Abstract

Disorders or differences in sex development (DSD) comprise a heterogeneous group of conditions with an atypical sex development. For optimal diagnosis highly specialized laboratory analyses are required across European countries. Working group 3 of EU COST (European Cooperation in Science and Technology) Action BM 1303 “DSDnet” “Harmonisation of Laboratory Assessment” has developed recommendations on laboratory assessment for DSD regarding the use of technologies and analytes to be investigated. This position paper on steroid hormone analysis in diagnosis and treatment of DSD was compiled by a group of specialists in DSD and/or hormonal analysis, either from participating European Countries or international partner countries. The topics discussed comprised analytical methods (immunoassay/mass spectrometry based methods), matrices (urine/serum/saliva) and harmonisation of laboratory tests. The following positions were agreed upon: Support of the appropriate use of immunoassay and mass spectrometry based methods for diagnosis and monitoring of DSD. Serum/plasma and urine are established matrices for analysis. Laboratories performing analyses for DSD need to operate within a quality framework and actively engage in harmonisation processes so that results and their interpretation are the same irrespective of the laboratory they are performed in. Participation in activities of peer comparison such as sample exchange or when available subscribing to a relevant external quality assurance program should be achieved. The ultimate aim of the guidelines is the implementation of clinical standards for diagnosis and appropriate treatment of DSD to achieve the best outcome for patients, no matter where patients are investigated or managed.
1. Introduction

Disorders or differences in sex development (DSD) comprise a heterogeneous group of conditions with an atypical sex development. Patients with DSD are complex and rare, and multi-disciplinary teams are needed for optimal diagnosis and management. Thus, highly specialized laboratory analyses are required across European countries. COST (European Cooperation in Science and Technology) Action “DSDnet” forms a network bringing together different stakeholders and people interested in DSD, scientists, clinicians, as well as people with DSD (www.dsdnet.eu). Working group 3 “Harmonisation of Laboratory Assessment” of the COST action “DSDnet”, has developed recommendations on laboratory assessment for DSD regarding the use of technologies and analytes to be investigated. This important work will form the basis of future European reference Network for rare endocrine disorders. This position paper on steroid hormone analysis in diagnosis and treatment of DSD was compiled by a group of specialists in DSD and/or hormonal analysis, either from participating European Countries or international partner countries.

1.1 Relevance of Clinical Steroid Analysis

The Chicago consensus statement and recent literature regarding disorders of sex development emphasizes the need for comprehensive diagnosis and treatment of DSD \(^1-5\). Diagnosis of DSD remains challenging for involved pediatricians, endocrinologists, geneticists, urologists and other related disciplines, as even with novel approaches a specific molecular diagnosis is only achieved in about 30-50% of patients with 46,XY DSD \(^4\). Thus, the diagnostic pathway in patients with DSD requires close interlinking between the clinical, biochemical and genetic diagnostic work-up.

Traditionally, hormonal analyses in blood or urine have been used as part of the first-line diagnostic approach. In current practice, this is more frequently used in combination with molecular genetic analyses. In addition to diagnostic data, biochemical analysis will provide additional functional information guiding further management, disease monitoring and explain
differences in phenotypic expression. However, this heavily depends on local and national
diagnostic pathways and regional differences in accessibility to highly specialized analyses.
There are significant differences in funding streams, clinical and laboratory resources as well as
the interplay with research laboratories, resulting in a heterogeneous situation in Europe. In
many countries, clinical endocrinology has increasingly become dominated by economic
constraints. While hormone measurement has traditionally been a mainstay of clinical
endocrinology, the absorption of hormone labs by centralized laboratory units is associated with
the risk of loss of expertise in hormone test development, selection, and data interpretation. A
Pan-European and ultimately a global approach should aim for a harmonisation of diagnostic
pathways according to requirements achieving the correct diagnosis.

The majority of 46,XX infants presenting with virilization of the external genitalia will have
congenital adrenal hyperplasia (CAH). In such cases a quantification of multiple steroids in a
steroid profile is very important in order to detect rare forms of steroid biosynthesis disorders. A
recent report on exome sequencing exemplifies the significant benefit of next generation
sequencing techniques for diagnosing 46,XY DSD. However, the paper indirectly illustrates the
requirement of detailed clinical and comprehensive biochemical data for a holistic
understanding of individual DSD cases.

