Abstract: This paper describes the development of Finite Element (FE) models for the study of the behaviour of unreinforced and Basalt Fibre Reinforced Polymer (BFRP) externally reinforced masonry walls under the action of in-plane seismic loading. Validated against experimental tests, the FE models were used to accurately predict the shear strength and reflect damage progression in multi-leaf masonry walls under in-plane cyclic loading, including the propagation of cracks beneath the BFRP reinforcement. The models have the potential to be used in practice to predict the behaviour and shear capacity of unreinforced and FRP-reinforced masonry walls.

Key words: Masonry walls; FRP; FE modelling; Cohesive element; Seismic performance; Shear capacity

1. Introduction

In the past few decades, the use of fibre reinforced polymers (FRP) to strengthen masonry structures has become increasingly popular. Experimental studies have shown that FRP strengthening technology can enhance the shear resistance and seismic capacity of masonry structures [1-4]. Of the different types of FRP that have been used to strengthen existing structures, basalt fibre reinforced polymer (BFRP) has proved to be one of the most cost effective [4, 5].

22 The mechanical behaviour of masonry is much more complex than that of concrete and steel, largely
 23 because masonry consists of two distinct components, namely the masonry units and the mortar
 24 joints as shown in Fig.1 (a). As a result masonry structures are inhomogeneous containing many
 25 discontinuities. This partly explains why, in experimental studies, the results from the testing of two
 26 identically built masonry walls are not identical [6]. The degree of complexity is heightened further
 27 by the inherent variations in the materials and variations in workmanship. Further difficulties exist
 28 when testing masonry structures in the laboratory such as the accurate detection and monitoring of
 29 cracks and their propagation beneath and around external reinforcement. Computational modelling
 30 technology provides a valid and useful alternative to experimental studies. To date, numerical
 31 models have been developed based on different theories such as the Finite Element Method (FEM)
 32 [7-22] and the Distinct and Discrete Element Methods (DEM) [11, 23-25]. Of these, FEM-based
 33 models and software are the most popular and widely available. FEM modelling strategies can be
 34 broadly classified into three categories [22]: micro-scale, meso-scale and macro-scale modelling.

35 Figure 1. Modelling of masonry: (a) real masonry; (b) meso- scale modelling with interfaces; (c) meso-
 36 scale modelling with springs.

37 Macro-scale modelling regards all the components of masonry as a single continuum in which solid
 38 elements or shell elements are widely adopted [7-12]. The constitutive material models are initially
 39 simplified to be homogeneous and isotropic and concrete damage plasticity and concrete smeared
 40 cracking are commonly used [10-12]. Some researchers have attempted to adapt the constitutive
 41 material models to represent the orthotropic feature of masonry. In the modelling by Dhanasekar
 42 and Haider [9], the material properties of head (perpend) and bed joints are considered separately.

43 Alternatively, with the use of homogenisation technology, a series of material models have been
44 developed where the behaviour of masonry is expressed by macro or average stresses and strains.
45 This concept was originally proposed by Lourenço in 2002 and was subsequently validated under
46 various loading conditions [13-15]. Essentially, because of the reduced computational cost and
47 material parameters, macro-scale modelling is suitable for large-scale structural analysis. However,
48 macro modelling does not always simulate some important mechanical behaviour of the interfaces
49 between the masonry units and the mortar and it fails to capture the cracking pattern in mortar
50 directly.

51 Unlike macro-scale modelling, the masonry units, mortar joints and the unit-mortar interfaces are
52 considered separately in micro-scale modelling. In this case, the masonry units and mortar are
53 modelled with real thickness and are assigned corresponding material properties, while zero
54 thickness unit-mortar interfaces are sandwiched between the masonry units and the mortar. With
55 the assumption that the interface is a mixture of units and mortar, Reikik and Lebon [16] used an
56 homogenisation approach to obtain the mechanical properties of the unit-mortar interface.
57 Although this approach seems to be straightforward, the large number of elements used in the
58 analysis requires the use of extensive computational resources. Also, the material properties of the
59 unit-mortar interfaces are difficult to measure experimentally which creates difficulties when
60 validating the complete model. Therefore, with micro-scale models it is often assumed that the
61 masonry units and/or the mortar joints remain elastic, which tends to mean that the modelling
62 strategy can only be used for small masonry specimens such as masonry shear triplets [12, 16].

63 Meso-scale models are routinely termed simplified micro-scale models. Similar to micro-scale
64 models, they can provide an insight into damage evolution in masonry. However, without the
65 masonry unit-mortar interface, the distinction between failure occurring at the unit-mortar interface
66 and within the mortar will be lost. Meso-scale modelling only allows cracks to initiate in the mortar
67 joints and to propagate along the well-defined pattern of lines. This modelling method is based on

68 observations from the experimental testing of masonry [26] and has been proved to be effective for
69 modelling some large elements of masonry construction [17, 18].

70 Meso-scale models can be divided into two groups; those that take into account de-bonding or slip
71 failures that occur between the masonry units and the mortar joints and those that do not. The
72 former can be achieved by coupling the coordination of nodes in the units and mortar joints in all
73 degrees [19], while the latter models normally use contact or some special-purpose elements
74 (interface elements, springs, *etc.*) to replace the mortar [17, 18, 20-22]. In the case of interface
75 elements or contacts, the masonry units are expanded in size by a half mortar joint thickness to
76 create a new component while the mortar joints are simplified as zero-thickness interface elements
77 or contacts (Fig1(b)). Alternatively, as shown in Fig.1(c), the masonry units are assigned their real
78 geometry and the distance between them represents the thickness of the mortar joints in real
79 construction [20]. It is also common to simulate the units using deformable solid elements when
80 interface elements or contacts are applied, while springs are used in conjunction with rigid elements
81 for bricks. Hence, it is evident that not all meso-scale models are the same.

82 ABAQUS finite element software provides several kinds of interface elements including cohesive
83 elements which are used widely to simulate de-bonding or sliding [27]. Cohesive elements can be
84 classified as element-based cohesive elements and surface-based cohesive elements, both of which
85 can reproduce the behaviour of mortar joints. In Ref. [22], element-based cohesive elements are
86 assigned with a user-defined constitutive model to represent the cyclic behaviour of mortar; the
87 unreinforced masonry models are validated under monotonic and cyclic loadings. The model in Ref.
88 [21] is set up with surface-based cohesive elements, but is only validated under monotonic loading.
89 Similar to a contact model, the material properties of surface-based cohesive elements are specified
90 as interaction features and the status of closure or opening between elements is checked at the
91 beginning of each step in the applied load. As a result, models using surface-based cohesive
92 elements tend to have a high risk of convergence problems and require larger computational

93 resources, especially under cyclic load simulations. For these reasons, the element-based cohesive
94 element is used for the modelling of masonry subjected to both monotonic and cyclic loading
95 described in this paper.

96 Although 2-D models are widely adopted for single leaf masonry wall construction [11, 16, 28, 29],
97 3-D models using non-linear analysis are preferred for masonry with more complex arrangements of
98 masonry units. Until relatively recently, a great deal of research effort has been devoted to the study
99 of single-leaf masonry, whereas numerical studies of the behaviour of multi-leaf walls and other
100 more complex forms of construction is less common. More complex forms of masonry are usually
101 analysed using either FEM or a 3-D FE kinematic limit analysis. The model proposed by Burnett et al
102 [17] is applied to masonry walls using contact in LS-DYNA. In Ref. [20] using non-linear spring
103 elements to represent mortar joints, meso-scale models of masonry walls are used in ABAQUS. In
104 the model developed by Macorini and Izzuddin [30], novel 2-D interface elements and 3-D solid
105 elements are used to account for different masonry unit arrangements. These models, validated
106 under monotonic loading, permit the study of masonry walls with complex geometry and unit
107 bonding patterns. However, due to the high computational demand and a lack of a suitable
108 representative constitutive material model for unloading and reloading, few models of this type
109 have been validated under cyclic load conditions.

110 In this paper, a meso-scale masonry model is developed in ABAQUS with element-based cohesive
111 element to simulate both unreinforced and FRP-strengthened masonry walls subjected to
112 monotonic and cyclic loading. In Section 2, the unreinforced and FRP-reinforced numerical models
113 with cohesive elements are described and the material constitutive model for cohesive elements is
114 explained. The laboratory testing of full-scale unreinforced walls and walls with externally bonded
115 BFRP reinforcement under cyclic loading is described in Section 3. Section 4 describes convergence
116 studies, the model validation and then the monotonic and cyclic load simulations. The results from
117 the computational model are discussed and compared with the experimental results and the

118 guidance provided in the Chinese and European codes for masonry [39, 46]. The principal
119 conclusions from the research are presented in Section 5.

