Summary

Two decades after the discovery that 20% of familial amyotrophic lateral sclerosis (ALS) cases were linked to mutations in the superoxide dismutase-1 (SOD1) gene, a substantial proportion of the remainder of cases of familial ALS have now been traced to an expansion of the intronic hexanucleotide repeat sequence in C9orf72. This breakthrough provides an opportunity to re-evaluate longstanding concepts regarding the cause and natural history of ALS, coming soon after the pathological unification of ALS with frontotemporal dementia through a shared pathological

signature of cytoplasmic inclusions of the ubiquitinated protein TDP-43. However, with profound clinical, prognostic, neuropathological, and now genetic heterogeneity, the concept of ALS as one disease appears increasingly untenable. This background calls for the development of a more sophisticated taxonomy, and an appreciation of ALS as the breakdown of a wider network rather than a discrete vulnerable population of specialised motor neurons. Identification of C9orf72 repeat expansions in patients without a family history of ALS challenges the traditional division between familial and sporadic disease. By contrast, the 90% of apparently sporadic cases and incomplete penetrance of several genes linked to familial cases suggest that at least some forms of ALS arise from the interplay of multiple genes, poorly understood developmental, environmental, and age-related factors, as well as stochastic events.

Introduction

In the autumn of 2011, a monumental discovery changed the way we understand amyotrophic lateral sclerosis (ALS). Some 150 years after Charcot provided the first description of ALS, a genetic variant was discovered that meant neuroscientists must revisit what they knew, or think they knew, about the disorder. Understanding of the cause of this therapeutically resistant neurodegenerative disorder has entered a new phase with the discovery of linkage to an expansion of an intronic hexanucleotide repeat in the previously unknown gene C9orf72. 1 and 2 At the most basic level, this breakthrough provides incontrovertible evidence that ALS and frontotemporal dementia are manifestations of a clinicopathological spectrum. Most tantalising however is the emergence of a unifying pathogenic theme of nuclear protein mishandling in ALS. The apparent RNA binding function of the C9orf72 expansion adds to known mutations in other key RNA-processing and proteosomal genes linked to ALS, notably the transactive-region DNA-binding protein gene TARDBP, 3 the fused in sarcoma gene FUS (also known as translocated in liposarcoma, TLS), 4 and the ubiquilin-2 gene UBQLN2, 5 whose proteins are widely expressed in human cells, with fundamental physiological roles.

The recent C9orf72 genetic breakthrough further reinforces the concept that ALS pathogenesis involves multiple pathways. 6 To date, models of disease have largely centred around mutant superoxide dismutase-1 (SOD1), discovered 20 years ago 7 (figure 1). This genetic discovery heralded development of the first animal model of ALS, 8 and the availability of a coherent strategy for development of successful therapy. Recent seminal findings including a recognition of the importance of TDP-43 deposition in most forms of ALS and some forms of frontotemporal dementia, 9 although not in SOD1-related disease, 9 and the likely role of RNA dysregulation in disease pathogenesis, suggest that translation of findings from the SOD1 model to benefit patients living with ALS might be more restricted than previously thought. Fundamental aspects of ALS, not least its striking clinical heterogeneity, still puzzle clinicians as much now as at the turn of the 20th century and remain the subject of debate. The juxtaposition of the new and exciting discovery of a major ALS gene, with the emergent problems in the translation of findings from the SOD1 mouse model, provided the backdrop to our debate, held as part of the 22nd International Symposium on ALS/MND with the specific aim of highlighting areas that with future research and prioritisation might lead to the development of treatments. To better guide this

therapeutic potential, we considered the clinical scope of ALS, dealing with concepts of heterogeneity, while also dissecting arguments concerning focality of disease onset, methods to identify patterns of disease spread, and predictors of prognosis, with implications for the design of future clinical trials. Recent genetic discoveries and controversies concerning heritability and the current models of ALS were incorporated into the discussion, in the context of emergent technology, with consideration of priorities for future ALS research.

Has the concept of ALS as one disease become untenable?

From a clinical viewpoint, ALS has been identified by most neurologists as a single entity because it characteristically involves a recognised pattern of progressive motor neuronopathy, with respiratory failure as the mode of death for most patients. This core phenotype is confidently diagnosed by an experienced clinician when progression is rapid, although the mean diagnostic delay has stubbornly remained around 1 year from symptom onset,¹⁰ reflecting the reality of more slowly progressing cases. Although ALS is a clinically recognisable condition, there are now strong reasons to consider the classic phenotype as a manifestation of a wider aetiopathogenic spectrum.

Although median survival is 3 years from symptom onset, the survival curve for the remaining cases tapers out to 20 years or more. Many of the long-term survivors appear to have either pure upper motor neuron (termed primary lateral sclerosis) or lower motor neuron (termed progressive muscular atrophy) involvement.¹¹ and ¹² There is an urgent need for reliable subclassification that goes beyond the number of body territories with combined clinical upper motor neuron and lower motor neuron signs that underpin the current diagnostic criteria.¹³ There is increasing frustration with this diagnostic framework (panel 1), which was developed principally as a research aid, since a substantial proportion of patients die with a diagnostic label of “ possible ALS” ¹⁴ even though the clinical progression is the same as that of “ definite ALS” , but with simply fewer demonstrable upper motor neuron signs.

At least 16 genes of major (typically dominant) effect are associated with ALS.¹⁵ Recognisable phenotypes have been reported for some known mutations (table 1), such as the SOD1 A4V variant, which produces a rapidly progressive, primarily lower motor neuron syndrome; ¹⁶ and FUS mutations linked to a juvenile onset, primarily lower motor neuron syndrome. ¹⁷ However, perhaps the most striking development has been the recent recognition of a characteristic phenotype associated with the relatively common C9orf72 hexanucleotide repeat expansion. Patients with the expansion have a younger age of onset, shortened survival, increased rates of cognitive and behavioural impairment, and a strong family history of neurodegenerative disease. ¹⁸ and ¹⁹ Postmortem studies also suggest that C9orf72-associated ALS has a different pathological signature to other forms of ALS.

Heterogeneity in neuropathology can also be discerned. Cytoplasmic inclusions of TDP-43 are found in nearly all autopsied cases of sporadic ALS, and suggest a consistent final common pathway. However, such inclusions are notably absent in ALS associated with pathogenic mutations of SOD1, ²⁰ and the pathophysiological processes underlying this and other abnormal protein aggregation have not been fully elucidated. Expansions of the C9orf72 hexanucleotide repeat have a characteristic neuropathological signature, with

TDP-43 inclusions but in a different distribution including hippocampal and cerebellar regions, and with prominent staining for p62, 21 supporting the view that different primary pathophysiological processes have a final common, clinically indistinguishable, endpoint. As such, the clinical, pathological, and genetic frameworks traditionally used to explain disease heterogeneity remain incomplete, with the corollary that therapeutic interventions might need to be tailored across different subgroups of patients, on the basis of the prevailing upstream pathological events. Understanding of the physiological roles of TDP-43 and C9orf72 will be an essential first step.

