27 Short Title: Bioavailable phosphorus in atmospheric dust

28 **Abstract**

29 Acidification of airborne dust particles can dramatically increase the amount of bioavailable
30 phosphorus (P) deposited on the surface ocean. Experiments were conducted to simulate
31 atmospheric processes and determine the dissolution behaviour of phosphorus compounds
32 in dust and dust precursor soils. Acid dissolution occurs rapidly (seconds to minutes) and is
33 controlled by the amount of H⁺ ions present. For H⁺ <10⁻⁴ mol per gram dust, 1-10% of the
34 total phosphorus is dissolved, largely as a result of dissolution of surface-bound forms. At H⁺
35 >10⁻⁴ mol per gram of dust, the amount of phosphorus (and Ca) released follows a power
36 law dependent on the amount of H⁺ consumed until all inorganic phosphorus minerals are
37 exhausted and the final pH remains acidic. Once dissolved, phosphorus will stay in solution
38 due to slow precipitation kinetics. Dissolution of apatite-P, the major mineral phase in dust
39 (79-96%), occurs whether CaCO₃ is present or not, though the increase in dissolved
40 phosphorus is greater if CaCO₃ is absent or if the particles are externally mixed. The system
41 was modelled adequately as a simple mixture of apatite-P and calcite. Phosphorus dissolves
42 readily by acid processes in the atmosphere in contrast to iron, which dissolves slower and
43 is subject to re-precipitation at cloud water pH. We show that acidification can increase
44 bioavailable phosphorus deposition over large areas of the globe, and may explain much of
45 the previously observed patterns of variability in leachable phosphorus in oceanic areas
46 where primary productivity is limited by this nutrient (e.g. Mediterranean).

47

48 **Significance statement**

49 Mineral dust is the most important external source of phosphorus, a key nutrient controlling
50 phytoplankton productivity and carbon uptake, to the offshore ocean. The bioavailable
51 phosphorus in dust exhibits considerable and poorly understood variability. Detailed
52 laboratory experiments elucidate and quantify the major processes controlling phosphorus
53 dissolution in the atmosphere. Dust exposure to acids is the main driver of phosphorus
54 mineral transformations, and a simple power law relationship is found between the amount
55 of bioavailable phosphorus dissolved from the dust and acid exposure. Simulations suggest

56 that dust acidification increases leachable phosphorus over large areas of the globe and
57 explains much of its variability in important oceanic areas where primary productivity is
58 limited by this nutrient (e.g. N. Central Atlantic and Mediterranean).

66 **Introduction**

67 Atmospheric inputs are an important source of externally supplied nutrients to the offshore
68 ocean (1). While all of the inorganic nitrogen is water-soluble and immediately bioavailable,
69 most phosphorus (P) and iron (Fe) is present as minerals that are not immediately soluble in
70 water, hence not bioavailable (2, 3). Such mineral particles, if deposited to the surface
71 ocean, may pass through the photic zone with no effect on primary productivity, owing to
72 their high settling velocity and low solubility (2).

73

74 Atmospheric P can be important as the major external supply to the offshore ocean
75 particularly in oligotrophic areas of the open ocean (1) and areas that are P limited such as
76 the Sargasso Sea (4) and Mediterranean (5). The most important source of atmospheric P is
77 desert dust, which has been estimated to supply 83% (1.15 Tg P a^{-1}) of the total global
78 sources of atmospheric phosphorus (6). Of that dust they estimate 10% is as leachable P.
79 However observations suggest that the fraction of leachable P in dust is highly variable (7-
80 100%) (7). Only one global modelling study primitively simulates such variability, considering
81 reaction of protons with apatite minerals using a kinetic approach (8). The same study
82 indicates that deposition of P from biological particles of terrestrial origin may be as
83 important as leachable P from dust over the ocean in some regions and certain seasons.
84 This translates to a large predictive uncertainty of the bioavailable P input to the oceans.
85 Studies show that, whilst atmospheric N and Fe supply are of importance on a global scale,
86 atmospheric P supply plays an important secondary role, especially through co-limitation
87 with either N or Fe (9, 10). The varying demands and resilience of different phytoplankton
88 communities can have feedbacks on local limiting nutrients on relatively short time scales
89 (11, 12). Additionally, evidence suggests feedbacks in the surface waters that may enhance
90 the impact of the atmospheric supply of P (1, 13). This complex picture is yet to be replicated
91 in global biogeochemistry models and therefore it is not currently possible to put a limit on
92 the importance of any atmospherically supplied P.