120 **2. Description of the finite element model**

121 **2.1 Finite element model for unreinforced masonry**

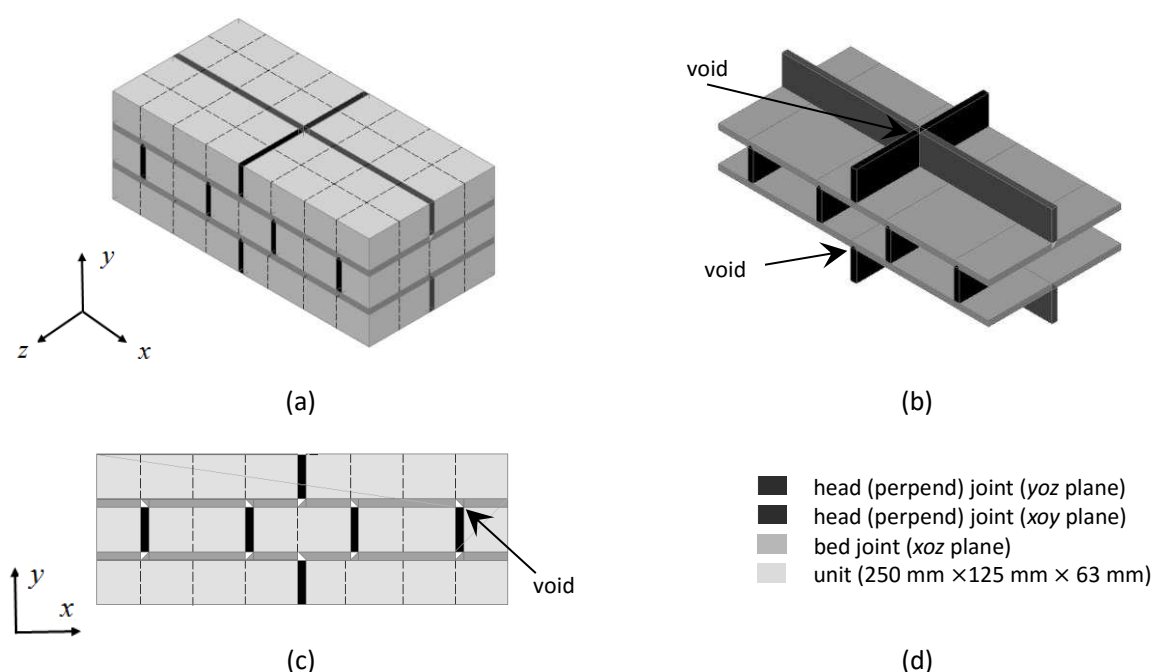

122 In the unreinforced masonry model, the bricks and mortar are simulated by two elements: solid
123 elements for groups or “blocks” of masonry units and element-based cohesive elements with zero
124 thickness for the mortar, as shown in Fig.1 (b). The element-based cohesive elements are, hereafter,
125 referred to for convenience as cohesive elements. ABAQUS provides three methods to create
126 cohesive elements. Of these, the authors selected the share node method as it is relatively simple to
127 implement. It should be noted that this method requires the use of cohesive elements with the
128 same mesh density as their surrounding elements. The process to build a multi-leaf masonry model
129 is listed as follows:

130 (1) Create a part of the structure to be modelled with the same geometry as its prototype, in this
131 case an area of multi-leaf masonry construction.

132 (2) Mesh the part referred to above and transfer it to be an orphan part taking care to ensure that
133 the layout of the mortar joints should be representative of the full structure as the subsequently
134 created cohesive elements are based on the initial mesh.

135 (3) Insert the cohesive elements into the region of mortar joints. Take a multi-leaf masonry block
136 where each masonry unit is meshed, for example the blocks shown in Figure 2(a) which are 4 bricks
137 long x 2 bricks wide x 1 brick high. The brick bonding pattern shown is typical of that used in China
138 for multi-leaf brick masonry walls. Each brick is 250mm x 125mm x 63mm in size laid in 10mm thick
139 mortar joints. The thickness of the cohesive elements, exaggerated in Fig.2 for clarity, is zero. The
140 points of intersection of the cohesive elements along different directions were treated as voids

141 (triangular and rectangular voids in Fig.2 (c) and triangular and quadrangular prisms in Fig.2 (b)), to
 142 permit co-ordination of the deformation between the cohesive elements and the adjacent solid
 143 elements. As the thickness of the cohesive elements is zero, the voids are infinitely small and would,
 144 therefore, not have a significant effect on the stiffness of the cohesive elements. It is recommended
 145 that the cohesive elements in the xoz plane and the xoy plane be generated in sequence. The others
 146 can then be created in the yoz plane, as shown in Fig.2 (b). Alternatively, a subroutine compiled in
 147 Matlab can be adopted to generate cohesive elements in all directions at once, as described in Ref.
 148 [31].

149 Figure 2. Meso-scale modelling of multi-leaf masonry: (a) multi-leaf masonry sample; (b) mortar
 150 joints; (c) side elevation of multi-leaf masonry sample; (d) legend. Note the FE mesh is depicted by
 151 dashed lines.

152 2.2 FRP-reinforced finite element model

153 The FRP-reinforced masonry model is based on the unreinforced masonry model described in
 154 section 2.1. Considering the thickness of FRP is typically around 0.15-0.3 mm, FRP strips are
 155 simulated by shell elements. Assuming that there is full bond (or adhesion) between the surface of

156 the masonry and the FRP, the FRP strips in the model are considered to be tied directly to the
157 masonry.

158 **2.3 Constitutive models**

159 **2.3.1 Constitutive behaviour of mortar joints**

160 Cohesive elements in ABAQUS were developed originally with the aim of modelling adhesives,
161 bonded interfaces, gaskets and rock fracture [32]. Constitutive material models described in
162 ABAQUS are based on a continuum description for adhesives, a traction-separation description for
163 the bonded interfaces, or a uniaxial stress state which is appropriate for modelling gaskets or
164 laterally unconstrained adhesive patches. For different modelling purposes, cohesive elements are
165 assigned with corresponding material constitutive laws. For instance, when the cohesive element
166 represents an adhesive material with a finite thickness, the use of continuum macroscopic
167 properties (such as the modulus of elasticity) is recommended. To reproduce tensile/shear fracture
168 in mortar joints, the behaviour of the zero-thickness cohesive elements is expressed by the
169 relationship of traction versus separation. The traction-separation law is commonly used to simulate
170 sliding or delamination at the interface and can reflect the damage progression of the cohesive
171 element under cyclic loading.

172 The nominal traction stress vector (t) consists of three components: the normal stress vector (t_n)
173 and shear stress vector along s - and t - directions (t_s and t_t), representing normal traction and two
174 shear tractions, respectively. Normal traction is assessed with different rules for tension and
175 compression vectors. With the assumption that the cohesive element is free from damage under
176 pure compression, the compressive traction is assumed to remain elastic throughout the numerical
177 analysis, while the tensile traction, the same as other two shear tractions, is initially defined with
178 linear elastic behaviour, followed by damage evolution behaviour after damage initiation. For
179 clarification purposes it is useful to think of the zero-thickness cohesive element as being composed
180 of two faces, namely the top face and the bottom face. The relative motion of those faces represents

181 the opening or closing of the cohesive element along the thickness direction, expressed by the
 182 spatial displacement of cohesive element (δ_n , δ_s and δ_t). The effective displacement δ_m can be
 183 defined by [32]:

$$\delta_m = \sqrt{\langle \delta_n \rangle^2 + \delta_s^2 + \delta_t^2} \quad (2-1)$$

184 where $\langle \quad \rangle$ is the Macaulay bracket, which is defined as below:

$$\langle x \rangle = \begin{cases} -x, & x < 0 \\ x, & x \geq 0 \end{cases} \quad (2-2)$$

185 It is also necessary to specify the constitutive thickness. It is not appropriate to define an actual
 186 thickness of the cohesive element as the constitutive thickness as the use of an infinitesimally small
 187 value causes the stiffness per unit length to be infinity. In this paper, the constitutive thickness is set
 188 as 1.0 in order to keep the nominal strains equal to the corresponding separations.

189 The traction-separation law involves three criteria in ABAQUS: linear elastic behaviour, a damage
 190 initiation criterion and a damage evolution law. Prior to damage initiation, the traction-separation
 191 model assumes initially linear elastic behaviour, expressed by equation (2-3) [32]. As coupled
 192 behaviour is not considered in this paper, the off-diagonal terms in the elasticity matrix, t , are set to
 193 zero.

$$t = \begin{Bmatrix} t_n \\ t_s \\ t_t \end{Bmatrix} = \begin{bmatrix} K_{nn} & K_{ns} & K_{nt} \\ K_{ns} & K_{ss} & K_{st} \\ K_{nt} & K_{st} & K_{tt} \end{bmatrix} \begin{Bmatrix} \varepsilon_n \\ \varepsilon_s \\ \varepsilon_t \end{Bmatrix} = K\varepsilon \quad (2-3)$$

194 The stiffness, K , can be regard as a penalty parameter. Basically, this penalty stiffness should be large
 195 enough to avoid penetrations of the adjacent surrounding elements under compression. However, a
 196 very large stiffness may result in the ill-conditioning of the elements. It is recommended that the
 197 penalty stiffness be calibrated by comparing experiments with simulations [31, 33] or it should be
 198 estimated using empirical formulae [34]. The influence of the penalty stiffness on the simulation
 199 results is discussed in Section 4.1.

200 Once the stress and/or strains of a material point satisfy the specified damage initiation criteria,
 201 degradation is triggered and the subsequent behaviour of the material will be determined by the
 202 damage evolution law. The quadratic nominal stress criterion in ABAQUS is adopted as the damage
 203 initiation criteria in this paper, while the evolution law is expressed by fracture energy with linear
 204 softening. The scalar damage variable, D , is introduced to represent damage progression. D evolves
 205 from 0 at damage initiation and monotonically increases up to $D_{max} (\leq 1)$, where the elements are
 206 considered to be fully damaged. Thus, with proper damage initiation criteria, cohesive elements can
 207 be used to reproduce crack initiation and progression in the mortar joints in a masonry assemblage.
 208 Even after D reaches D_{max} it is important to retain the cohesive elements in the model otherwise
 209 ABAQUS will delete the fully damaged elements by default and they will no longer be available to
 210 resist any subsequent penetration of the surrounding elements.