Although cognitive and behavioural impairment are now recognised features of ALS, not all patients become impaired. Population based studies suggest that 14% of incident cases have frontotemporal dementia, and a further 30% have evidence of cognitive impairment, mostly but not exclusively in executive dysfunction.²² One of the strongest predictors of cognitive or behavioural impairment in ALS is the presence of the C9orf72 repeat expansion. Taken together, these findings point perhaps to a distinct phenotype in ALS that includes roughly 10% of all cases. Patients with early features of executive impairment progress more rapidly, whereas those who are cognitively normal at the time of diagnosis have a better prognosis and largely do not exhibit features of cognitive decline on serial testing.²³ Furthermore, cognitive impairments common to classic ALS have been notably less prevalent in progressive muscular atrophy²⁴ and primary lateral sclerosis.²⁵ Such observations might reflect an increased resistance in some individuals to the penetration of pathology beyond its initial clinical focus, with obvious therapeutic value if the biological substrate for this resistance could be identified.

Going forward, clinical and genetic studies will require stratification with respect to the presence or absence of the C9orf72 expansion and deeper analysis of clinical phenotyping and genotyping will clearly be needed, including development of a greater understanding of the extreme phenotypes. This process has recently been commenced in several population cohorts with C9orf72-related repeats,¹⁸ and has shown distinct clinical and family signatures. Separately, studies of the typically more slowly progressive clinical phenotypes such as primary lateral sclerosis²⁶ and progressive muscular atrophy²⁷ have also been undertaken, although major gaps persist in our understanding of molecular changes associated with these disorders, in addition to delineation of the extent and timing of upper motor neuron versus lower motor neuron involvement.²⁸ Moreover, there is a particular lack of detailed clinicopathological studies in primary lateral sclerosis,²⁹ regarded by some as a separate disease altogether. The development and application of novel in-vivo neurophysiological and neuroimaging methods to specific clinical subtypes³⁰ and³¹ have the potential to circumvent the end-stage pathology perspective of traditional histopathology.

Should ALS even be regarded as a neuromuscular disease?

Many ALS physicians are also specialists in neuromuscular disease, and the characteristic presence of progressive muscle wasting, weakness, and fasciculations clearly reflects degeneration of anterior horn cells and lower motor neurons. The electromyogram is an adjunct to clinical evaluation, and the Awaji criteria, based on features of denervation and

reinnervation, have recently been established as a useful diagnostic aid.³² However, as originally recognised by Charcot, corticospinal tract involvement is nearly always seen pathologically, even in cases without any clinical evidence of upper motor neuron involvement. The emergence of a close biological relation between ALS and frontotemporal dementia argues strongly in favour of a realignment of specialist expertise towards neurodegenerative and behavioural clinics, rather than concentration exclusively within the neuromuscular domain. And although the transgenic SOD1 model might have some value for understanding of the process of anterior horn cell degeneration, the extramotor manifestations of the disease, including significant cognitive and behavioural impairments, command attention that is not provided by existing animal models.

Further to such discussion, a causal primacy of lower motor neuron over upper motor neuron degeneration³³ remains an issue of debate. Many of the initial pathological changes in models of ALS occur in the peripheral motor system, supporting a dying-back view of pathogenesis.³⁴ However, ALS can also be viewed primarily as a disease of the upper motor neurons, or corticomotoneurons, which connect monosynaptically with anterior horn cells, ³⁵ supported by the clinical observation that the oculomotor, abducens, and Onuf's motor nuclei, which all lack direct corticomotorneuron connections, are strikingly resistant to degeneration.

At the cortical level, premotor and motor regions might seem dominant, although frontal and anterior temporal regions, in addition to subcortical pathways, are key structures. Because motor planning, motor abstraction, emotional expression, and language, which are important aspects of human neocortical evolution, are all affected in ALS, these might hold clues to selective vulnerability and disease progression.³⁶ As such, future studies need to consider ALS as a systems degeneration, rather than focusing on individual neuronal populations. Advanced MRI is uniquely able to study the brain at such a network level. Application of graph theory to structural data concerning white matter tract integrity,³⁷ and independent component-type analysis to cerebral functional data,³⁸ in parallel with detailed clinical and neuropsychological characterisation, offers a comprehensive in-vivo approach to probing disease activity in ALS.³⁹ and 40

Can apparently sporadic ALS be inherited?

In populations of European origin, only 5–10% of patients with ALS report a family history of the disease (figure 2). It seems likely that there is a complex set of genetic determinants, each with potentially small but significant effect.¹⁵ Standard practice has been to reassure patients without an apparent family history of ALS. However, early studies of the C9orf72 hexanucleotide repeat expansion suggest that the repeat expansion is also present in a sizeable minority of apparently sporadic cases, ¹⁹ and ⁴¹ and careful interrogation of kindreds of these patients, supported by death certification, shows increased rates of neurodegenerative conditions, most notably frontotemporal dementia. Such findings suggest that a family history of frontotemporal dementia, which might have been misclassified as Alzheimer's disease, must now be considered in a revised definition of familial ALS.

Furthermore, the definition of familial ALS is increasingly being recognised as inconsistent.⁴² The definition is based on the presence of known disease in other members of a kindred.

In this context the size of the kindred also becomes important in determining heritability. Specifically, the presence of a small number of first-degree and second-degree relatives might erroneously lead to a diagnosis of sporadic ALS, whereas large extended kindreds might serve to increase the risk of a second case of ALS occurring by chance alone. Perhaps more reassuringly for patients with sporadic disease is the limited evidence obtained from clinic-based populations to date, suggesting that although there is approximately an eight-fold increase to first-degree relatives of patients with ALS, the absolute increase in risk seemed to be very small in a follow-up study over 16 years.⁴³

As with previous familial linkage to ALS, there appears to be incomplete penetrance of the C9orf72-related repeat expansion. Incomplete family histories and small family sizes might blur the distinction between sporadic and familial ALS further, suggesting that the reassuring figures for recurrence within offspring cannot be applied across all patients.⁴⁴ A clearer definition of familial ALS, followed by more extensive analyses of disease penetrance, might ultimately lead to a change in the routine counselling of patients. Whether the routine screening of all apparently sporadic cases of ALS for the known familial genetic abnormalities is the optimum approach at present, with the potential to register psychological harm, needs urgent debate.