Hormonal analysis is not only important for initial diagnosis of DSD. It also remains a decisive
cornerstone for monitoring adequate hormone replacement in various conditions with the goal
of avoiding adrenal crises, ensuring optimal development of growth, weight and puberty,
supporting sexual function and optimizing quality of life in patients with DSD. It is of paramount
importance that any meaningful hormone data interpretation in relation to DSD has to take into
consideration the patient’s individual clinical picture and requires age- and sex-specific
reference intervals due to the changing physiology of the developing child and young person.
1.2 Advantages of Clinical Steroid Analysis:

Clinical steroid profiling remains an important first line approach to the diagnosis of DSD, as it provides fast and comprehensive results and thus allows for a rapid differential diagnostic orientation. In cases of CAH it has a good phenotype-genotype correlation.

1.3 Challenges of Clinical Steroid Analysis

Over the course of recent years it has become increasingly difficult to recruit healthy volunteers in childhood and adolescence to establish normative reference data from a control cohort. This is mainly the result of ethical concerns and prevents the implementation of accurate age- and sex-specific reference intervals. Soeborg et al. (2014) emphasize that medical treatment, such as exogenous steroids, hepatic metabolism interacting agents, or liquorice containing sweets can influence steroid metabolism and may influence the interpretation of results. Recent studies also describe an impact of nutritional status on steroid hormone concentrations. This indicates that there is an ongoing need for establishing reference intervals. However, through the harmonisation of laboratory tests there is the potential to develop common reference intervals. The work required to generate this data should be shared thus allowing results from different laboratories to be directly compared.

2. Analytical Methods

The main aim of clinical guidelines is to implement clinical standards for diagnosis and appropriate treatment in order to achieve the best outcome for patients, no matter where patients are investigated or managed. Therefore all methods require appropriate validation to ensure they are fit for their intended clinical purpose. This includes the important peer comparison processes of sample exchange or, if available, participation in an external quality assurance scheme (EQA).
2.1 Immunoassay Methods

The principle of all immunoassay-based methods is the binding of an antigen to an antibody. In the late 1970s, the radioligands were replaced with chemoluminescence, enzymatic or fluorescent ligands. In general, immunoassay-based methods for steroid measurements detect a tracer rather than directly the analyte. Most clinical biochemistry laboratories adopted these assays due to their low cost, simplicity, and fast turn-around times. Immunoassays are available for various steroidal analytes as commercial kits on automated platforms. One advantage of RIA methods is the wide and extensive experience as these assays have been used for almost 50 years in clinical routine and research laboratories. During this time, a considerable amount of data has been accumulated and numerous studies have enriched the field of endocrinology. For some analytes such as estradiol very sensitive techniques exist. Thus, immunoassays can produce highly specific results, particularly in combination with preceding extraction and/or chromatography of the samples. Improved separation through extraction is particularly important for newborns, especially if born early, as the fetal adrenal zone which produces a different mix of steroids persists until at least the equivalent of term.

However, numerous commercial assays, especially automated immunoassays, have recently been shown to have impaired specificity due to cross-reactivity of the antibody and other unidentified interferences from the matrix. Therefore, tests evaluated in serum/plasma from healthy adults do not necessarily produce reliable values in neonates or pregnant women or when applied in different matrices such as saliva or urine. The rapid analysis time in many high throughput analytical platforms may also be observed at the expense of poorer sensitivity (detection limit). Furthermore, immunoassays can only measure one steroid per analysis. Thus, larger volumes of serum/plasma are required for analysis. This can be particularly challenging when measuring small-volume samples from newborns and infants. The use of radioactivity in RIAs requires special laboratory facilities and generates radioactive waste. The lack of standardization of immunoassays represents a major problem for the comparability of laboratory results, and in many cases method specific reference intervals must be considered for interpretation. In the current European landscape, immunoassays are still commonly employed.
for steroid hormone analysis. However, in the light of future developments it can be expected that immunoassays will increasingly be replaced by mass spectrometry based methods.