211 2.3.2 Constitutive behaviour of units and FRP

212 The concrete damage plasticity (CDP) model is selected to simulate the non-linear behaviour of the
 213 masonry blocks. This approach can be used to effectively model two typical failure mechanisms,
 214 namely tensile fracture and compressive crushing, and also to capture the degradation of the
 215 material in cyclic load simulations. The compressive and tensile stress-strain relationships are
 216 formulated by equations (2-4) and (2-5). These formulations were originally used for masonry and, in
 217 the model described in this paper, are applied for the blocks [21] which are composed of masonry
 218 units and mortar joints (as explained in Section 1). The compression constitutive model is deduced
 219 from the compression testing of a large number of masonry assemblages [35], while the tensile
 220 stress-strain relationship is modified from the design code for concrete and has been verified to be
 221 suitable for masonry [36].

$$\frac{\sigma}{f_{cm}} = \frac{h}{1 + (h - 1)(\varepsilon/\varepsilon_{cm})^{h/(h-1)}} \frac{\varepsilon}{\varepsilon_{cm}} \quad (2-4)$$

$$\begin{cases} \frac{\sigma}{f_{tm}} = \left(\frac{\varepsilon}{\varepsilon_{tm}} \right) & \varepsilon/\varepsilon_{tm} \leq 1 \\ \frac{\sigma}{f_{tm}} = \left(\frac{\varepsilon/\varepsilon_{tm}}{2(\varepsilon/\varepsilon_{tm} - 1)^{1.7} + \varepsilon/\varepsilon_{tm}} \right) & \varepsilon/\varepsilon_{tm} > 1 \end{cases} \quad (2-5)$$

222 Where f_{cm} and f_{tm} represent the compressive and tensile strength of masonry respectively, ε_{cm} and
 223 ε_{tm} are the corresponding strains. The compressive factor, h , is set as 1.633 by default. Damage
 224 parameters (d_t, d_c) are calculated from eq. (2-6) which is based on the Energy Equivalence Principle
 225 [37]. This equation assumes that the residual elastic energy caused by stress in the damaged
 226 material can be evaluated using the same relationship used for the undamaged material.

$$d = 1 - \sqrt{\sigma/E_0\varepsilon} \quad (2-6)$$

227 where E_0 is the initial stiffness.

228 In the property modulus of ABAQUS, the viscosity parameter is set as 0.001, and the other plasticity
 229 factor is set by default. The FRP is assumed to be orthotropic and is characterised by the behaviour
 230 of lamina which are assumed to remain elastic. Fracture and delamination failure of the FRP are not
 231 considered in this paper.

232 3. Description of cyclic tests of masonry walls

233 Cyclic load-testing of full-scale brick masonry wall panels reinforced with surface-mounted BFRP
 234 strips was carried out in the laboratory at Wuhan University to study the seismic responses of BFRP-
 235 reinforced masonry. With identical geometry and materials, the referred specimens are divided into
 236 two groups: Group-A with W1 and BW1-1, and Group-B with W2 and BW2-1. The details and
 237 configuration of specimens are illustrated in Table 1 and Fig.3. As shown in Fig.3, each specimen
 238 consists of three parts: multi-leaf masonry wall, cap beam and base beam. The brick arrangement of
 239 the multi-leaf masonry wall is commonly used in China. All the multi-leaf masonry walls were
 240 constructed by brick (also called as 'fired common brick' in China) with typical size of 240 mm×115
 241 mm×53 mm (L×B×H) and 10mm thickness cement mortar. Both cap beam and base beam are made

242 of concrete and installed together with multi-leaf masonry part by using epoxy mortar. The epoxy
 243 mortar used has extremely high bond strength so that the horizontal loadings applied on beams
 244 would be transferred to masonry parts effectively. Material properties of masonry unit and mortar
 245 are measured from the material property tests, as listed in Table 1.

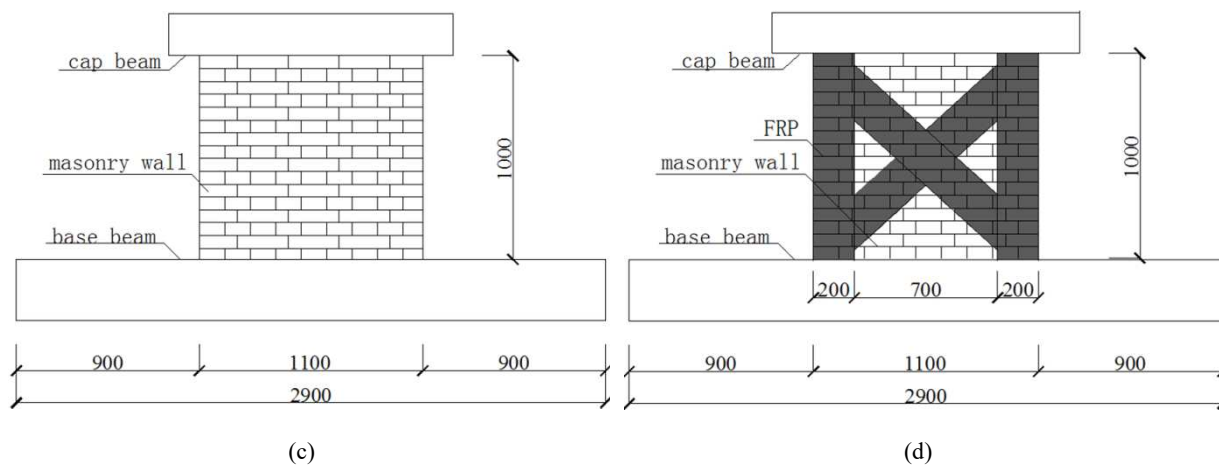

246 The unidirectional basalt fibres were adopted for reinforcement, and the reinforcement schemes are
 247 shown in Fig.3. The BFRP with the width of 300 mm for BW1-1 and 200 mm for BW2-1 was installed
 248 on both side of the wall with cross layout. The horizontally and vertically BFRP strips are attached for
 249 BW1-1 and BW2-1, respectively. The material properties of BFRP were measured according to the
 250 GB/T3354-1999 [38]: density=330 g/m²; tensile strength=1350 MPa; elastic modulus=96 GPa;
 251 ultimate tensile strain=2.6 %.

252 Table 1 Details of the test specimens

Specimen	Dimension (mm)	E_m (MPa)	f_{cm} (MPa)	$f_{b,c}$ (MPa)	$f_{m,c}$ (MPa)	
Group-A	W1	1500×1000×240	1807	2.46	11.53	5.38
	BW1-1	1500×1000×240	1807	2.46	11.53	5.38
Group-B	W2	1100×1000×240	2400	2.56	11.53	6.23
	BW2-1	1100×1000×240	2400	2.56	11.53	6.23

253 Note: E_m is the modulus of elasticity of masonry; f_{cm} , $f_{b,c}$ and $f_{m,c}$ are the average compressive strength of masonry, brick
 254 and mortar, respectively.

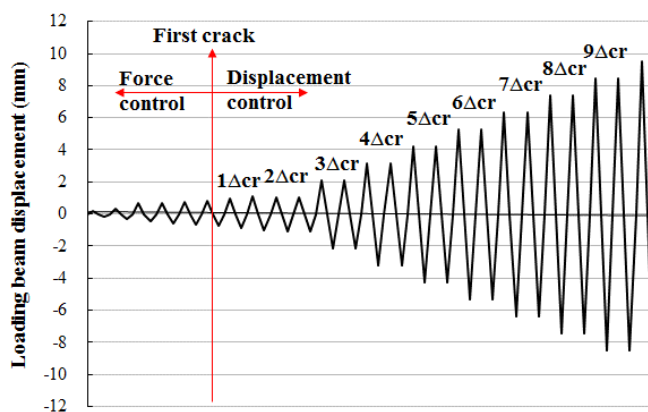

255

Figure 3. Configurations of specimens: (a) W1; (b) BW1-1; (c) W2; (d) BW1-1.