The explosion in ALS genetics has challenged other long held doctrines relating to known genes of major effect, and evidence of an oligogenic cause in familial and sporadic ALS further compounds the problem of ALS heritability. Until recently, there had been an assumption that single genes of major effect with incomplete penetrance accounted for most cases of familial ALS. As each new ALS gene has been identified, ALS DNA banks have been screened to identify pathogenic variants in the new gene. DNA samples containing known variants are then excluded from further analyses. However, emerging evidence suggests a more complex genetic cause, in which the phenotypic variability might be due to a small number of genetic variants that co-occur with greater frequency than would be expected by chance. Recently described examples include FUS and TARDBP mutations in combination with ANG mutations and C9orf72 repeat expansions combined with TARDBP, SOD1, and FUS mutations.⁴⁵ If replicated, these findings will have important implications for the design and interpretation of ALS genetic studies. Whether this explanation accounts for the substantial phenotypic variations within C9orf72 kindreds remains to be established.

That the most important gene in ALS was identified with conventional genetic approaches, rather than the newer technologies of genome-wide association studies (GWAS) and next-generation sequencing perhaps seems ironic. Whereas the chromosome 9 locus was identified a decade before its characterisation in sporadic ALS,⁴⁶ the intronic repeat expansion could never have been identified with more modern sequencing methods because of the insensitivity of these technologies to detect very large intronic repeat expansions.

The history of GWAS in ALS started with fairly small studies (table 2) that initially had negative results or results that were not replicated in independent studies.⁴⁷ and ⁵⁰ Through international collaborations and data sharing, ongoing combined analysis of available data has now provided consistent results. Nevertheless, by contrast with other neurodegenerative diseases such as Parkinson's or Alzheimer's disease, the results of GWAS looking for

common variability have been disappointing in ALS, again suggesting that ALS is not one clinical entity, but is heterogeneous by nature. The best example of consistent GWAS results to date was the identification of the chromosome 9 locus, which appears aberrant in 5–8% of sporadic ALS. The larger GWAS effectively fine mapped the 9p locus from several megabases to a 110 kb region containing three genes, allowing the C9orf72 discovery. Nevertheless, continuing international collaboration will be needed to generate sample sizes that are comparable with other complex diseases, such as diabetes and inflammatory bowel disease. Also, the combined analysis of GWAS data of ALS with other neurodegenerative diseases (eg, Alzheimer's disease, Parkinson's disease, and frontotemporal dementia) will probably be of great value.

In view of the recent findings of intronic variation and repeated sequences in ALS, and the notion that rare genetic variants as opposed to the common genetic variants underlie pathogenesis, high-throughput exome sequencing and analysis of non-coding DNA by whole-genome sequencing in large samples are now needed to fully elucidate the genetic contribution to ALS pathogenesis.⁶¹ As has been the case for other diseases such as breast cancer, the discovery of one gene that affects a large minority of patients will probably help to identify other genes, since all datasets will now need to be reanalysed after removal of people with the C9orf72 expansion.

Is there a premorbid phenotype that reflects vulnerability to ALS?

Despite conflicting results regarding premorbid athleticism from case-control studies,⁶² and ⁶³ a clinical impression remains that patients who develop ALS frequently have a higher than average level of physical activity or fitness, perhaps best exemplified by the American baseball player Lou Gehrig. Whether the findings of reduced coronary artery disease premorbidly in patients with ALS,⁶⁴ and a cardioprotective vascular profile of patients⁶⁵ and their first degree relatives,⁶⁶ are significant in terms of premorbid fitness or athleticism remains uncertain. Several occupations likely to be linked with high physical activity and fitness have been associated with increased incidence of ALS, including professional footballers in Italy, the military, and manual workers.⁶⁷ and ⁶⁸ Separately, a lower than average body-mass index appears more commonly associated with ALS, linked to the observation of hypermetabolism that often develops in ALS. The biological processes accounting for these changes remain unclear. Mitochondrial impairment has been long considered as a possible pathogenic mechanism in neurodegeneration, and increasing the efficiency of oxidative phosphorylation remains one of the proposed mechanisms of the drug dextroamphetamine, recently the subject of a phase 3 trial for ALS.⁶⁹

It has been argued that physical activity might be harmful to a minority of the population who carry a complex genetic profile that adversely affects the metabolic response to vigorous muscle activity, including oxidative stress.⁷⁰ Many patients with ALS specifically ask whether they can safely continue to exercise regularly without fear of accelerating their disease.⁷⁰ Although low-grade exercise programmes might even have some benefit,⁷¹ there is no firm evidence that exercise exerts a harmful effect, although avoidance of very strenuous activity seems reasonable.

An alternative formulation, which is not mutually exclusive, is that athleticism or fitness in patients with ALS is a reflection of a shared set of genetic determinants that predispose to neurodegeneration, without there being a direct causal link between ALS and exercise.⁶² In a cortically focused model of pathogenesis there might even be preferred loci for neurodegeneration,⁷² and ⁷³ perhaps reflected in regional involvement,⁷⁴ and an athletic profile might then also reflect a distinct motor system architecture. There would be an evolutionary advantage for a configuration associated with fitness, that is perhaps only rendered disadvantageous for a minority as a result of the relatively recent increases in life expectancy. Potential evolutionary trade-offs have been noted in other neurodegenerative disorders.⁷⁵

When does ALS begin?

Longitudinal studies in presymptomatic individuals carrying pathogenic SOD1 mutations have shown apparently abrupt changes in both lower motor neuron loss ⁷⁶ and the development of cortical hyperexcitability ⁷⁷ within a year of symptom onset. Whether the nervous system of people who later develop ALS was normal immediately before disease onset or whether, like in Alzheimer's and Parkinson's diseases, a more prolonged presymptomatic phase of disease might have been detectable, seems uncertain. In support of a prolonged presymptomatic phase, changes in parenchymal metabolites (N-acetylaspartate in relation to choline and myoinositol) were detected in the spinal cord of presymptomatic individuals carrying pathological SOD1 mutations long before clinical disease onset. ⁷⁸ The intriguing suggestion that the risk of ALS develops from factors operating at the time of conception or perhaps during early development warrants further consideration. ⁷⁹

Detailed study of presymptomatic individuals carrying pathogenic mutations could provide unique insight into the nature of the earliest events before the tipping point of symptom onset. This pursuit is likely to be relevant to the long-term strategy of primary prevention, although these studies will be necessarily long term and costly. Although there might be ethical concerns associated with testing and studying of asymptomatic family members, a robust framework for this process has recently been established.⁸⁰

How does ALS spread?

Typically, ALS has a striking focal clinical presentation, although this view must be interpreted with the understanding that most biological systems have a degree of redundancy and also in view of emerging data covering presymptomatic changes. For example, at least a third of muscle fibres have already been lost before clinical wasting occurs in ALS.⁸¹ Nonetheless, post-mortem studies suggest that the pathological changes in ALS radiate from an area in which maximum upper motor neuron and lower motor neuron dysfunction aggregate together in the spinal region of first symptom onset.⁸² Spread of symptoms then appears to occur via an anatomically contiguous space within both upper motor neuron and lower motor neuron systems, although the rate might appear to differ within these two anatomical axes. Separately, a complete model of the ALS system failure requires incorporation of a third extramotor axis; namely, the substrate for cognitive and behavioural impairments.