93

94 Previous studies have shown that atmospheric processes can increase Fe bioavailability in
95 dust before being deposited to the ocean. Insoluble Fe, principally as iron oxides, can be
96 solubilised by, interaction with acid gases that reduce the pH of atmospheric water to the
97 level where solid phase Fe species can start to dissolve (14), by interaction with organic
98 ligands or by UV photoreduction at predicted considerable amounts (15). By contrast, the
99 principal mineral species of P in aerosols, apatite minerals (e.g., hydroxyapatite,
100 $\text{Ca}_5\text{OH}(\text{PO}_4)_3$), are only expected to be solubilised by acid processes in the atmosphere
101 since they do not undergo photoreduction and Ca is not strongly complexed by organic
102 ligands. Nenes et al. (7) in a study on dust particles sampled in the eastern Mediterranean,
103 found a correlation between increased leachable inorganic phosphorus (LIP) and increased
104 acid exposure in the aerosol particles. Furthermore, the amounts of P released during
105 acidification were consistent with the thermodynamic limit of solubility. However, no further
106 insight on the mechanism and dissolution kinetics could be obtained.

107
108 The principal acid precursor species in the atmosphere are NO_x and SO_x . These can be the
109 result of natural processes such as the oxidation of dimethyl sulphide (DMS) released by
110 phytoplankton in oceanic surface waters (16), volcanic eruptions (17), or lightning. However,
111 at present the main source of such gases is anthropogenic (18). To a lesser degree, low
112 molecular-weight carboxylic acids (such as formic, acetic, and oxalic) are generated in large
113 amounts in the atmosphere and can contribute acidity, especially in evaporated cloud
114 droplets (18, 19).

115
116 Fresh and aged dust particles can be contained within cloud droplets that dissolve acidic
117 gases but with pH levels that do not drop much below 4 (18). Although some cloud droplets
118 condense to form rain, most cloud droplets evaporate to form wet aerosol particles. This
119 process results in a substantial drop in pH and an increase in ionic strength (IS) of the
120 resultant film of water (20). This cycling between cloud droplet and wet aerosol can occur
121 several times (an average of 10 cycles throughout the troposphere (18)) before the aerosol

122 drops to earth by wet or dry deposition. Thus the chemical conditions within and between
123 clouds are very different, with relatively high pH and low IS in cloud droplets and low pH and
124 high IS in wet aerosols (20-22). This cycling was investigated for its effect on Fe dissolution
125 in the atmosphere by Shi et al. (23) who show that Fe is solubilised in wet aerosols and then
126 re-precipitated as Fe nanoparticles in clouds. By contrast, the impact of pH changes or
127 proton addition to atmospherically processed mineral dusts and subsequent P dissolution is
128 virtually unknown (see also SI.1.2.).

129
130 This study sets out to investigate the nature, magnitude and controls of atmospheric acid
131 processes on the solubilisation of mineral P in dust particles using samples collected during
132 dust storms in Israel and Greece, and on dust precursors collected from surface soils in a
133 variety of locations across the Sahara desert (map included in the supporting information,
134 SI.F1.1.). Experiments were carried out using principally natural dust particles to mimic
135 atmospherically relevant conditions and thereby represent the amount of P solubilised by
136 atmospheric acid processes. Results are interpreted by modelling the experimental systems
137 using the geochemical PHREEQC model (24). Calculations using a global 3-D atmospheric
138 chemical transport model (TM4-ECPL; 25) were used to estimate the potential global
139 importance of these processes.

140

141 **Results**

142 **Properties of dusts.** The highest P concentration was found in the dust sample from Israel
143 (Fig. 1 top panel). The sequential phosphate extractions (SEDEX; 26) revealed that apatite
144 was the dominant P mineral (Fig. 1, bottom panel). Total inorganic P (which includes
145 leachable P, iron bound P, apatite P, and carbonate P) varied between 7.7 and 60.0 μmol
146 g^{-1} , and represents 55 to 92% of the total SEDEX phosphorus in the sample. The remainder
147 of the phosphorus was made up of organic P (for full SEDEX data, mineral composition and
148 BET surface area see SI.3.1.2.).