(a)

(b)

256

Figure 4. Test procedure: (a) test setup; (b) loading scheme

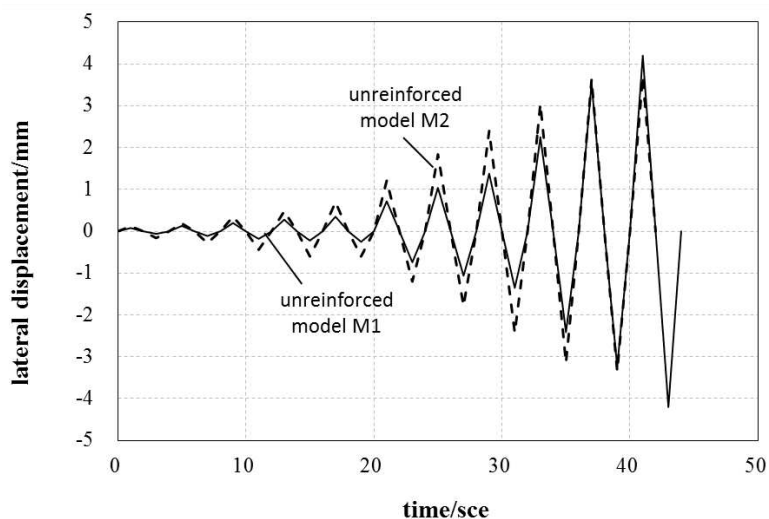

257 The test setup is shown in Fig.4 (a). The base beam was constrained by four screws in vertical
258 direction and two jacks in lateral direction. In order to keep compressive loadings uniform and
259 vertical, steel rollers were placed between cap beam and transfer beam with equal distances. In
260 addition, rollers were cleaned and polished to eliminate the influence of friction. All specimens were
261 then subjected to a combination of compressive and cyclic lateral loading up to failure. Before the
262 application of the lateral loadings, compressive loadings (namely pre-compression) were firstly
263 applied with value of 0.72 MPa for Group A (W1 and BW1-1) and 1.20 MPa for Group B (W2 and
264 BW2-1), and maintained constantly towards the end of the test. During the test, the cyclic lateral
265 loadings were controlled by force initially and by displacement after cracking occurred. The
266 displacement at cracking initiation is set as Δ_{cr} , and the identical lateral loading scheme for the in-
267 plane cyclic tests is depicted in Fig.4 (b). The test was stopped when the lateral bearing capacity of
268 the specimen declined to 15% of its peak strength, or the specimen was severely damaged and not
269 capable of standing any further load.

270 **4. Validation of the FEM model**

271 In this section, the developed numerical models are validated by the aforementioned masonry
272 specimens. Firstly, the influences of numerical parameters, including mesh density and penalty
273 stiffness of cohesive elements, are investigated in Section 4.1, where cyclic and monotonic loading
274 cases are discussed. The unreinforced models (M1 and M2) are constructed with the same geometry,
275 brick arrangement and material properties as the specimens W1 and W2, respectively. Those two
276 models are subjected to monotonic and cyclic loadings in Section 4.2 to assess the shear capacity
277 and aseismic performance of the unreinforced/reinforced masonry walls. Furthermore, according to
278 the BFRP-reinforced specimens (BW1-1 and BW2-1), the BFRP-reinforced models (BM1-1 and BM2-
279 1) are assembled and implemented under monotonic and cyclic loadings in Section 4.2. Similar to
280 Group-A and Group-B, M1 and BM1-1 are grouped as Group-MA, while M2 and BM2-1 are classified

281 as Group-MB. According to the studies in Section 4.1, for Group-MA and Group-MB, each unit are
282 meshed by $4 \times 2 \times 2$ (LxBxH); the value of penalty stiffness is set as 5×10^5 N/mm³.

283 All the numerical models are simplified into two parts: masonry wall and concrete cap beam. The
284 bottom faces of masonry walls are fixed, while vertical and horizontal loads are applied on concrete
285 cap beam. The compressive pressures of 0.72 MPa and 1.2 MPa, used in cyclic tests, are applied to
286 Group-MA and Group-MB respectively. By referring to the loading process used in the cyclic tests,
287 the compression is firstly loaded which keeps constant in the subsequent simulation, and then the
288 horizontal displacements are introduced on one side of the cap beam. In every numerical model, the
289 horizontal loading mode is the only numerical parameter modified in the monotonic and cyclic
290 simulation. For the monotonic validation, the maximum displacements recorded in tests are loaded
291 for the corresponding numerical models. The tests in Section 3 are mainly focused on the cyclic
292 behaviour of FRP-reinforced and unreinforced masonry walls, the monotonic behaviour of masonry
293 models was verified against existing research achievements as discussed later in Section 4.2.1, *e.g.*
294 the crack patterns agreed well with those reported in [3] and the shear strength of masonry
295 wall agreed with the calculated value using the Chinese Code [39], which has been verified
296 practically to calculate masonry shear strength in [47]. To verify the numerical models under
297 cyclic loadings, the cyclic loading protocols recorded during tests are applied in the corresponding
298 numerical models. In order to save computational resources, the displacement-time loops are only
299 loaded once, rather than twice in tests. This is based on the assumption that the cyclic degradation
300 at the same lateral displacement is minimum, which is validated by the comparison of hysteresis
301 loops from experimental tests and ABAQUS modelling. The cyclic loading protocols for the
302 unreinforced models M1 and M2 are depicted in Fig.5.

303

304

Figure 5. Cyclic displacement applied on the numerical models.

305 The numerical models under cyclic loadings are validated with the cyclic experimental results, while
306 the modelling results for monotonic loading cases are verified by the related cases in codes
307 (GB50003-2001 [39] and GB50608-2010[40]). It is important to mention that testing procedure plays
308 an significant role on the behaviour of masonry structures [41]. For example, the shear resistance of
309 masonry walls under cyclic loadings is about 10% lower than the one under monotonic loadings [42].
310 Therefore, in terms of monotonic validation, the calculations based on codes are more applicable
311 than the skeleton curves obtained in cyclic tests.

312 Under the assumption that the cap beam does not undergo any damage, it is assigned with an elastic
313 behaviour. The material parameters for masonry units and mortar joints are listed in Table 1 and
314 Table 2. Note that it is hard to obtain the fracture energies of mortar joints in traditional property
315 tests, and different values of fracture energies are used in references (for example, ref. [1], ref. [16]
316 and ref. [19]). Therefore, with reference to those reported values the fracture energies in Table 2
317 were determined by comparing the results of failure strength between standard compressive/shear
318 test specimens and the corresponding numerical models. Mortar joints herein are assumed to be
319 isotropic in the first and second shear directions. Basalt Fibre was measured as 0.1 mm thickness,

320 and after grouted with resin it was combined to become FRP with 0.2 mm thickness. The FRP
 321 material parameters are listed in Table 3.

322 Table 2 Material parameters for mortar joints

Material parameter	Group-MA	Group-MB
normal stiffness $E_{n,coh}/(\text{N}/\text{mm}^3)$	5×10^5	5×10^5
shear stiffness $E_{s,coh}/(\text{N}/\text{mm}^3)$	5×10^5	5×10^5
normal strength $f_{t,coh}/\text{MPa}$	0.13	0.15
shear strength $f_{s,coh}/\text{MPa}$	0.75	0.55
Model I fracture energy $G_{f,coh}^I/(\text{mJ}/\text{mm}^2)$	0.09	0.065
Model II fracture energy $G_{f,coh}^{II}/(\text{mJ}/\text{mm}^2)$	1.126	0.91

Thickness in average t (mm)	0.2	obtained from property tests

325

326 Considering that the penalty stiffness and fracture energies of mortar joints are hard to measure
 327 directly, those parameters (in Table1) are determined by comparing the results of
 328 compressive/shear masonry strength between standard compression/shear tests and the
 329 corresponding ABAQUS models (as shown in Fig.6 and Fig.7, respectively). According to the Chinese
 330 Code, those masonry compress/shear standard test specimens were built to detect the
 331 compression/shear strength of masonry. As shown in Table 4 and Table 5, those sample ABAQUS

332 models can well reflect the compression and shear strength of the masonry standard
 333 compression/shear test specimens.

341

342 4.1 Convergence study

343 4.1.1 Influence of mesh density

344 The unreinforced model M2 is used as a benchmark for mesh sensitivity study. The units are meshed
 345 as $4 \times 1 \times 1$, $4 \times 2 \times 1$, $4 \times 2 \times 2$, $8 \times 2 \times 2$ and $8 \times 4 \times 2$ (L×B×H), respectively. Those models were tested under
 346 cyclic and monotonic loadings, and a comparison of simulation results are depicted in Fig.8. Except
 347 for the case of $4 \times 1 \times 1$ (the coarsest mesh size), the difference between cases is not significant and
 348 mainly occurred at the last loading cycle. It is illustrated that the numerical model in this paper is less
 349 sensitive when the mesh density along the width is larger than two. In order to save computer
 350 resource while still maintain the accuracy of the model, the mesh size ($4 \times 2 \times 2$) is adopted.