Irrespective of the basis for the regional pattern of involvement in ALS, important and unexplained differences remain in sex and age, particularly in relation to the site of disease onset. For example, respiratory-onset disease tends to be more prevalent in men,⁸³ and a predilection for isolated corticobulbar disease has been noted in elderly women.⁸⁴ Bulbar-onset ALS is strikingly under-represented in young-onset patients,⁸⁵ and the biological reasons for these phenomena require dedicated investigation.⁸⁶ By contrast, regional onset could be purely stochastic⁸² or perhaps related to patterns of use or development.⁷⁴ The convergence of upper motor neuron and lower motor neuron features might then reflect the topography of muscle innervation. Separately, there are also physiological differences between short and long axons that must be considered, including axonal membrane conductances and the Na⁺/K⁺ pump, the dysfunction of which might be relevant to pathogenesis.⁸⁷

The development of advanced neuroimaging techniques has allowed novel assessment of structural and functional connections within the brain of patients with ALS that has further guided concepts about disease spread, individual susceptibility, and prognosis. Cortical correlates for regional symptoms can be shown with volumetric MRI.⁸⁸ Neuronal connections are organised in networks and appear to have their own characteristics. Properties include the overall connectivity of the network, clustering of network nodes, the efficiency of the network, and the degree to which there are identifiable hubs.⁸⁹ Recent investigations concerning functional connectivity in ALS have identified that patients with a strong connectedness of the motor network have a fast progression of disease, suggesting a potential role for assessment of the functional organisation of the motor network as a marker of disease progression.³⁹ and ⁹⁰ Positive correlation might also suggest patterns of disease spread along functional connections of the motor network in ALS, by contrast with the theory that ALS solely affects a fixed set of primary motor connections.⁴⁰ These more widespread effects on the brain network suggest that focal damage in primary motor regions in ALS might ultimately manifest in connectivity disturbances elsewhere in the brain, with patterns of change potentially serving as biomarkers for disease progression. At the synaptic level, parallels have also been drawn for a prion-like spread of abnormal protein conformation and propagation of cellular toxicity in ALS,⁹¹ and ⁹² perhaps involving exosomes or autophagy.⁹³

How can the course of ALS be predicted and the design of therapeutic clinical trials improved?

Prediction of the rate of progression in a heterogeneous disorder such as ALS has clear value in care-planning, but also in the assessment of potential therapeutic agents. Typical inclusion criteria for therapeutic trials have tended to be based on time from symptom onset (typically with a cutoff less than 3 years) and a minimum level of respiratory function as measured by vital capacity. Within only these criteria there will inevitably be a wide range of prognoses, thereby greatly reducing statistical power.

However, broad phenotypes with consistent prognostic patterns can be identified in a population-based context. These patterns include rapid decline in patients with respiratory-onset disease,⁸³ reduced survival in those with executive impairment,²³ and slower

progression in those with upper motor neuron-predominant disease (consistent with the extreme example of primary lateral sclerosis).¹² and 94 Consistent regional (generally contiguous) patterns of symptom spread are also recognisable,^{95, 96} and 97 and simple clinical parameters at diagnosis can allow robust stratification of prognosis for clinic-based patients.⁹⁸ and 99 In view of these developments, a formal staging system for ALS has been proposed that attempts to better incorporate clinical phenotype.¹⁰⁰ Stratification by rate of disease progression (time to spread to a new region) and degree of cognitive impairment, rather than the traditional divisions by site of onset or upper motor neuron- dominance versus lower motor neuron dominance, might yet prove more useful for future clinical trial enrolment.

At the individual patient level, prognostication soon after symptom onset remains difficult; for instance, it is difficult to distinguish typical bulbar-onset ALS (with progression to limb weakness) from a more atypical, isolated bulbar onset, which might remain isolated sometimes for several years before the involvement of other body regions (sometimes termed progressive bulbar palsy).¹⁰¹ Intrinsic heterogeneity among trial participants can obscure treatment effects that might be more obvious in specific clinical (or genetic) subgroups, and various strategies have been proposed to improve efficiency of clinical trials in ALS.¹⁰² Subgroup analysis of patients involved in previous clinical trials might have value; for example, some have suggested that riluzole could have an effect in delaying cognitive involvement.

Pending validation of the numerous and varied candidate biomarkers (summarised in panel 2),^{103, 104} and 105 the revised ALS functional rating score (ALSFRS-R; panel 3) is a frequently used outcome measure in therapeutic trials.¹⁰⁶ This score has good intrarater and inter-rater reliability, and prognostic value as a single measurement at the point of diagnosis as well as an indicator of the rate of change.¹⁰⁷ However the slope of its decline might not be consistently linear, with deviations noted in early and late stages of the disease,¹⁰⁸ so that statistical assumptions based on a linear model in trials involving patients early in their disease might be incorrect. Patient dropouts due to disease progression further complicate the design of ALS clinical trials, in addition to inherent and progressive problems for patients to attend the protocol centres, leading to potentially critical loss of statistical power. A method to combine survival and ALSFRS-R into one primary outcome measure was developed as the primary endpoint for the failed phase 3 trial of dexpramipexole.¹⁰⁹ There is also increasing momentum to consider a further adjustment of the ALSFRS-R to include assessment of executive function, although further data are needed to validate available cognitive tools for ALS.

Motor unit number estimation, axonal excitability, electrical impedance myography, the neurophysiological index (NI), and cortical excitability all have potential as alternative outcome measures.¹⁰⁵ The neurophysiological index has been shown to have good intrarater reliability and sensitivity to change in ALS, including the differentiation of fast and slow progressing patients.¹¹⁰ Longitudinal analysis supports incorporation of the NI into future therapeutic trials.¹¹¹ More generally, that future trials must routinely incorporate candidate biomarkers if the historical reliance on survival as the primary outcome measure is to be overcome is widely agreed.

Has the SOD1 mouse model outlived its usefulness?

The transgenic mouse model overexpressing SOD1 contains multiple copies of mutant human DNA. The model has been used extensively to dissect the likely pathogenic mechanisms of mutant SOD1 and to evaluate the possible benefits of new therapeutic agents. There has been a disappointing lack of drugs that meaningfully affect disease progression in the model and also in the translation of any modest disease-delaying benefits from mouse to human ALS. The repeated failures of phase 2 and 3 trials in human beings based on SOD1 mouse studies have led to calls for a reappraisal of the usefulness of the model.

Although the SOD1 mouse recapitulates several core clinical features of ALS—namely, a predictable and progressive loss of motor neurons, associated with muscle weakness commencing at approximately 90 days, and premature death—the pathological cascade plays out over a short period of time. 8 Therein might lie an inherent problem in the attempt to translate the results of therapeutic challenges to the human disease, in which symptoms do not emerge for several decades and where the disease develops through a combination of factors that are beyond genetic mutations and not captured by any model to date. Separately, therapeutic agents that have been tested and judged beneficial in the mouse model have been administered well before symptom onset.