149

150 **Effect of protons and fluid volume on the dissolution of Ca and P minerals.** Fig. 2

151 shows the combined effects of pH and volume on the release of phosphorus from the Israel

152 dust (legends used in this Figure are used consistently in all subsequent Figures and within

153 the *Supporting Information*). Both more acid pH values (at equal water volume) and higher

154 volumes (at equal pH) yield greater P concentrations. The amount of P (Fig. 2 and 3) and Ca

155 (Fig. 4) released from the dust was controlled by the amount of H⁺ ions present and not the

156 initial pH. Fig. 3 shows the released P plotted versus the absolute concentration of protons

157 in the experiments (i.e., mol of H⁺ per g of dust). The data showed that below a critical

158 proton concentration of ~0.1 mmol per gram of dust (-4 log mol(H⁺)/g dust), the released P

159 was only affected by water volume and not the proton concentration. Above this proton

160 concentration, an approximately linear increase in P with increasing initial proton

161 concentration was seen, until a plateau was reached (~-2.1 log mol(H⁺)/g dust), where the

162 acid reactive mineral phosphate pool was exhausted. A similar pattern was seen with Ca

163 (Fig. 4), although the critical proton concentration was slightly lower than that seen for P.

164 These Figures indicate that above a given proton concentration, both Ca and P mineral

165 phases are subject to dissolution. Fe was only above the detection limits in limited

166 experiments where excess protons allowed the pH to remain low throughout the experiment.

167 Results for the other dust samples yielded similar trends for all analytes (see SI.3.2.).

168

169 In all experiments the dust-solution mixtures tended to become buffered to neutral or alkali

170 pH end-points after 48 hr of reaction. The exceptions were experiments where protons

171 remained in excess and all Ca and P minerals were dissolved (SI.3.2.1.). Even using

172 buffered solutions (SI.3.1.1.) the release profiles for P did not change from those described

173 above. Similarly, instantaneous acid addition or slow acid diffusion also did not significantly

174 alter the evolution of dissolved P in the experiments (SI.3.2.2.). When we tested a sequential

175 batch addition of acid, the results (Fig. 3, 1 mL experimental data connected by solid line;

176 see also SI.3.2.3.) were similar to experiments performed at higher concentration through a

177 single acid addition, implying consistent Ca and P mineral dissolution as the total proton
178 exposure is increased. Finally, high IS also played a minimal role in driving P release
179 (SI.3.2.3.).

180

181 All experiments with the real dusts described above assumed that the reactive minerals
182 (calcite and apatite) are found in every particle (“internally mixed”) at the ratio that can be
183 calculated from the apatite and calcium concentrations determined in our study (Table
184 SI.T3.1.). Although dust particles may be in reality “externally mixed” (particles of a given
185 size have only calcite or apatite but not both), the low volume experiments brought the acidic
186 fluid in contact with all particles, and thus the system behaved as internally mixed. CaCO_3
187 controlled the H^+ content and the released phosphorus was totally dependent on reactive
188 mineral composition. These results were confirmed experimentally through analogue dusts
189 made up of single reactive mineral components (i.e., apatite only) or mixed reactive mineral
190 components (apatite and calcite) that we used as dust proxies (SI.3.2.4.). The analogue
191 experiments demonstrate that if dust particles were externally mixed then there would have
192 been more P released per H^+ amount compared to our real dust experiments (Fig. 2 and 3)
193 because more protons are available for direct reaction with apatite.

194

195 **Comparison of experimental results with modelling.** The close agreement between our
196 precursor and real dust samples (SI.3.2.4.) suggests that the interaction between calcite and
197 apatite with acidity, is the primary control of P solubility. This is confirmed by thermodynamic
198 calculations for a system containing only calcite, apatite and solution (Fig. 5 and SI.3.3.).
199 Above approximately 10^{-6} mol L^{-1} for P and 10^{-4} mol L^{-1} for Ca there was agreement
200 between measurements and predictions. Below these concentrations, predicted Ca and P
201 deviated somewhat from the measurements; likely owing to desorption of loosely bound P
202 (SEDEX sorbed pool, Fig. 1, SI.T3.1.) and Ca.