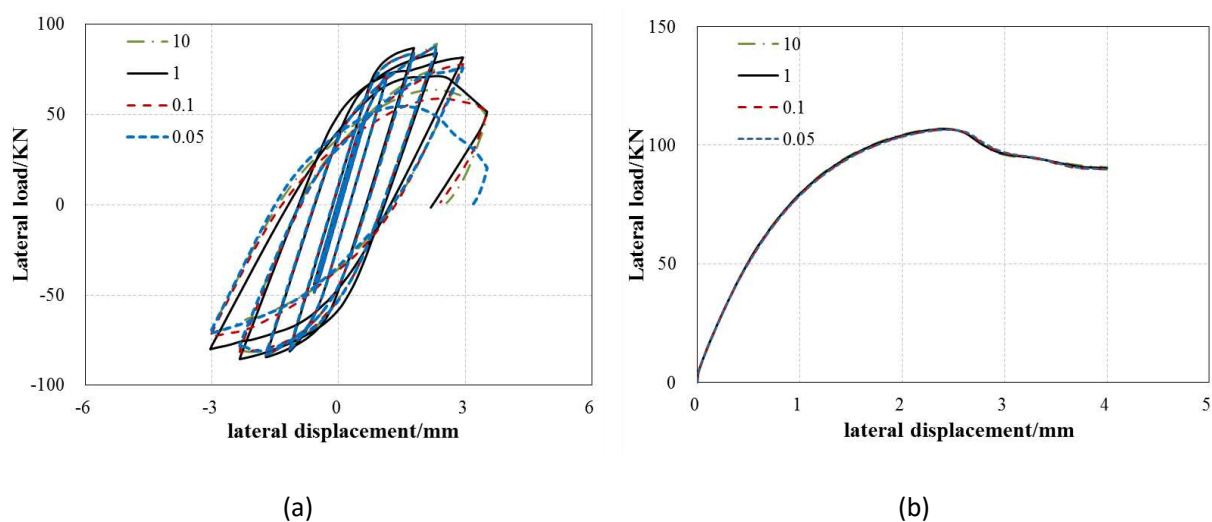

351 Figure 8. Influence of mesh density in the unreinforced numerical model: (a) cyclic; (b) monotonic.

352 4.1.2 Influence of penalty stiffness

353 As referred in Section 2.3.1, the influence of penalty stiffness on cohesive elements was assessed.
 354 Take the unreinforced model M2 and the BFRP-unreinforced model MB2-1 as example and set the
 355 meshed size as $4 \times 2 \times 2$ for each unit. The interface stiffness was factored by 0.1, 0.05 and 10 (i.e.
 356 5×10^4 N/mm³, 2.5×10^4 N/mm³ and 5×10^6 N/mm³), with the reference value of 5×10^5 N/mm³ (factor
 357 is 1.0). The simulation results are compared in Fig.9 and Fig.10.

358 Except for the case of the smallest penalty stiffness ($2.5 \times 10^4 \text{ N/mm}^3$) under cyclic loadings, the
 359 unreinforced model is almost insensitive to penalty stiffness under cyclic and monotonic loadings, as
 360 shown in Fig.9. In Fig.10, for the BFRP-reinforced model, the influence of penalty stiffness is
 361 negligible in cyclic case and is small in the monotonic case. Overall, penalty stiffness does not play a
 362 significant role on both unreinforced and FRP-reinforced numerical models when models are under
 363 cyclic and monotonic loadings. Only the smallest penalty stiffness causes the deterioration of
 364 cohesive elements and a sudden loss of strength, so the value of penalty stiffness is recommended
 365 to be larger than $2.5 \times 10^4 \text{ N/mm}^3$. Accordingly, $5 \times 10^5 \text{ N/mm}^3$ is used for penalty stiffness.

 369 monotonic.

370 4.2 Unreinforced FEM model

371 4.2.1 Monotonic loading

372 According to GB50003-2001[39], the shear strength of unreinforced masonry V_0 is calculated by:

$$V_0 = (f_v + \alpha\mu\sigma_0)A \quad (4-1)$$

373 where the design value of shear strength for masonry (f_v), the modified coefficient (α) and the
 374 influence coefficient under shear-compression load (μ) are determined by GB50003-2001[39]; σ_0 is
 375 the compressive loading, which equal to 0.72 MPa for Group-A and 1.2 MPa for Group-B; A is the
 376 cross sectional area of a masonry wall.

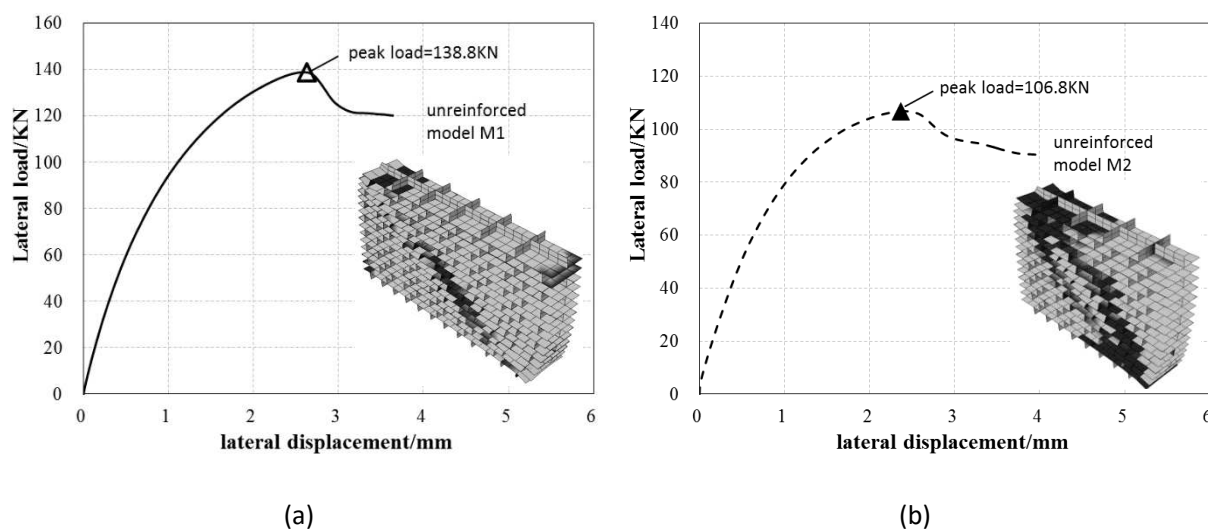

377 Table 6 Calculated results for monotonic loading

Specimen	f_v (MPa)	$\alpha\mu$	$\alpha_2\mu_2$	η	V_0 (KN)	$V_{u,m}$ (KN)	$V_{u,f}$ (KN)	V_u (KN)
W1	0.29	0.13	--		138.0	--	--	--
BW1-1	0.29	0.13	0.195	1.36	138.0	155.75	43.93	199.68
W2	0.312	0.11	--		117.2	--	--	--
BW2-1	0.312	0.11	0.187	1.38	117.2	143.93	8.56	152.49

378 The calculated and numerical results are shown in Table 6 and Fig.11, respectively. A good
 379 agreement between the calculated and simulation results can be observed, in terms of the shear
 380 strength. The shear strength of M1 is only 0.57% larger than that of W1; the error between M2 and
 381 W2 is 8.87%. in Fig.11, The colour of mortar layers are ranged from white to black, to represent
 382 damage evolution from intact to overall damaged degrees. It is found the crack patterns in
 383 numerical models are mainly caused by shear failure, similar to cracks observed in monotonic tests
 384 [3, 26]. Therefore, the unreinforced FEM models can accurately assess the peak strength of the

385 unreinforced masonry walls, and cracking patterns are successfully captured to reflect the
 386 monotonic behaviour of the unreinforced masonry walls.

387

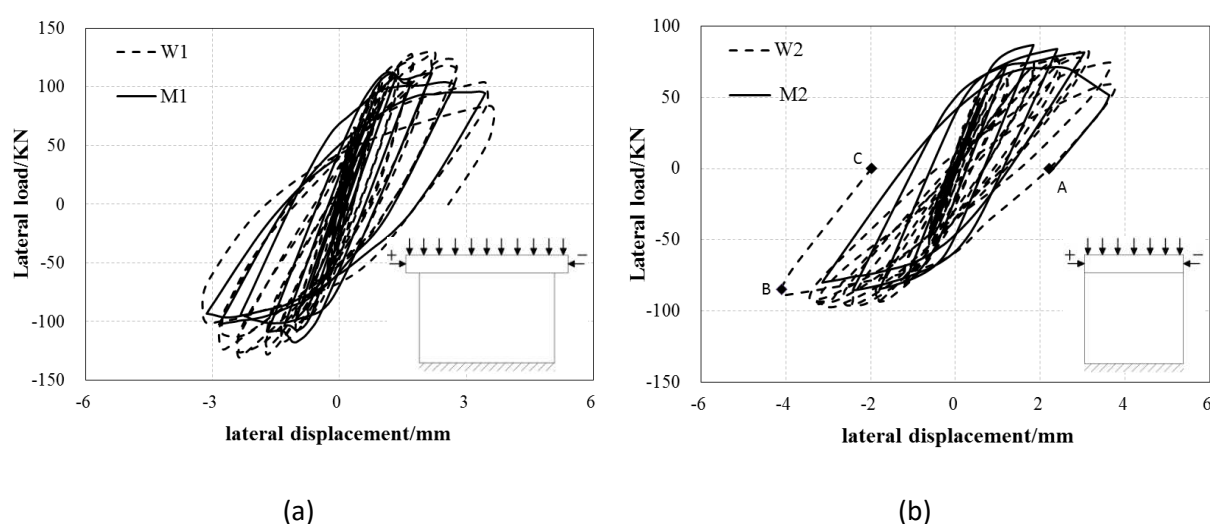

388 Figure 11. Numerical results of unreinforced masonry walls under monotonic loading:

389 (a) M1; (b) M2; (insert) cracking patterns.

390 4.2.2 Cyclic loading

391 In this section, the numerical results from the unreinforced model under cyclic loadings are verified
 392 by the experimental results, in terms of hysteresis loop, degradation of stiffness and cracking
 393 pattern. For the specimen W2, the experimental results, marked as ABC curve in Fig.12(b), are
 394 regarded as invalid. Because at that time, the specimen was severely damaged with large
 395 deformation, causing the reading of several LVDTs deviated to the extent that they are deemed as
 396 unreliable. Comparisons of the hysteresis loop between the experimental and numerical results are
 397 illustrated in Fig.12. A good agreement among hysteresis loop between the results of experiments
 398 and simulation can be observed. And the trend of stiffness degradation is similar between
 399 experimental and simulation results. For specimens W1 and W2, the loss of strength was relatively
 400 more significant than that of the numerical models (M1 and M2) after the peak strength is reached.