A further failure of translation might partly relate to errors in early mouse studies, which were often inadequately powered and confounded by factors including differential effects of sex, failure to control for variations in copy number, differences in animal husbandry, and variability in mouse strain genetic backgrounds, leading to potentially erroneous conclusions. However, to address these issues, two recent workshops have generated guidelines that could largely resolve the confounders of early mouse studies, thereby rendering comparative analysis more robust.^{112, 113, 114 and 115}

Proponents of the mouse model point out that translation from mouse to human being will always be imperfect because of cross-species differences in neuroanatomy, pharmacokinetics, and dynamics, as well as longevity. They also point to the reproducible murine phenotype and the similarities in neuropathology, including the early and selective degeneration of anterior horn cells. Conversely, some issues need to be further considered including the requirement for large copy numbers of mutant DNA to generate a phenotype, the absence of phenotype in the mouse with highly penetrant human mutations that lead to a severe phenotype in human beings (eg, the A4V mutation), and the observation that SOD1-related ALS is not associated with TDP-43 inclusions—the pathological signature common to nearly all other forms of human ALS, including those associated with hexanucleotide repeat expansions in C9orf72. Although recent genetic advances have led to the development of new animal models based on transgenic TDP-43 and FUS mutants, no other model identified to date has recapitulated the clinical disease phenotype to the extent of the SOD1 mouse, despite the aforementioned caveats.

Novel approaches to understanding of ALS pathogenesis

The cost of whole-genome sequencing is falling exponentially to a level that will soon make this approach feasible for a large number of patient samples. An internationally collaborative approach to sequence whole genomes from large cohorts of well characterised patients with ALS seems the next logical step. As a result, the characterisation of the genetic architecture of ALS might soon be complete, but is likely to be only the first step towards identification of key pathways amenable to therapeutic intervention. A limitation of the downstream transcriptomic approach is the difficulty in distinguishing primary (initiating) and secondary (responsive) changes in gene expression from the mass of data generated, although this approach holds promise.¹¹⁶ High-throughput proteome-wide studies are still beyond the horizon.

The bioinformatics task presented by the enormous volume and complexity of both genomic and RNA expression data has become the immediate challenge. It requires the neuroscience research community to engage those with the mathematical expertise needed to meaningfully interrogate and interpret such datasets, in conjunction with more sophisticated clinical phenotyping of patients.

Although animal modelling for ALS remains challenging, and rodent models have limitations, new models that engage technological developments hold promise for rapid assessment of therapeutic potential. Such models include the *Caenorhabditis elegans* worms, established for high-throughput, large-scale functional validation of candidate protective genes, including lines expressing forms of TDP-43 or FUS.^{117, 118 and 119} Selection of nematode promoters can now also be used to express these proteins in neurons or more specifically only in motor neurons. In addition to the development of phenotypic assays, such studies could also unlock a holy grail in ALS research—the mechanism of disease spread at a molecular level.

The development of induced pluripotent stem cell technology offers an additional and potentially cost-effective approach as a platform for early modelling pathology and testing therapeutic candidates (so-called disease-in-a-dish). It marks a significant divergence from the traditional view of stem cells as a potential therapy for ALS.¹²⁰ One of the major challenges will be to overcome the great heterogeneity across cell colonies, and to model the in-vivo network environment of such cells, which might be as important as any individual cellular dysfunction observed in isolation.¹²¹ Emerging themes might be common to other neurodegenerative disorders, in particular protein degradation pathways,^{6 and 122} making overlap in treatment strategy between ALS and other disorders increasingly likely.¹²³

Conclusion

The enormous advances in scientific research during the past two decades have revealed the complexity of ALS pathogenesis (figure 3), which might have been underestimated at the time of the discovery of SOD1. Developments in molecular biology, particularly the discovery of C9orf72, when combined with new approaches in clinical neurophysiology and neuroimaging have accentuated rather than lessened the importance of detailed clinical assessment. The multiple pathogenic processes support the view of multiple routes to a

common endpoint of progressive upper motor neuron and lower motor neuron loss, which might mean that successful treatment will ultimately involve multiple targets.

The search for biomarkers in ALS is one of several research priorities (panel 4). Despite a large number of negative trials, ALS remains attractive to biotechnology companies with an array of approaches that are increasingly based on combating hypothesis-led mechanisms. Examples include small molecules to potentially interfere with protein aggregation, gene therapy to replace specific mutations, stem cell therapy to support glial as well as motor neuronal cells, and oligonucleotides to interfere with abnormal RNA processing. With improved understanding of the chemical structure of the drugs most likely to be effective, there is also potential for the repositioning of compounds held in pharmaceutical company drug libraries, abandoned for their original purposes, but in which extensive pharmacological and toxicity studies have often been completed.

Advances in the understanding of pathogenesis in ALS have occurred despite limitations in our understanding of fundamental aspects of the disorder and its taxonomy. These advances, coupled with the positive effects of the globalisation of scientific discussion and debate, will drive the emergence of the therapeutic era of ALS within the first half of this century.

Search strategy and selection criteria

We searched PubMed (1966, to Dec 31, 2012), Embase (1980, to Dec 31, 2012), and the Cochrane Library using the search terms “ amyotrophic lateral sclerosis” or “ motor neuron disease” in combination with “ diagnosis” , “ epidemiology” , “ fronto-temporal dementia” , “ imaging” , “ neurophysiology” , “ management” , and “ neuroprotection” . Further articles were included from reference lists, review articles, and major textbook chapters. Abstracts and reports from relevant meetings were also included. The final reference list was generated on the basis of originality and relevance to the topics covered in this report. Emphasis was placed on publications from the past 5 years, but did not exclude commonly referenced and highly regarded older publications.

Acknowledgements

The Fort Denison consensus meeting was supported by Neuroscience Research Australia and the University of New South Wales. MCK receives funding support from the National Health and Medical Research Council. MRT is supported by the Medical Research Council & Motor Neuron Disease UK Lady Edith Wolfson Clinician Scientist Fellowship. OH received funding from the Health Seventh Framework Programme (FP7/2007-2013) under grant agreement No 259867, ALSA (the ALS Association), HRB (the Health Research Board) Clinical Scientist Award, and Research Motor Neuron (previously named Motor Neuron Disease Research Foundation). BJT is supported in part by the Intramural Research Programs of the NIH, National Institute on Aging (Z01-AG000949-02). We are grateful to Olaf Ansorge for his expert advice on table 1. Helpful discussion with Linda Greensmith and Denise Figlewicz regarding the SOD1 mouse model of ALS is gratefully acknowledged.