203

204 **Discussion**

205 We studied the dissolution of P-containing phases in the surface soils from areas that are
206 known to be sources of Saharan dust (27) as well as two samples of dry deposited
207 Saharan/Arabian dust. There was a relatively constant P speciation in the mineral
208 composition of these dusts (Fig. 1). Given that the principal acid soluble mineral apatite-P
209 (Ap-P), was on average 89 ± 7 % of the total inorganic P and Fe bound-P was only 7 ± 4 %
210 of the acid reactive mineral phases, we consider the proton reactions of only Ap-P and
211 CaCO_3 as controlling the atmospheric conversion of mineral P to leachable forms. Other
212 processes that affect the solubilisation of Fe, such as photoreduction and organic
213 complexation (12), are likely to have a minor role in increasing P bioavailability because only
214 Fe bound-P will be affected by such processes. There is no evidence of organic P being
215 affected by acidification. In addition to these acid soluble phases, a small amount ($< 7\%$)
216 was in the sorbed inorganic-P pool (extracted by 1M MgCl_2), which is likely to be solubilised
217 directly into seawater (26).

218

219 Although our samples were collected or derived from widespread areas from the Sahara and
220 Arabian deserts, they all had similar relative fractions of Ap-P, Fe-bound-P and adsorbed-P.
221 This is consistent with a common weathering regime across these deserts, which combines
222 some chemical weathering, little plant growth to convert P minerals into plant biomass in-situ
223 and often reprecipitation of CaCO_3 as caliche. However, we recognise that other regions of
224 the Sahara, with different mineralogy (e.g. the Bodélé (28)), may exert an influence on the
225 bulk properties of some Sahara dust plumes. Our samples had 7×10^{-4} to 3.3×10^{-3} mol g^{-1}
226 acid soluble Ca, which is 6-33% by mass of CaCO_3 . Although the P mineral speciation was
227 similar between samples, there was considerable variability in the total P concentration (9.1
228 $\times 10^{-6}$ to 6.3×10^{-5} mol g^{-1}).

229

230 In the atmosphere, dust particles cycle between clouds where they can become cloud
231 condensation nuclei and wet aerosols. In clouds there is a high water:dust ratio, low IS and

232 generally high pH except in the unusual situation of very highly polluted air masses. Wet
233 aerosols, which are generally formed when cloud water evaporates, contain a film of water
234 and can have very low water:dust ratios, high IS and low pH (23). Our experiments were
235 designed to span these conditions within the practical limitations of laboratory handling. The
236 key parameter in controlling the amount of P (and Ca) liberated from acid processing was
237 the total amount of H⁺ ions in the aqueous layer surrounding the dust particle and not the
238 initial pH (Fig. 2-4). For all of our experiments, both CaCO₃ and Ap-P were rapidly dissolved
239 (as measured by Ca²⁺ and PO₄-P liberated) and H⁺ ions consumed, on a timescale of
240 second to minutes (SD3.1.1.). In most cases the pH was controlled by rapid reaction with
241 CaCO₃ to circumneutral values as shown by the simple relationship between the decrease in
242 H⁺ ions being twice the increase in Ca²⁺ cations.

243

244 At low H⁺ amounts ($< 10^{-4}$ mol g⁻¹ dust) P was liberated over a wide range of H⁺ ion
245 concentrations. This was interpreted as being due mainly to simple leaching of dissolved P
246 from the samples into water, independent of the reaction of H⁺ with acid soluble minerals.
247 This corresponds to the leachable P previously measured when dust was treated by
248 deionised water or a very low strength leach (e.g. (29)). The amount of leached P is likely to
249 be independent of whether there is CaCO₃ in the dust sample or not.

250

251 At proton concentrations above 10^{-4} mol H⁺ per gram of dust, there was a power law
252 relationship between P (and Ca) released and the amount of H⁺ ions consumed (Fig. 2-4).
253 This relatively simple pattern of P release continued until the level where all of the P
254 minerals were exhausted. This was also the value at which the final pH in solution was no
255 longer circumneutral but remained acidic. This value corresponded approximately to the
256 value of total inorganic P determined by SEDEX extraction. Similar trends were obtained for
257 all the other dust and dust precursor samples.