2.2 Mass Spectrometry Based Methods

Mass spectrometry based steroid hormone assays are physico-chemical analytical techniques identifying the analyte by determining typical mass to charge ratios of the respective molecule or its typical fragments. In contrast to conventional isotopic and non-isotopic immunoassay techniques, mass spectrometry allows for higher specificity. Liquid chromatography linked with tandem mass spectrometry (LC-MS/MS) enables targeted steroid hormone analysis of multiple analytes from a single sample. Gas chromatography coupled with mass spectrometry (GC-MS) allows for the simultaneous determination of steroid hormones and metabolites within targeted as well as non-targeted approaches.

At first glance, mass spectrometry based methods may appear rather costly due to the price of sophisticated instrumentation, maintenance of equipment and the need for qualified personal operating the instruments. However, in comparison to other diagnostic procedures, such as molecular genetics, imaging procedures (computed tomography, magnetic resonance imaging, isotope-based imaging techniques) or multiple immunoassays, hormone profiling by mass spectrometry is actually very cheap. The use of LC–MS/MS for steroid analysis is still challenging. One of the main complicating factors in mass spectrometric steroid analysis is the presence of isobaric interferences caused by ions of identical mass to charge ratio and similar fragmentation patterns. Although steroid analysis by LC-MS/MS is becoming increasingly available for routine use, validation and quality control present important future challenges. Reference intervals are not widely available and in contrast to earlier anticipation these are considerably dependent on individual specific laboratory settings, such as sample work up and/or instrumentation.

Position 1: Whilst mass spectrometry is purported to be a superior technique, it is not available for all hormones and is currently not a realistic analytical option in all regions of Europe. Our
position is therefore to support the appropriate use of both immunoassay and mass spectrometry based methods for the diagnosis and monitoring of DSD. It is essential that clinicians should also know the characteristics and limitations of analytical methods used.

3. Analytical Matrices

Blood (serum vs. plasma), urine, and saliva are the biomaterial (i.e. matrices) most commonly used for clinical steroid hormone analysis. Saliva is less broadly established and few studies on steroids analyzed in saliva exist for the differential diagnosis of DSD, and the working group does not have a stance for or against the inclusion of this matrix currently. It is recommended that clinicians contact their laboratories in advance to follow their recommendations regarding appropriate type of sample as well as mode of shipment.

Position 2: Both, serum/plasma and urine, are established matrices for analysis for steroids and dependent on the specific DSD condition under consideration, analysis of steroids in either matrix may be appropriate.

4. Harmonisation of Laboratory Tests

Initiatives in laboratory medicine that support harmonisation stem from Europe and are now being embraced globally. Bias, imprecision and interferences can all lead to erroneous results. As such, method validation is fundamental in establishing the extent and acceptability of each of these studies for clinical diagnostic assays to ensure they operate within an accepted quality framework. Whilst each of these validation parameters is important, minimization of bias is essential for harmonisation.

Harmonisation and, where practical standardization with traceability, are enormous challenges. The process has been described in terms of five supporting pillars, these are aimed at...
establishing: 1) certified reference materials (CRM); 2) reference measurement procedures (RMP); 3) reference laboratories; 4) participation in an EQA program; and 5) reference intervals and decision limits.

In principle, full standardization with traceability should be achievable for all steroids as they are small compounds of defined molecular weight. The Joint Committee for Traceability in Laboratory Medicine (JCTLM) was established in 2002 to support this process worldwide through the development of a database to recognize primary reference materials, methods and laboratories (www.bipm.org/jctlm. Accessed 19th June 2016). This JCTLM database, which is hosted by the Bureau International of Weights and Measures (BIPM) [Sevres Cedex, France], currently lists some (e.g. serum cortisol, estradiol, progesterone and testosterone) but not all steroids important for the assessment of DSD (e.g. serum 17-hydroxyprogesterone, androstenedione, cortisone and dihydrotestosterone).

Participation in an EQA program is generally recognised to be the central pillar as it provides the framework for objective comparison of the result obtained by many laboratories for the one sample. However, in order to proceed down this pathway for the harmonisation of laboratory assessment, we first need to establish a collaborative agreement on the analytes and their matrices that should be measured for the differential diagnosis of a DSD. Recently, a first EQA program for the harmonisation of serum dihydrotestosterone analysis has been launched.