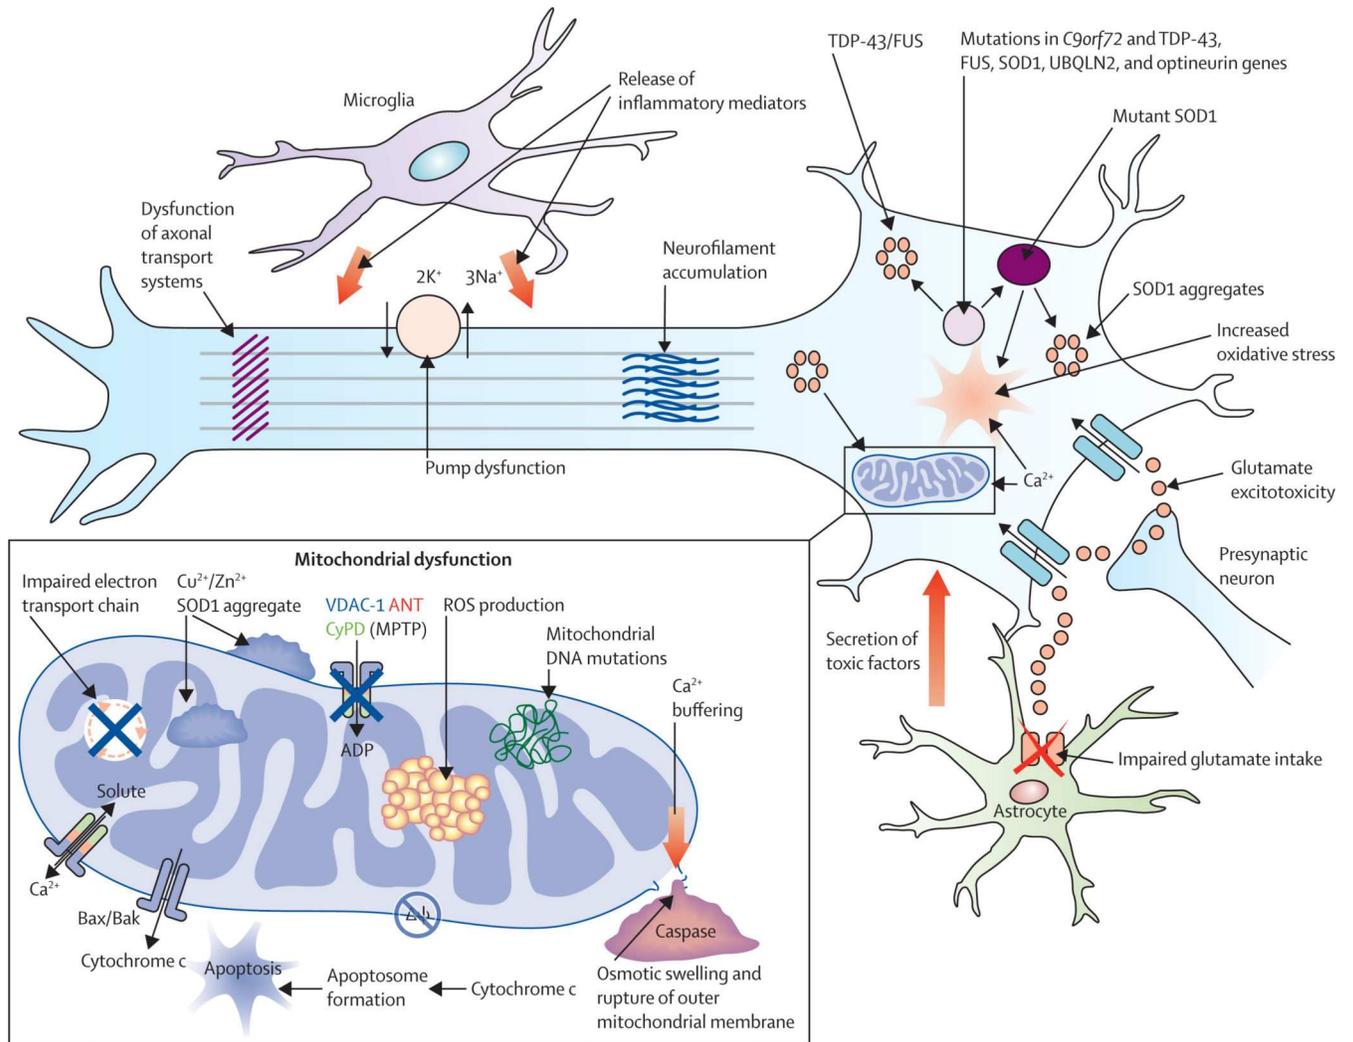

Figure 1. Proposed mechanisms underlying neurodegeneration in ALS

Many of these pathways are mechanisms of cell death common to a range of neurological disorders, although in the case of amyotrophic lateral sclerosis (ALS), have been derived from studies undertaken predominantly using the SOD1 mouse model. Pathophysiological mechanisms involving more recent genetic discoveries, particularly the *C9orf72* hexanucleotide repeat expansion, have yet to be elucidated. Neurodegeneration in ALS might reflect combinations of glutamate excitotoxicity, generation of free radicals, mutant SOD1 enzymes, along with mitochondrial dysfunction and disruption of axonal transport processes through accumulation of neurofilament intracellular aggregates. Mutations in several ALS-related genes are associated with the formation of intracellular aggregates, which appear harmful to neurons. Activation of microglia results in secretion of proinflammatory cytokines resulting in further toxicity. Failure of cytoplasmic mitochondria induces increased susceptibility to glutamate-mediated excitotoxicity, perturbations in motor neuronal energy production, and apoptosis. Mitochondrial dysfunction is associated with increased production of reactive oxygen species (ROS). Cytoplasmic aggregates of SOD1

might directly inhibit conductance of VDAC1, thereby reducing the supply of ADP to mitochondria for ATP generation. ψ =mitochondrial membrane potential.