258

259 The relationship between P, Ca^{2+} and H^+ ions for all the test samples was confirmed by
260 PHREEQC equilibrium modelling in which there were similar increasing trends of P and Ca^{2+}
261 obtained assuming a simple 3-component model of calcite, hydroxyapatite and H^+ ions. The
262 model fit was better for Ca^{2+} (controlled by calcite and H^+ ions) than P where there was more
263 scatter. This is considered reasonable as there is more than one acid-soluble P mineral
264 present in all the natural samples and the Ap-P is also likely to be made up from a number of
265 different apatite minerals with different solubility behaviour.

266

267 Our results also showed that increased IS caused slightly more dissolved phosphate to be
268 liberated into solution. Where the major contributor to increased IS was ammonium and
269 sulphate, the most common ionic species in aerosols (18), it was found that the amount of P
270 released fits on the trend for the HCl-only data if the proton availability from the dissociation
271 of ammonium ions (predicted from a final pH of 8) is allowed for. In our experiments using
272 NaCl (IS = 2), which was used as a surrogate for evaporated sea salt, the liberated P
273 increased by a factor of 4.3. In both cases even if the IS decreases to that of rainwater the
274 dissolved P will remain in solution due to very slow precipitation kinetics and will be
275 delivered as bioavailable P to the surface ocean (30 and references therein).

276

277 In the atmosphere some mineral particles have both CaCO_3 and Ap-P on the same particle
278 (internally mixed) while other particles have only one or the other mineral (externally mixed).
279 Because acidity in the atmosphere is transferred to dust via the gas phase, the amount of
280 dissolved P will vary between particles, depending on the amount of CaCO_3 . There were no
281 data available characterising the degree of external mixing of CaCO_3 and Ap-P in dust
282 samples. However, we expect many of the particles to contain both CaCO_3 and Ap-P
283 because in many sedimentary rocks and desert soil systems there is a close association
284 between CaCO_3 and Ap-P. Both minerals precipitate in marine sediments during diagenesis
285 (31) and such marine sediments are generally the source of Ap-P in desert soils (32).
286 Furthermore, caliche forms in many desert soils as Ca and bicarbonate produced by in-situ

287 weathering are precipitated (33). However, our results show that in the situation where
288 external mixing does occur, more P would be solubilised because on those particles with
289 only Ap-P, there was no consumption of H^+ by $CaCO_3$ because it was absent from this
290 experiment (Fig. SI.F3.3.). In reality, although we predict that many dust particles will be
291 internally mixed, there will be a continuum and the balance between these two extremes
292 may not be the same for all dust events.

293

294 **Comparison with Fe processes.** The fraction of bioavailable Fe supplied to the ocean is
295 also increased by acidic atmospheric processes (34). However, Fe dissolution is much
296 slower than Ap-P (35). This means that for internally mixed particles, essentially all the H^+
297 ions will be neutralised by $CaCO_3$ before they react with Fe minerals. However Fe-bearing
298 particles are often externally mixed as clays (36) or Fe-rich particles (37). Thus, dissolution
299 of Fe and P can happen simultaneously on different particles. Furthermore, Fe dissolution
300 occurs principally in wet aerosols (low pH with high IS; 23). When the aerosol particles are
301 activated into clouds at lower pH, the Fe is likely to re-precipitate as nanoparticles (38) while
302 P does not re-precipitate. The only removal of P will be adsorption onto fresh Fe
303 nanoparticles if both processes occur on the same particle/droplet. In that situation both Fe
304 and sorbed P are likely to be bioavailable.

305

306 **The potential importance to the global P cycle and supply to the ocean.** The main acids
307 in the atmosphere, H_2SO_4 and HNO_3 , are generated by the oxidation of sulphur and nitrogen
308 gases emitted by biogenic, volcanic and anthropogenic sources (16-18), the latter of which is
309 dominant at present. It has been noted that there is a higher fraction of LIP in polluted air
310 masses (39, 40). Based on field samples collected in Crete, Nenes et al. (7) provided direct
311 evidence of the increase in LIP in aerosols with increasing aerosol acidity. They suggest that
312 this is from polluted air masses from southern Europe bringing acid gases from the north to
313 mix with Saharan air mass. The increased fraction of LIP in atmospheric aerosols over the
314 Bay of Bengal compared to those over the Arabian Sea, has also been interpreted as due to