Position 3: Laboratories should aim to participate in activities of peer comparison such as a sample exchange or preferably when available subscribe to a relevant external quality assurance program.
5. Steroid Analysis in Conditions Associated with DSD

5.1 46,XX DSD Conditions

**21-hydroxylase deficiency.** CAH due to 21-hydroxylase deficiency (21OHD) is the most common cause of DSD in 46,XX individuals. Due to overproduction of androgens, 46,XX individuals usually present with ambiguous genitalia without palpable gonads. The condition is treated with glucocorticoids and if required mineralocorticoids. In serum/plasma, 17-hydroxyprogesterone and 21-deoxycortisol with or without ACTH (adrenocorticotropic hormone) are the indicative diagnostic parameters for 21OHD. Usually, no ACTH stimulation is required in classic CAH. Urinary steroid profile analysis, a non-invasive means, also allows for definitive diagnosis: 17-hydroxypregnanolone, pregnanetriol and pregnanetriolone are the key diagnostic urinary metabolites. Steroid monitoring of 21OHD is performed by determination of the above mentioned hormones and their metabolites in either serum, plasma, urine or saliva.

**11β-hydroxylase deficiency,** is characterized by elevated serum/plasma 11-deoxycortisol and deoxycorticosterone. Individuals with 46,XX DSD suffering from 11β-hydroxylase deficiency also present with virilization of the external genitalia. The onset of hyporenemic, hypokalaemic, hypertension is variable. The urinary steroid profile is dominated by elevated tetrahydro-11-deoxycortisol.

**3β-Hydroxysteroiddehydrogenase deficiency (3βHSDD).** This condition is clinically characterized by undermasculinisation in 46,XY individuals and virilization in 46,XX individuals. The pathognomic hormonal pattern is characterized by elevation of 17-hydroxypregnenolone, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEAS) in serum/plasma and increased excretion rates of their corresponding urinary metabolites including androstenetriol.

**P450 oxidoreductase deficiency.** This condition presents biochemically as combined 17-hydroxylase/lyase and 21-hydroxylase deficiency. It is caused by a defect of the electron donating protein to microsomal cytochrome P450 type 2 enzymes. The typical presentation is...
child with ambiguous genitalia and Antley-Bixler-syndrome; however, a wide spectrum of clinical presentations has been described. 45

5.2 46,XY-DSD-Conditions

Steroid Acute Regulatory Protein (StAR) deficiency and P450 side-chain cleavage enzyme (P450scc) deficiency. StAR deficiency leads to lipoid CAH, whereas deficiency of P450scc commonly leads to small adrenals. Both conditions present with similar clinical appearance. Only a few patients might have a severe salt loss crisis in the first months of life. The majority of 46,XY individuals, shows undervirilization or complete feminization. In 46,XX patients no further clinical features might be present in the first months of life. Typically, glucocorticoids, mineralocorticoids and sex steroids are all low to undetectable. Treatment with glucocorticoids (e.g. hydrocortisone) and later with sex hormones should be monitored by determining the respective steroids. 46

17-hydroxylase/17,20 lyase deficiency. Typically, 17-deoxygenated steroids, e.g. corticosterone, are elevated, while 17-oxygenated steroids, such as cortisol and sex steroids, are markedly reduced or absent in serum/plasma. Urinary steroid profile analysis likewise reflects an increase in 17-deoxygenated over 17-oxygenated metabolites. 47 Patients are clinically often glucocorticoid replete despite impaired cortisol synthesis as corticosterone excess with its glucocorticoid action is compensating for the lack of cortisol. The deficiency of sex hormone biosynthesis is causing DSD in these individuals. All affected individuals (46,XY and 46,XX) with complete deficiency classically fail to develop secondary sexual characteristics. Similar to 11β-hydroxylase deficiency, the onset of hyporenemic, hypokalemic hypertension is highly variable.

P450OR deficiency: see above

3βHSDD: see above

5α-reductase deficiency. Patients with mutations in the 5α-reductase type 2 gene usually show undermasculinisation at birth. Usually there is some degree of masculinisation at puberty due to increasing concentrations of testosterone. Diagnosis can be established using the ratio
of testosterone to dihydrotestosterone in serum/plasma before and after hCG (human chorionic
gonadotropin) stimulation \(^{48, 49}\). The diagnosis can also be made by assessing the ratio between
5α- and 5β-reduced steroids in the urinary steroid profile \(^{50}\).