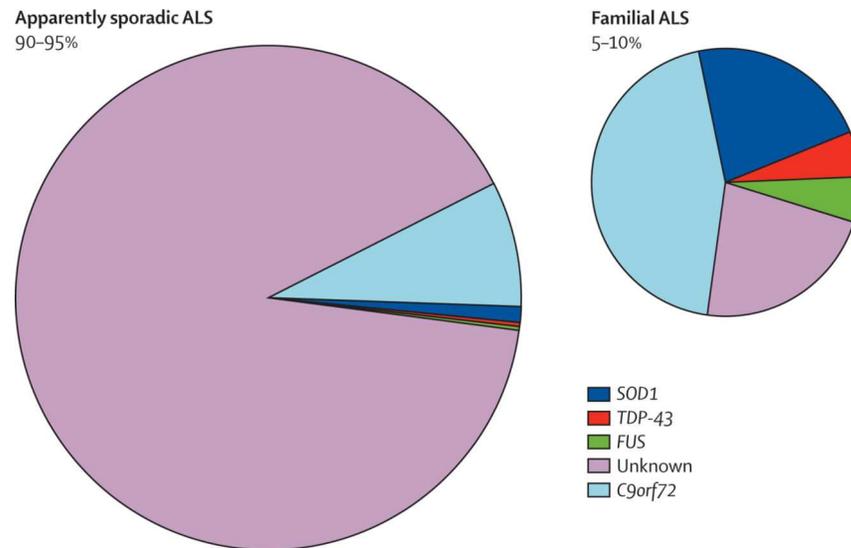

Figure 2. The current macrogenetic landscape in ALS, highlighting the increasingly blurred boundary between familial and apparently sporadic disease

Only 5–10% of cases of amyotrophic lateral sclerosis (ALS) presenting to specialists report a positive family history of ALS or frontotemporal dementia (FTD). At least two-thirds of such cases can now be linked to one of four major genes, the largest group being those with expansions of the hexanucleotide repeat sequence in *C9orf72*. However, this expansion and mutations of the other genes identified are also detectable in a small but significant proportion of the 90–95% of cases of apparently sporadic ALS reporting no family history.

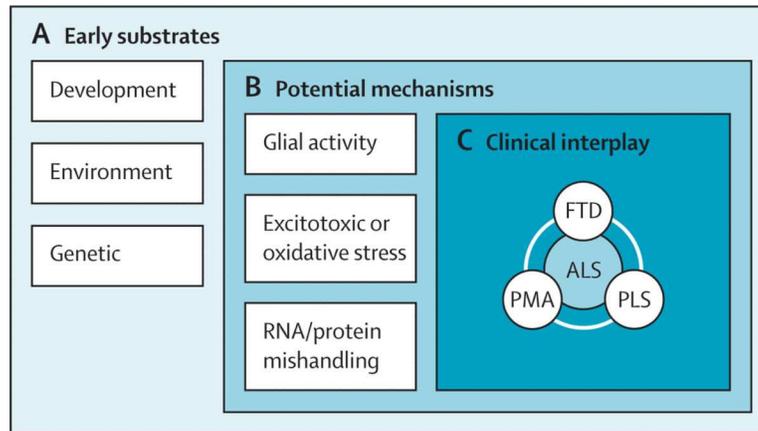

Figure 3. Hypothesised sequence of events in the pathogenesis of the ALS syndrome

The early substrate for amyotrophic lateral sclerosis (ALS; A) is likely to involve genetic, developmental, and environmental factors. For most apparently sporadic cases, multiple genetic factors with small individual effects might in part affect development and maturation of the nervous system. This process might result in a motor system architecture that is more permissive to pathological changes later in life, for example. Environmental triggers might then operate on an already primed system. Several molecular mechanisms for neurodegeneration have been postulated (B), common themes including excitotoxicity (or loss of inhibitory neuronal buffering) and oxidative stress. A common endpoint seems to be protein misaggregation, in which several recent genetic discoveries have implicated abnormal RNA biology. ALS is a syndrome with cases showing variable involvement of upper and lower motor neurons, and extramotor cognitive impairment (C), in which there can be significant variation in rates of progression. Although there are extremes of relatively isolated involvement of each of these compartments, termed primary lateral sclerosis (PLS), progressive muscular atrophy (PMA), and frontotemporal dementia (FTD), all of these overlap with classic ALS on post-mortem neuropathological examination. A greater understanding of the nature of the apparent barriers between upper, lower, and extramotor neuronal populations might ultimately offer a disease-modifying strategy.

Table 1

Genes (in order of discovery) associated with dominant mutations linked to adult-onset motor-predominant syndromes, showing the range of clinical phenotypes and principal neuropathological protein aggregates

	Clinical involvement	Neuropathological protein aggregates
SOD1	LMN, UMN	Cytoplasmic inclusions of SOD1, or neurofilaments (eg, I113T); generally no TDP-43 aggregates
VAPB	LMN, UMN	Probable TDP-43 aggregates
ANG	LMN, UMN, FTD	TDP-43 aggregates
TARDBP	LMN, UMN, FTD	TDP-43 aggregates
FIG4	UMN	Not known
FUS	LMN, UMN, FTD	FUS aggregates, no TDP-43 aggregates
OPTN	LMN, UMN, FTD	TDP-43 aggregation (Glu478Gly)
C9orf72	LMN, UMN, FTD	TDP-43 aggregates, but also pathognomonic TDP-43-negative aggregates in cerebellar and hippocampal neurons (molecule currently unknown)
UBQLN2	LMN, UMN, FTD	Ubiquilin-2, also TDP-43-positive and FUS-positive

Table 2

Genome-wide association studies in amyotrophic lateral sclerosis

	n (cases/controls)	Genome-wide significant* result in or near gene	Independent samples or overlap	Remarks
Schymick et al 2007 ⁴⁷	276/271	None	Overlap	..
Van Es et al 2007 ⁴⁸	461/450	None	Overlap	SNP in or near ITPR2 replicated in third phase of study
Cronin et al 2008 ⁴⁹	958/932	None	Overlap	..
Van Es 2008 ⁵⁰	461/450	DPP6	Overlap	Genome-wide significant in GWAS data plus replication cohort
Simpson et al 2009 ⁵¹	781/702	ELP3	Unknown	Different kind of genetic markers used (microsatellites)
Chio et al 2009 ⁵²	553/2338	None	Overlap	Original SNPs in or near DPP6, ITPR2, FGGY not replicated
Landers et al 2009 ⁵³	1821/2258	None	Overlap	..
Van Es et al 2009 ⁵⁴	4855/14953	C9orf72 (9p21.2), UNC13A (19p13.3)	Overlap	..
Li et al 2009 ⁵⁵	58/52	None	Independent	SNP in or near DPP6 not replicated
Shatunov et al 2010 ⁵⁶	4312/8425	C9orf72 (9p21.2), UNC13A (19p13.3)	Overlap	..
Laaksovirta et al 2010 ⁵⁷	442/521	C9orf72 (9p21.2), SOD1	Independent	..
Iida et al 2011 ⁵⁸	92/233	None	Independent	Stepwise case-control association study, combined analysis genome-wide significant at SNP in or near ZNF512B; SNPs in or near DPP6, ITPR2, FGGY, UNC13A not replicated
Kwee et al 2012 ⁵⁹	442/348 [†]	None	Independent	Original SNP in DPP6 not replicated, other SNP in DPP6 (p=0.0004) with same direction; ITPR2 not replicated; other SNP in ELP3 (p=0.0004); SNP in UNC13A, odds ratio 1.2 (same direction; p=0.04)
ALSGEN Consortium 2012 ⁶⁰	4243/5112	UNC13A (recessive model)	Overlap	No replication in samples independent from previous studies of DPP6 (69% power), ITPR2 (30% power), UNC13A (17% power)

Most replication attempts in these genome-wide association studies (GWAS) were underpowered because of a considerable overlap between samples included, so for these genes larger independent replication studies are needed to definitively assess their role. Additionally, when susceptibility genes also have a detrimental effect on survival, population-based cohorts will be needed that automatically will include patients with short survival in order to avoid underestimation of allele frequencies. Finally, this table clearly shows the need for combined analysis of available data to arrive at the so-called latest and greatest GWAS in amyotrophic lateral sclerosis, such as in the ALSGEN Consortium publication. Even more GWAS datasets are available now and will be in the near future. SNP=single nucleotide polymorphism.