315 the effect of acid processing of aerosols caused by anthropogenic activities (41). The action
316 of the processes identified here may explain why aerosol samples across the N central
317 Atlantic can have greater fractions of soluble P than dust soil precursors or aerosols
318 collected closer to the dust source (42). Our results demonstrate that atmospheric acid
319 processes are extremely efficient in solubilising P and provide further support to Nenes et al.
320 (7) that acids can increase the delivery of bioavailable P from dust to the oceans. The
321 amount of N fixation is also likely to increase since dust that has been acid processed will
322 contain increased amounts of both bioavailable P and Fe which have been shown to limit N
323 fixation (9).

324

325 To examine whether acid dissolution of dust P can be globally important, we simulate the
326 acid exposure of dust, and examine the extent to which it can occur. For this, we quantify the
327 ratio between dust Ca and its acid exposure. We quantify the ion balance, $I_b = 2[\text{SO}_4] +$
328 $[\text{NO}_3] + [\text{Cl}] - 2[\text{Ca}] - [\text{NH}_4] - [\text{Na}] - 2[\text{Mg}] - [\text{K}]$ (where $[X]$ represents the concentration of
329 species X in the aerosol sample, in mol m^{-3} air) over aerosol Ca (Fig. 6). Calculations are
330 carried out with the global model framework of Myriokefalitakis et al. (25) using current day
331 aerosol emissions and results are shown for coarse fraction of dust and the model surface
332 layer, which is representative of the dust that deposits to the surface. Values of the ratio
333 above 10^{-1} indicate regions where considerable solubilization of dust P is expected. The
334 simulations clearly indicate that the flux of bioavailable P over considerable regions of the
335 ocean can be substantially increased by acidified dust. This increase is likely to be greater
336 than the $0.53 \text{ Tmol C yr}^{-1}$ that can be calculated from the predicted P solubilised by the
337 kinetic apatite-P dissolution process presented in recent global modelling work (8).

338

339 In many locations there has been a greater increase in N containing gases (particularly NO_x
340 and NH_3) than particulate P, which is transported in the atmosphere. The molar ratio is
341 typically greater than 16:1 and often much larger. It has been reported that this supply tends
342 to make surface waters more P limited (43, 44). Our results suggest that this transformation

343 is somewhat moderated by the relative increase in bioavailable P due to interaction between
344 NO_x and dust particles. As a result, phytoplankton biomass and carbon uptake will increase
345 even in areas of the ocean which are N limited in the short term since P remains the element
346 which causes longer-term increase in primary productivity (45). The implications of this
347 added carbon export from anthropogenic pollution to ocean ecosystems has the potential to
348 be widespread and considerable, affecting global primary productivity and the carbon cycle.

349

350 **Methods**

351 **Dust and precursor dust sources.** Two dust samples and six size fractionated dust
352 precursor samples were used in this study (Table 1). The majority of the experiments were
353 carried out with a dust sample deposited on a clean, flat surface during a dust storm in Rosh
354 Pina, Israel (collected 1st May 2012). A second dust sample was collected between June 1st
355 and 9th, 2013 from a solar panel in Heraklion (Crete, Greece). Based on back trajectory data
356 from the HYSPLIT model (<http://ready.arl.noaa.gov/HYSPLIT.php>), the origins of these dusts
357 were the deserts of Saudi Arabia/Jordan/Iraq, and North Africa, respectively. These two real
358 dusts were used directly as collected, without size fractioning or other pre-conditioning. In
359 addition, six dust precursor samples collected from a variety of locations (mainly dry stream
360 or lake bed soils) within the Sahara Desert (Table 1) were used to generate size fractionated
361 dusts using a dust tower separation and filtration methods (46). We used the <10 µm
362 (PM₁₀) fractions for our experiments, similar to previously used dust precursors that have
363 been shown to be analogous to atmospherically sampled dust (46, 47). In this present study
364 the term dust is used to refer to both the dust precursor and the real dust samples unless
365 otherwise stated.