401 For the specimen W2, the positive peak strength and its corresponding displacement are
 402 distinctively different from the negative ones, as shown in Fig.12 (b). It indicates that even for one
 403 single wall, the mechanical properties of its two sides are not the same. The deviation is primarily
 404 caused by the heterogeneity of masonry materials and possibly workmanship as well. That is one of
 405 the reasons that the positive peak strength of the specimen W2 occurred much later than that of the
 406 model M2, but the negative peak strength of W2 and M2 were achieved at the same displacement.
 407 Another reason is the internal damage caused by hoisting and instalment of specimens during the
 408 preparation stage.

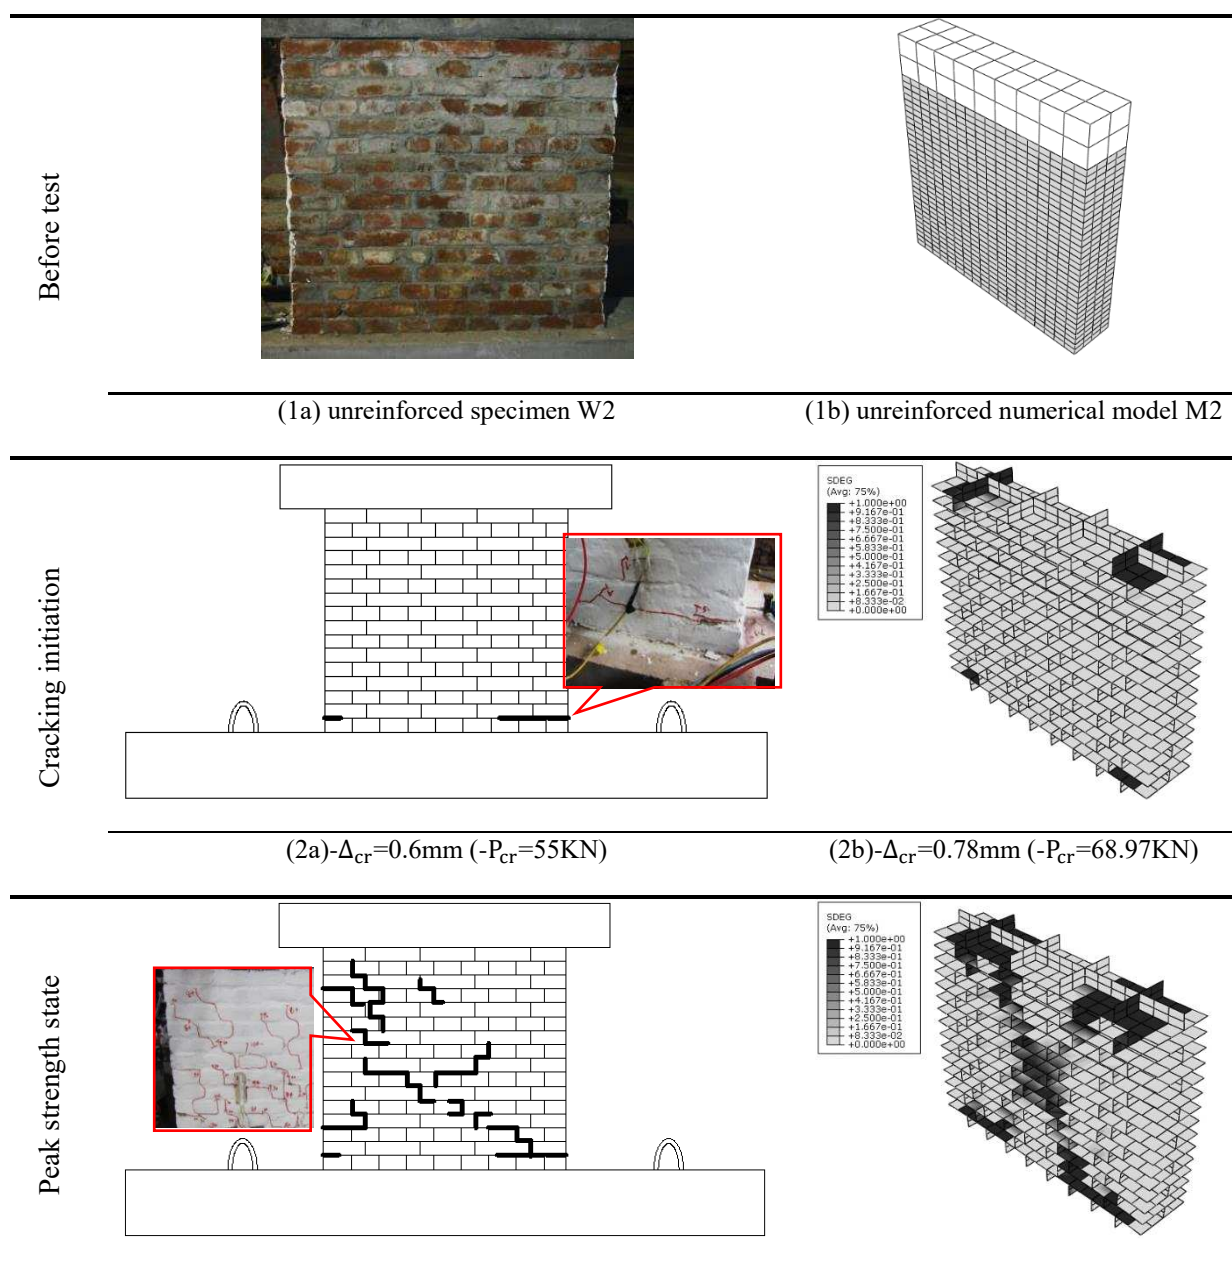

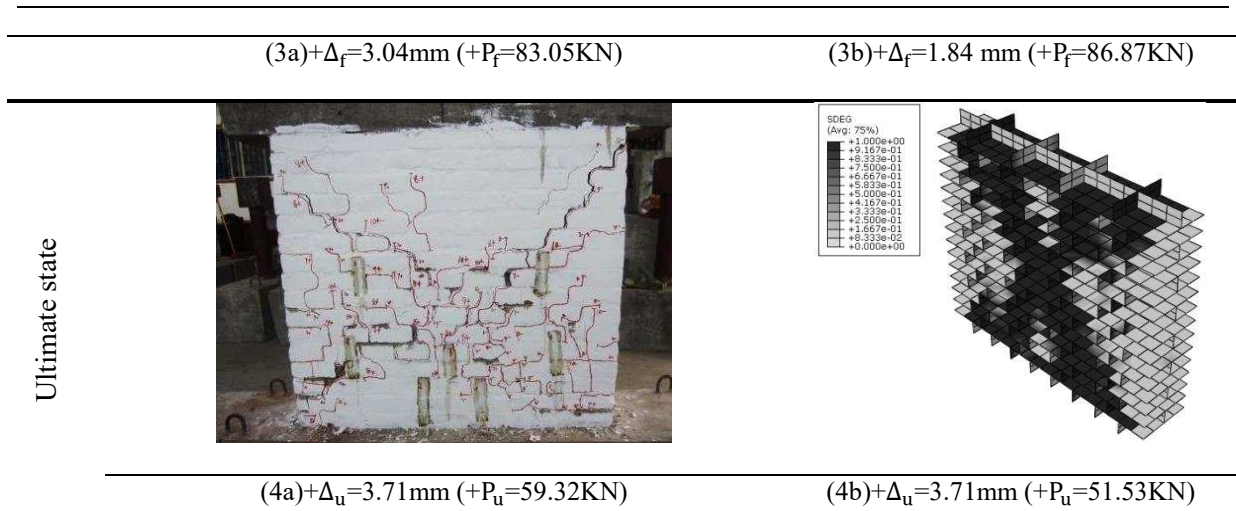

409 Figure 12. Comparison of hysteresis loop: (a) W1 and M1; (b) W2 and M2; (insert) definition of
 410 loading direction, “+” is the positive loading direction and “-” is the negative loading direction.

411 To investigate the cracking progression, the cracking patterns of W2 and M2 at the key loading
 412 stages are listed in Table 7. The left column (Table7 (1a)–(4a)) depicts the cracks on the specimen
 413 W2, while the right column (Table7 (1b)–(4b)) presents the simulation results of M2. For the
 414 specimen W2, the initial cracks were detected at the corners of the masonry wall when the lateral
 415 loading of 55KN was loaded (as shown in Table 7 (2a)). Afterwards, cracks progressed from the
 416 corners towards the centre, forming a diagonal cracking pattern. The specimen failed with
 417 brittleness after reaching the peak strength at 3.04mm displacement. At ultimate displacement of

418 3.71 mm, W2 fractured into four pieces and the maximum crack was up to 1-2 cm in width, as shown
 419 in Table 7 (4a). In the case of the numerical model M2, cracks initiate from corners and continued to
 420 develop to a diagonal pattern. Similar to experimental records, the diagonal cracks in numerical
 421 model extend in width during the cyclic loading, as shown in Table 7(4a)-(4b). Therefore, the
 422 unreinforced models proposed in this paper can accurately reflect the cyclic responses of the
 423 unreinforced masonry walls.