**17β-Hydroxysteroiddehydrogenase type 3 deficiency.** Due to the lack of testosterone during
male sex differentiation, 46,XY children are often born with almost female-appearing external
genitalia \(^{51}\). In serum/plasma, the ratio of androstenedione / testosterone after hCG stimulation
is elevated. Urine steroid metabolomic profiling for this enzyme deficiency might not always be
indicative for this gonadal enzyme defect.

**Position 4:** Harmonisation of the primary analytes for analysis of specific DSD is required. We
propose that laboratories measure the diagnostic key steroids mentioned as described above.

### 6. Conclusions

Since DSD represents a very heterogeneous and highly complex group of conditions, the
integration of clinical, biochemical and genetic diagnostic approaches is required. The
knowledge of steroid hormone biosynthesis is vital in understanding the pathogenesis of the
specific condition. Furthermore, monitoring strategies of these entities are to a great extent
based on biochemical parameters. Therefore, only most reliable methods are required. To
achieve this aim, laboratories performing analyses for DSD need to operate within a quality
framework and actively engage in harmonisation processes so that results and their
interpretation are the same irrespective of the laboratory they are performed in.

However, the situation with respect to access to analytical technologies is very heterogeneous
within Europe. This is due to essential differences in health care systems, modes of payment,
different economical coverage, and structure of biochemical services. This compromises the
development of common strategies for Pan-European diagnosis and follow up in DSD.

There is an urgent demand for establishing a network of highly specialized endocrine reference
laboratories with expertise in DSD. These centers should have the required knowledge of
analytical techniques, should have age- and sex-specific reference intervals to provide
normative data, and should provide experience with proper interpretation of values. It is
essential to maintain and support existing laboratories with expertise in DSD. Therefore, the
area of DSD also holds a deep political dimension. Interested parties are encouraged to contact
head of working group 3 for setting up a network of suitable reference laboratories. Investments
to create and maintain such reference centers of expertise are vital to achieving a Pan-
European and ultimately a global landscape ensuring access to optimal laboratory assessment
for DSD.

7. Declaration of Interest
No conflict of interest.

8. Funding
O.H. (chair of COST action), S.A.W. (chair of working group 3) and all further members of
(international partner) appreciate support from BMBS COST Action BM1303.

11. Figure legends

Legend of figure 1

Synthesis and metabolism of hormonal steroids. This figure illustrates the formation of the major hormone classes from cholesterol. Steroid names in conventional script are steroid hormones and precursors; those in italics are urinary metabolites of the aforementioned. The major transformative enzymes are in rectangular boxes, the cofactor (“facilitator”) enzymes in ovals. Mitochondrial CYP type I enzymes requiring electron transfer via adrenodoxin reductase (ADR) and adrenodoxin (Adx) CYP11A1, CYP11B1, CYP11B2, are marked with a labelled box ADR/Adx. Microsomal CYP type II enzymes receive electrons from P450 oxidoreductase (POR), CYP17A1, CYP21A2, CYP19A1 and are marked by circled POR. The 17,20-lyase reaction catalyzed by CYP17A1 requires in addition to POR also cytochrome b5 indicated by a circled b5. Similarly, hexose-6-phosphate dehydrogenase (H6PDH) is the cofactor-generating enzyme for 11β-HSD1 (HSD11B1). The asterisk (*) indicates the 11-hydroxylation of 17-hydroxyprogesterone to 21-deoxycortisol in 21-hydroxylase deficiency. The conversion of androstenedione to testosterone is catalyzed by HSD17B3 in the gonad and AKR1C3 (HSD17B5) in the adrenal. StAR, steroidogenic acute regulatory protein; CYP11A1, P450side-chain cleavage enzyme; HSD3B2, 3β-hydroxysteroid dehydrogenase type 2; CYP17A1, 17α-hydroxylase/17,20-lyase; CYP21A2, 21-hydroxylase; CYP11B1, 11β-hydroxylase; CYP11B2, aldosteronesynthase; HSD17B, 17β-hydroxysteroid dehydrogenase; HSD11B1, 11β-hydroxysteroid dehydrogenase type 1; HSD11B2, 11β-hydroxysteroid dehydrogenase type 2; SRD5A2, 5α-reductase type 2; SULT2A1, sulfotransferase 2A1; PAPSS2, 3′-phosphoadenosine 5′-phosphosulfate synthase 2.