366

367

368 **Experimental procedures.** *SEDEX sequential phosphorus extraction.* Phosphorus
369 speciation amongst the different operationally-defined P pools was determined on 50-100
370 mg of each dust (Table 1) following the SPEXMan SEDEX sequential extraction scheme

371 (48), with the modification that step IIA for Fe bound P followed the procedure of (49). This
372 modification removes the use of citrate, slightly alters the pH to 7.5 and increases the
373 reaction time to ten hours. The absence of citrate means that the resulting solutions do not
374 require any pre-treatment, other than dilution, before analysis by the molybdate blue method
375 (see below). Five P species were differentiated, namely: leachable or loosely sorbed; Fe
376 bound; a combined pool containing authigenic apatite, biogenic apatite and CaCO_3 bound;
377 detrital apatite plus other inorganic P, and organic P. We defined apatite (Ap-P) as the
378 combined phases extracted as diagenetic and detrital apatite, and CaCO_3 bound-P in the
379 sequential SEDEX extraction scheme. Total Inorganic P was defined as the sum of all the
380 phases except organic P. Methods for mineral composition and surface area analysis are in
381 SI.2.2.

382

383 *Phosphorous release experiments.* The following experiments were performed on the dust
384 samples using pH adjusted but unbuffered solutions (HCl, Sigma-Aldrich $\geq 37\%$ ACS reagent
385 grade in $18.2 \text{ M}\Omega\text{-cm}$ MQ water) in an end-over-end stirrer for 48 hours. Israel dust (55 ± 3
386 mg); pH 2 HCl with volumes 70, 140, 210, 500 μL & 1, 2, 5, 15 mL; 0.2 mL HCl at pH 0, 1, 2,
387 3, 4, 5.5; 1 mL HCl at pH 0, 1, 3, 4, 5.5; 2 mL HCl at pH 0.3, 1.3, 2.3, 3.3, 4.3, 5.5; and 5 mL
388 HCl at pH 1, 3, 5.5. Other dusts (30 ± 1 mg); used 1.2 mL at pH 0, 1, 1.8, 2.4. Several initial
389 experiments were carried out to determine the pH buffering capacities and the proton-dust
390 reaction rates. We showed that almost all protons were consumed within ~ 200 seconds of
391 starting the reaction and that the phosphate release was equally fast regardless of initial pH
392 (SD2.2.1. and SI.3.1.1.). Nevertheless, we performed the majority of our experiments over a
393 conservative time period of 48 hours, by which time all changes in concentration had been
394 completed. At the end of these experiments, the mixture was passed through a $0.45 \mu\text{m}$
395 syringe filter (13 mm Whatman Puradisc polyethersulfone) and dissolved phosphate was
396 determined as described below. In the experiments with solution volumes ≥ 2 mL the final
397 pH was measured following the 48 hr exposures. The effect of high ionic strength was tested

398 by adding either ammonium sulphate or NaCl to reach IS = 2 (SI.2.2.2). Furthermore,
399 additional experiments were carried out to evaluate the effect of sequential solution addition
400 (SI.2.2.3.), the effect of acid addition via dialysis (SI.2.2.4.), and the behaviour of simple lab
401 prepared dust analogues (SI.2.2.5.).

402

403 **Chemical analysis of supernatants.** Dissolved inorganic phosphorus was analysed using
404 the molybdate blue reaction (50) after suitable dilution with matrix-matched standards on a
405 segmented flow analyser. For high concentrations (>50 nmoles L^{-1}) this was done on a
406 SEAL Analytical AA3. The RSD was 2.2% ($n=8$) and limit of detection (LOD; $3 \times$ s.d of
407 blank) was 12 nmoles L^{-1} . Lower concentration samples were analysed using a 100 cm WPI
408 Liquid Waveguide Capillary Cell coupled to an Ocean Optics USB2000+ spectrophotometer
409 with a precision ($n=6$ of 60 nmoles L^{-1} samples) of 1.6% and a LOD of 2 nmoles L^{-1} .
410 Dissolved calcium and iron concentrations in the supernatants were measured using a
411 Thermo Scientific iCAP 7400 Radial ICP-OES. The Ca and Fe detection limits were <0.1
412 nmoles and 500 nmoles L^{-1} respectively; with RSD of 1.5% and 1.8% respectively (based on
413 8 replicates of a 13 mmol L^{-1} (Ca) or 9.0 μ mol L^{-1} (Fe) standard). Finally, pH was measured
414 with a Mettler Toledo Seven Excellence meter coupled to an Inlab Expert Pro-ISM pH
415 electrode calibrated with three NIST traceable standard buffers (pH 4, 7 and 9.2; Mettler
416 Toledo).