424 Table 7 Cracking pattern of unreinforced masonry

425 Note: Δ_{cr} , Δ_f and Δ_u are the displacement at cracking initiation, peak state and ultimate limit state; P_{cr} , P_f and P_u are their
 426 corresponding strength.

427 4.3 BFRP-reinforced FEM model

428 4.3.1 Monotonic loading

429 According to the Eurocode for masonry [46] and the Chinese code (GB50608-2010) [40], the shear
 430 capacity of the FRP-reinforced masonry is the sum of two parts, *i.e.*, the shear capacity of the
 431 unreinforced masonry wall ($V_{u,m}$) plus the additional capacity provided directly by the FRP
 432 reinforcement ($V_{u,f}$):

$$V_u = V_{u,m} + V_{u,f} \quad (4-2)$$

433

434 As a result of the interaction between the FRP strips and the masonry, $V_{u,m}$ is larger than the peak
 435 strength of the corresponding unreinforced masonry wall (V_0). According to the Chinese code
 436 [40], $V_{u,m}$ herein is calculated by equation (4-3). The increase caused by the FRP-masonry interaction
 437 is basically expressed by the value of the modified coefficient and the influence coefficient under
 438 shear-compression load for the reinforced masonry walls (α_2 and μ_2) and the influence coefficient of
 439 reinforcement η .

$$V_{u,m} = (f_v + \eta\alpha_2\mu_2\sigma_0)A \quad (4-3)$$

440

441 To date a number of codes define the formulae to obtain the contribution of FRP reinforcement. Eq.
 442 (4-4) from the Chinese standard [40] is adopted to assess $V_{u,f}$. Although studies [47] show that that
 443 the Chinese standard has a relatively higher deviation, it is a developed code that takes the
 444 reinforcement scheme into consideration.

$$V_{u,f} = \zeta E_f \varepsilon_{fd} \sum_{i=1}^n A_{fi} \cos \theta_i \quad (4-4)$$

445

446 where ζ is the efficient coefficient of FRP reinforcement, set as 1.0 for the single cross layout [40]. E_f
 447 and ε_{fd} represents the elastic modulus and effective strain of FRP strips (equals to $\varepsilon_{fe}/\gamma_e$). ε_{fe} is the
 448 effective strain of FRP strips. Due to that the kind of FRP material do not have significant influence
 449 on the improvement of peak strength [47], ε_{fe} can be a fixed value, with 0.001 for unanchored FRP
 450 strips and 0.0015 for anchored FRP strips [40]. γ_e accounts for the environmental influence; for the
 451 BFRP reinforcement indoor, $\gamma_e=1$. A_{fi} account for the cross section area of masonry and FRP strips.
 452 The angle between the FRP reinforcement and courses, θ , is 35° for BW1-1 and 42° for BW2-1. This
 453 confirms what has been reported in previous studies that different configurations of FRP
 454 reinforcement lead to different increase rates of masonry shear strength [3, 48]. Apart from the
 455 shear capacity obtained from cross reinforcement, the horizontal FRP strips can obviously enhance
 456 the shear capacity of masonry walls under monotonic loading, while far less contribution to the
 457 shear capacity is assumed for the vertical FRP strips without anchors [3]. Therefore, in this case, $V_{u,f}$
 458 is the sum of the cross and horizontal reinforcement, as listed in Table 6.

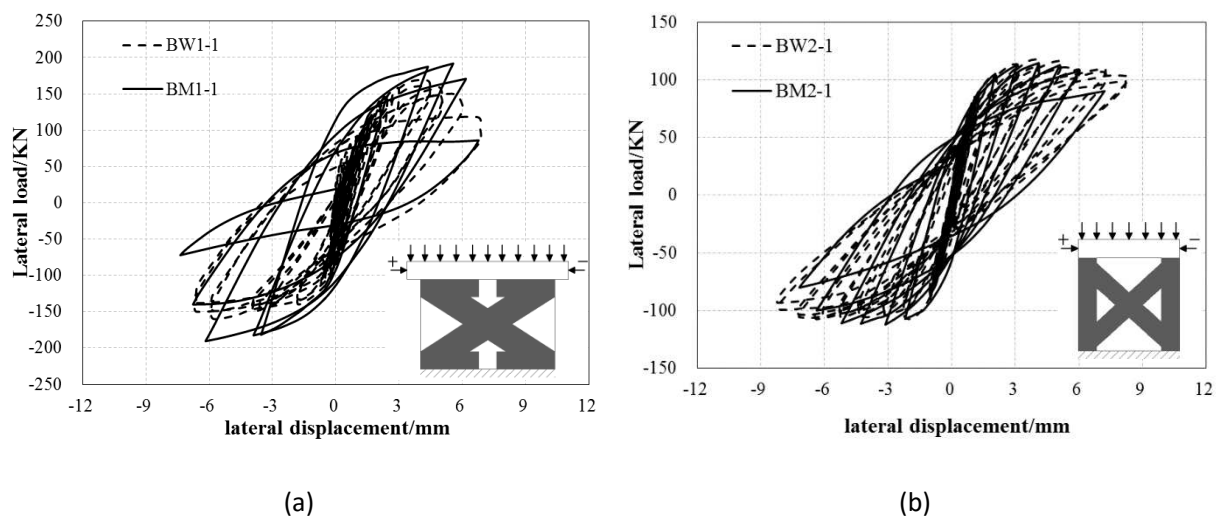

459 The numerical results, V_c , are 227.87KN for BM2-1 and 134.12KN for BM2-2. The corresponding ratio
 460 of calculated and numerical results is 1.14 and 0.88, respectively. It indicates that the FRP-reinforced
 461 models are almost in accordance with the Chinese code within an acceptable deviation. Considering
 462 that many factors influence the accuracy of code calculation [47], the FRP-reinforced models in this

463 paper can effectively assess the peak strength of the FRP reinforced masonry walls under monotonic
464 loadings.

465 **4.3.2 Cyclic loading**

466 The load-displacement envelope curves obtained by experiment and simulation are presented in
467 Fig.13. It can be observed that the simulation and experimental results have a good agreement with
468 each other. Fig.14 illustrates a similarity in cracking patterns between the BFRP-reinforced specimen
469 BW2-1 and numerical model BM2-1. Meanwhile, similar shear cracks are observed for the specimen
470 BW2-1 and the model BM2-1 within the unreinforced areas (Table 8 (4a) and (4b)), indicating that
471 the developed numerical models for BFRP-reinforced masonry can effectively reproduce the damage
472 progression in the FRP-reinforced masonry walls.

473 For the experiment studies on the FRP-reinforced masonry, the cracks under FRP strips are very
474 difficult to detect and monitor precisely. This drawback can be overcome by the FRP-reinforced
475 numerical model. The cracks underneath FRP in BM2-2 are presented from Table 8 (2b) to Table 8
476 (4b), where the damage progression under BFRP reinforcements is clearly captured. As shown in
477 Table 8 (2a)-(2b), the initial cracks in BW2-1 are accurately reproduced in BM2-1, but more cracks
478 emerge at the upper reinforced parts which are the undetected area in experiments. Furthermore,
479 by removing the FRP strips in the display of the modelling results, the cracking pattern under FRP
480 reinforcement can be revealed. Overall, the FRP-reinforced models can successfully reflect the
481 seismic behaviour and the cracking progression of the FRP-reinforced masonry walls.

482 Figure 13. Hysteresis loop of BFRP-reinforced masonry: (a) W1 and M1; (b) W2 and M2; (insert)
 483 definition of loading direction, “+” is the positive loading direction and “-” is the negative loading
 484 direction.

485 Figure 14. Cracking pattern of the BFRP-reinforced masonry (BW1-1 and BM1-1): (a) displayed with
 486 horizontal reinforcement; (b) displayed without horizontal reinforcement; (insert) zoomed-in images from
 487 experiments at corresponding positions for comparisons.

