi-centre studies are needed for evaluating the implementation of these pragmatic approaches on patient outcomes, for evaluating the feasibility of an US approach, and to evaluate the cost-effectiveness, as compared to standard of care.