417

418 **Geochemical modelling of experimental systems.** In order to evaluate the experimental
419 results in terms of predicted equilibrium results, we used the geochemical modelling code
420 PHREEQC (24), with the Lawrence Livermore National Laboratory database. Input
421 conditions were based on the experimental starting solution conditions and assuming only
422 hydroxyapatite and calcite were the reactive minerals present. The relative concentrations of
423 these components were based on the dissolved Ca and P concentrations measured in the
424 experiment for each dust under the most acid conditions.

425

426 **Global 3-D atmospheric chemistry transport modelling using TM4-ECPL.** The ratio of I_b
427 $(2[\text{SO}_4] + [\text{NO}_3] + [\text{Cl}] - 2[\text{Ca}] - [\text{NH}_4] - [\text{Na}] - 2[\text{Mg}] - [\text{K}])$, where $[X]$ represents the
428 concentration of species X in the aerosol sample, in mol m^{-3} air) to Ca at surface has been
429 calculated using model TM4-ECPL (25) that takes into account anthropogenic and natural
430 emissions as described in the supporting information (SI.2.2.6) and uses ECMWF
431 (European Centre for Medium – Range Weather Forecasts) Interim re-analysis project (ERA
432 – Interim) meteorology to drive atmospheric transport. The model uses the ISORROPIA II
433 thermodynamic model (51) to solve the $\text{K}^+ - \text{Ca}^{2+} - \text{Mg}^{2+} - \text{NH}_4^+ - \text{Na}^+ - \text{SO}_4^{2-} - \text{NO}_3^- - \text{Cl}^- - \text{H}_2\text{O}$
434 aerosol system and enables calculation of the aerosol water pH.

435

436 **Acknowledgements**

437 Funding was provided by Leverhulme Trust entitled “Understanding the delivery of
438 phosphorus nutrient to the oceans” Grant Number RPG 406. We thank N. Mihalopoulos for
439 fruitful discussions and for providing dust samples and N. Drake for providing dust precursor
440 samples. Z.S. acknowledges support from NERC (NE/I021616/1). A.N. acknowledges
441 support from a Cullen-Peck Fellowship and Georgia Power Scholar funds.

 572 Fig. 1. Phosphorus speciation in the dust and dust precursor samples, as determined by
 573 SEDEX. The top panel shows the concentrations of P present in the different samples, the
 574 bottom panel details the relative fraction of the different inorganic P species.

575

576
 577 Fig. 2. Dissolved phosphate released from Israel dust in relation to pH and solution volume.
 578 Values are presented as moles per gram of dust. Dust masses were ~55 mg, and dust to
 579 volume ratios were 3.5 to 704.3 g L⁻¹. Inset panel shows the same data with the volume axis
 580 on a log scale.

581
 582 Fig. 3. Dissolved phosphorus (moles per gram of dust) released from Israel dust in relation
 583 to the absolute concentration of protons that were available for reaction at the start of the
 584 experiment. Dust masses were ~ 55 mg, and dust to volume ratios were 3.5 to 704.3 g L^{-1} .
 585 The crossed boxes connected by a solid line represent a sequential acid addition experiment
 586 (SI.2.2.3).
 587

588
 589 Fig. 4. Dissolved calcium (moles per gram of dust) released from Israel dust in relation to the
 590 absolute concentration of protons that were available for reaction at the start of the
 591 experiment. Dust masses were ~ 55 mg, and dust to volume ratios were 3.5 to 704.3 g L^{-1} .

592

593 Fig. 5. Comparison of measured P and Ca dissolution from all dusts compared to equilibrium
 594 predictions made using PHREEQC.

595

596

597 Fig. 6. Annual average ion balance over aerosol Ca. Calculations are performed with the
 598 global model framework of Myriokefalitakis et al. (25) using current day aerosol emissions.
 599 Values of the ratio above 10^{-1} indicate regions where considerable solubilization of dust P is
 600 expected, presuming that dust aerosol is present.