488

Before test

(1a) BFRP-reinforced specimen BW2-1

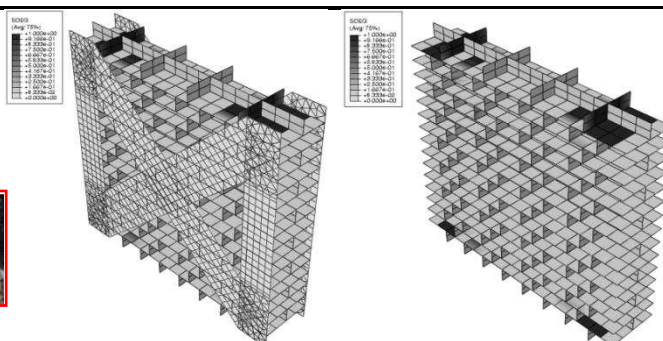

(1b) BFRP-reinforced numerical model BM2-1

Cracking initiation

(2a) $-\Delta_{cr}=1.06\text{mm}(-P_{cr}=90.17\text{KN})$

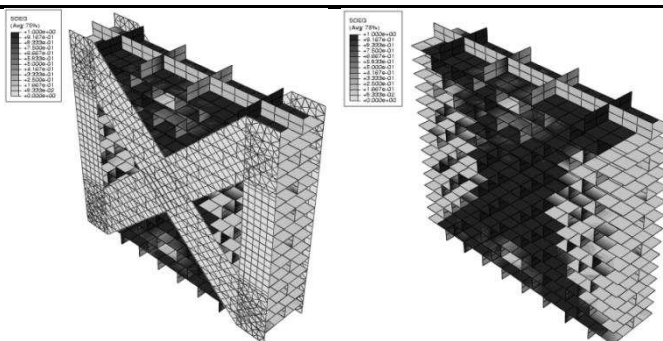

(2b) $-\Delta_{cr}=1.06\text{mm}(-P_{cr}=86.76\text{KN})$

Peak strength state

(3a) $+\Delta_f=4.23\text{mm}(+P_f=117.63\text{KN})$

(3b) $+\Delta_f=4.23\text{mm}(+P_f=114.54\text{KN})$

Ultimate state

(4a) $+\Delta_u=8.53\text{mm}(+P_u=98.81\text{KN})$

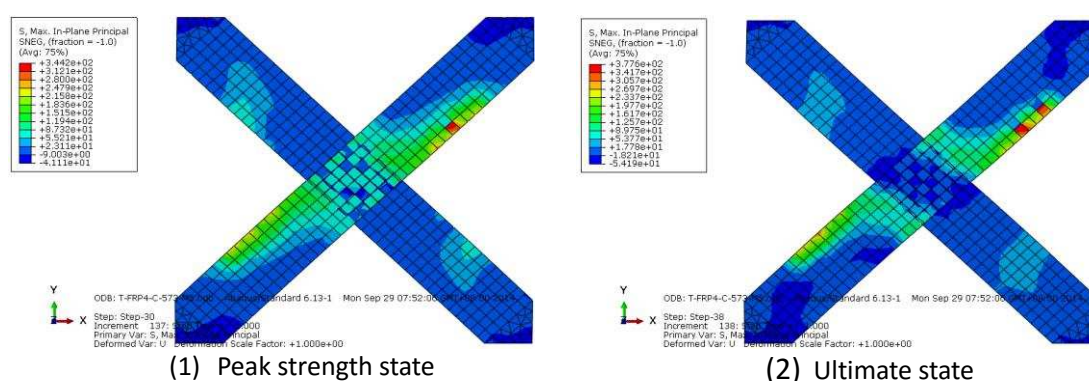

(4b) $+\Delta_u=7.43 (+P_u=90.24\text{KN})$

490

491 For the diagonal FRP strips in BM2-1, the contour of the maximum principal stress is depicted at peak

492 strength and ultimate states (shown in Figure 15). According to Figure 15, when the reinforced
 493 masonry wall reaches its peak strength state and ultimate state, the maximum stresses of the
 494 diagonal FRP strips are approximately equal to 344 MPa and 378 MPa, respectively, which are both
 495 far less than the typical tensile failure strength of BFRP. The finite element simulations also show that
 496 the maximum stress of FRP strips increase progressively during the last few circles and the FRP strips
 497 still work without failure.

498 Figure 15. Maximum principal stresses in FRP

499

500 4.4 Assessment of FRP reinforcement

501 Since the late 1990s, a large number of experimental studies have been carried out to assess the
 502 effectiveness of reinforcement [1-3]. With the help of numerical analysis, the reinforcing
 503 effectiveness can be assessed or predicted in a general and economic way. In this section, the effects
 504 of FRP reinforcement on masonry are analysed.

505 Table 9 illustrates a comparison between the ductility factors obtained from experiments and
 506 simulations. The ductility factors are calculated according to Ref. [41]. Compared with the
 507 unreinforced specimen W2 and numerical model M2, the ductility and resistance to cyclic load are
 508 greatly improved for the BFRP-reinforced specimens BW2-1 and numerical models BM2-1 with
 509 similar amplitude. It indicates that the FRP reinforcement with cross layout and vertical anchors can
 510 effectively enhance the ductility of masonry walls and the numerical model can capture the

511 development of ductility accurately. As shown in Table 9, the horizontal anchors have minimal
 512 influence on the ductility capacity, although the FRP reinforcement with cross layout is adopted for
 513 masonry walls. It is worth noting that the horizontal FRP anchored at the base of the masonry wall
 514 causes high compressive stresses at the base corner. This indicates that the horizontal strips are hard
 515 to slow down the shear-sliding effectively, which shows good agreement with the conclusions in Ref.
 516 [49]. For the specimen BW1-1, the high compressive stresses causes the brittle fracture at ultimate,
 517 including brick crushing at the corners and the de-bonding between BFRP and masonry. However,
 518 the de-bonding behaviour is assumed to be neglected during simulations. That may be the reason
 519 why, the development of ductility for the specimen BW1-1 is less than the numerical model BM1-1.

520 Table 9 ductility factors for the experiment specimens and numerical models

Specimen		P_f (KN)	H_u (KN)	d_e (mm)	d_u (mm)	μ_u	Δ (%)
Experiment							
Group-A	W1	130.34	117.31	0.28	3.5	12.68	
	BW1-1	168.14	151.33	0.49	6.7	13.75	8.42
Group-B	W2	83.05	74.75	0.52	3.71	7.12	
	BW2-1	117.63	105.87	0.71	8.53	11.99	68.32
Simulation							
Group-MA	M1	111.55	100.39	1.06	3.5	3.32	
	BM1-1	191.48	172.332	1.656	6.7	4.045	21.95
Group-MB	M2	86.87	78.19	1.05	3.71	3.54	
	BM2-1	114.54	103.09	1.31	7.43	5.66	59.96

521 Note: d_e is the displacement at the idealised elastic limit; d_u is the maximum displacement for the idealised force-
 522 displacement relationship for masonry; μ_u is the ductility factor; Δ is the improvement between unreinforced and
 523 reinforced masonry walls.

524 For the unreinforced specimen W2, the cracking pattern was typically diagonal, while the shear
 525 cracks in the BFRP-reinforced specimen BW2-1 were found in every unreinforced part. Besides, the

526 lower part of BW2-1 was seriously damaged, but almost no crack was recorded at that part of W2.
527 The experimental observation illustrates that the FRP reinforcement develops the attribution of
528 cracks much more evenly, indicating that the BFRP reinforcement brings changes in the cracking
529 pattern. Similar changes in cracking pattern are also observed in the numerical results of the
530 unreinforced and FRP-reinforced models, M2 and BM2-1, (Table 7 and Table 8). In addition, in Table
531 8(4b), the BM2-1 has a wider diagonal cracking pattern than M2 and additional shear cracks are
532 observed in the unreinforced zones. Therefore, the developed models can reflect and assess the
533 effectiveness of FRP reinforcement on the masonry walls before and after reinforcement in terms of
534 cracking pattern.

535 **5. Conclusions**

536 This paper describes a new development in modelling the behaviour of the unreinforced and FRP-
537 reinforced masonry walls under monotonic and cyclic loading conditions. In the developed meso-
538 scale models, the element-based cohesive element is adopted to simulate mortar joints. Simulations
539 were conducted to evaluate the accuracy and effectiveness of the developed models under both
540 monotonic and cyclic loadings. The numerical results are analysed and compared with code and
541 experimental results. The conclusions are summarised as following:

- 542 (1) The unreinforced masonry specimens are effectively simulated by the developed models.
543 The cracking initiation takes place at the same time and positions; the similar diagonal
544 cracking pattern is also observed. Compared with experimental observations, the cracks in
545 simulation results are relatively wider and evenly distributed.
- 546 (2) The FRP-reinforced masonry models also produced similar cracking patterns observed in the
547 FRP-reinforced masonry experiments. Besides, the cracks under reinforcement can be clearly
548 displayed by removing the reinforcement in the display of the simulation results, but cannot
549 be observed directly in the lab tests. The developed models can provide more insights of the

550 behaviour of FRP-reinforced masonry walls than experimental studies.

551 (3) Under cyclic loadings, the seismic behaviours of the masonry before and after reinforcement
552 are effectively simulated by the developed models. Comparison between the experimental
553 and numerical results shows a close agreement of stiffness degradation and peak strength.
554 Based on the related codes, the calculated results of masonry walls are adopted to validate
555 the monotonic simulation. The simulations match the calculated results accurately.

556 (4) The unreinforced masonry models successfully capture the feature of brittleness for the
557 unreinforced masonry walls. After installing with FRP strips, the reinforced masonry models
558 improve the ductility as well as the seismic resistance of the wall. By comparing with the
559 experimental results, the numerical simulation is verified to have the capacity to assess the
560 effect of FRP reinforcement. Therefore, the developed models are applicable to predict the
561 reinforcement effects.

562 (5) With the built-in constitutive material model in ABAQUS, the element-based cohesive
563 element can effectively reflect the damage progression and the nonlinear behaviour of at
564 mortar joints.

565 (6) The convergence studies on mesh density and penalty stiffness indicate that the proposed
566 models are moderately sensitive under monotonic and cyclic loadings. Thus, the numerical
567 models with cohesive elements are able to overcome the convergence and stability problem.

568
569 Although the developed models have been proved to be efficient and accurate for the cases
570 studied, more work still needs to be carried out for improvement. A perfect adhesion
571 between FRP and masonry was assumed in the current model, and as a result a significant
572 loss of strength after reaching the peak value is observed in the simulations of FRP reinforced
573 cases. Thus, the fracture caused by de-bonding and slipping between FRP and masonry need
574 to be considered in future models. Another improvement can be made by considering the
575 cracks within bricks.