* $p < 5 \cdot 0 \times 10^{-8}$.

[†] Also second cohort (n=5909).

Panel 1**Diagnostic criteria for amyotrophic lateral sclerosis (ALS) derived from El Escorial¹³ and modified Airlie House criteria¹⁴**

Diagnosis of ALS requires:

- (1) The presence of: (a) evidence of lower motor neuron degeneration by clinical, electrophysiological, or neuropathological examination; (b) evidence of upper motor neuron degeneration by clinical examination; and (c) progression of the motor syndrome within a region or to other regions, as determined by history or examination; and
- (2) The absence of: (a) electrophysiological and pathological evidence of other disease processes that might explain the signs of lower or upper motor neuron degeneration; and (b) neuroimaging evidence of other disease processes that might explain the observed clinical and electrophysiological signs.

El Escorial criteria

Definite ALS: upper and lower motor neuron signs in three regions.

Probable ALS: upper and lower motor neuron signs in at least two regions with upper motor neuron signs rostral to lower motor neuron signs.

Possible ALS: upper and lower motor neuron signs in one region, upper motor neuron signs alone in two or more regions, or lower motor neuron signs above upper motor neuron signs.

Suspected ALS: lower motor neuron signs only in two or more regions.

Airlie House (modified) criteria

Clinically definite ALS: clinical evidence alone of upper and lower motor neuron signs in three regions.

Clinically probable ALS: clinical evidence alone of upper and lower motor neuron signs in at least two regions with some upper motor neuron signs rostral to (above) the lower motor neuron signs.

Clinically probable-laboratory-supported ALS: clinical signs of upper and lower motor neuron dysfunction are in only one region, or upper motor neuron signs alone in one region with lower motor neuron signs defined by electromyography criteria in at least two limbs, together with proper application of neuroimaging and clinical laboratory protocols to exclude other causes.

Possible ALS: clinical signs of upper and lower motor neuron dysfunction in only one region, or upper motor neuron signs alone in two or more regions; or lower motor neuron signs rostral to upper motor neuron signs and the diagnosis of clinically probable-laboratory-supported ALS cannot be proven.

Suspected ALS: this category has been deleted from the revised El Escorial criteria.

Panel 2

Leading candidate biomarkers in amyotrophic lateral sclerosis^{103, 104 and 105}

CSF

- Neurofilaments
- Cystatin C
- TDP-43
- Neuroinflammatory molecules

Blood

- Neurofilaments
- TDP-43
- Neuroinflammatory molecules

MRI

- Reduced motor cortical density or thickness
- Fractional anisotropy of the corticospinal tract or corpus callosum
- Functional connectivity of the cortex
- Altered motor cortical metabolites

Neurophysiology

- Neurophysiological index
 - Motor unit nerve estimation
 - Electrical impedance myography
 - Threshold-tracking transcranial magnetic stimulation
-

Panel 3Amyotrophic lateral sclerosis functional rating scale, revised¹⁰⁶

-
- 1 Speech
 - 4 Normal speech
 - 3 Detectable disturbance
 - 2 Intelligible without repeating
 - 1 Speech with non-verbal communication
 - 0 Loss of useful speech
 - 2 Salivation
 - 4 Normal
 - 3 Slight, but definite excess of saliva
 - 2 Moderate excessive saliva, minimum drooling
 - 1 Marked excessive of saliva, some drooling
 - 0 Marked drooling, needs constant tissue
 - 3 Swallowing
 - 4 Normal eating habits
 - 3 Early eating problems, occasional choking
 - 2 Dietary consistency changes
 - 1 Needs supplemental tube feeding
 - 0 Nil orally
 - 4 Handwriting
 - 4 Normal
 - 3 Slow or sloppy, all words legible
 - 2 Not all words legible
 - 1 Able to grip pen, but cannot write
 - 0 Unable to grip pen
 - 5 Cutting food and handling utensils
 - 4 Normal
 - 3 Slow and clumsy, but no help needed
 - 2 Can cut most foods, although clumsy and needs some help
 - 1 Food must be cut by someone else
 - 0 Needs to be fed
 - 6 Dressing and hygiene
 - 4 Normal
 - 3 Independent, but decreased efficiency
 - 2 Some help with closures and fasteners
 - 1 Provides minimum assistance to caregiver
 - 0 Unable to perform any task
 - 7 Turning in bed
 - 4 Normal
 - 3 Slow and clumsy
 - 2 Can turn alone with difficulty

- 1 Can initiate but cannot turn or adjust sheets
0 Total dependence
- 8 Walking
4 Normal
3 Early ambulation difficulties
2 Walks with assistance
1 Non-ambulatory, functional movement
0 No purposeful leg movement
- 9 Climbing stairs
4 Normal
3 Slow
2 Mild unsteadiness or fatigue
1 Needs assistance
0 Cannot do
- 10 Dyspnoea
4 None
3 Occurs when walking
2 Occurs when eating, bathing, or dressing
1 Occurs at rest
0 Considerable difficulty
- 11 Orthopnoea
4 None
3 Some difficulty, does not routinely use more than two pillows
2 Needs extra pillows to sleep
1 Only sleeps sitting up
0 Unable to sleep
- 12 Respiratory insufficiency
4 None
3 Intermittent use of non-invasive ventilation
2 Continuous use of non-invasive ventilation at night
1 Continuous use of non-invasive ventilation, day and night
0 Mechanical ventilation via tracheostomy
-

Panel 4Priority areas for amyotrophic lateral sclerosis (ALS) research

- Understanding of the development of cortical and spinal motor neuron populations, their interaction with each other, and how it changes with normal ageing and in ALS
 - Factors determining rate of disease progression
 - Development of in-vitro and in-vivo models that accurately mimic ALS-related protein misfolding, aggregation, and accumulation
 - Identification of the complete ALS-related genome
 - Identification of the earliest, presymptomatic characteristics of ALS through the collaborative identification and study of relatives of patients with familial ALS
 - Identification and standardisation of a biomarker for presymptomatic or early ALS and incorporation (with a view to validation) of at least one biomarker candidate in future therapeutic trials
 - High-throughput compound screens in cellular and animal models of ALS (including zebrafish and worm models)
 - Identification of possible environmental factors through large-scale international collaboration
-
