Abstract

Context:
Recessive mutations in TMEM38B cause type XIV osteogenesis imperfecta (OI; OMIM 611236) by dysregulating intracellular calcium flux.

Objectives:
Clinical and bone material phenotype description and osteoblast differentiation studies.

Design and Setting:
Natural history study in paediatric research centres.

Patients:
Eight patients with type XIV OI.

Main Outcome Measures:
Clinical examinations included; bone mineral density, radiographs, echocardiography and muscle biopsy. Bone biopsy samples (n=3) were analysed for histomorphometry and bone mineral density distribution by quantitative backscattered electron microscopy and Raman microspectroscopy. Cellular differentiation studies were performed on proband osteoblasts and normal murine osteoclasts.

Results:
The clinical phenotype of type XIV OI ranges from asymptomatic to severe. Previously unreported features include vertebral fractures, periosteal cloaking, coxa vara and extraskeletal features (muscular hypotonia, cardiac abnormalities). Proband L1-L4 bone density Z-score was reduced (median -3.3 [range -4.77 to +0.1; n=7]), and increased by +1.7 (1.17 to 3.0; n=3) following bisphosphonate therapy. TMEM38B mutant bone has reduced trabecular bone volume, osteoblast and particularly osteoclast numbers, with >80% reduction in bone resorption. Bone mineralization density is normal/slightly increased. We demonstrate a complex osteoblast differentiation defect with decreased
expression of early markers and increased late, mineralisation-related markers. 

Predominance of TRIC-B over TRIC-A expression in murine osteoclasts supports an intrinsic osteoclast defect underlying low bone turnover.

**Conclusions:** OI type XIV has a bone histology, mineralization and osteoblast differentiation pattern that is distinct from type I OI. Probands are responsive to bisphosphonates but show muscular and cardiovascular features possibly related to intracellular calcium flux abnormalities.
INTRODUCTION

Osteogenesis Imperfecta (OI) is a clinically and genotypically heterogeneous, heritable connective tissue disorder which results in fragile, deformed bones, short stature and low bone mass\(^1\). Most cases of OI are due to dominantly inherited mutations in COL1A1 or COL1A2 which affect the structure or quantity of type I collagen (Types I-IV)\(^2\)\(^3\). Rare, mostly recessive, forms of OI are caused by defects in genes whose products are involved with collagen folding or post-translational modification\(^2\)\(^4\)\(^7\).

Recessively inherited mutations in the TMEM38B gene (OMIM#611236), which encodes the ubiquitously expressed ER protein Trimeric Intracellular Cation channel type B (TRIC-B), cause OI type XIV (OMIM #615066). TMEM38B mutations reported to date include an exon 4 deletion among Bedouins\(^8\)\(^9\), an exon 1-2 deletion in an Albanian child\(^10\) and two point mutations in exon 4 and intron 3 in three Chinese children\(^11\). Using primary fibroblasts and osteoblasts from affected individuals, we recently demonstrated that absence of TRIC-B disrupts ER calcium flux kinetics, consistent with increased activation of the PERK/ATF4 pathway of ER stress\(^12\). Expression of multiple genes for collagen-interacting proteins is altered in proband cells, leading to dysregulated type I collagen synthesis, including decreased hydroxylation of collagen helical lysine residues and intracellular retention of misfolded collagen\(^13\). The full clinical and skeletal phenotype, bone histomorphometry, bone material properties, osteoblast differentiation pattern and response to bisphosphonate (BP) therapy have not previously been presented.

MATERIAL AND METHODS

Clinical Data, Samples and Bone Imaging

Clinical information and anthropometric data were taken from medical records of six patients
(P1-6) with genetically confirmed type XIV OI attending OI specialist clinics at Birmingham Children’s Hospital (BCH), UK; two brothers (P7,8) were studied at the NIH Clinical Center, Bethesda, MD, USA. At BCH and NIH, all patients with clinical signs suggestive of OI are offered genetic testing using a ‘do you mean targeted exome OI gene panel. Blood, bone biopsy and DNA samples were collected from the patients and their parents after obtaining informed consent/assent. Bone densitometry, including lateral vertebral assessment (Hologic or GE Lunar iDXA™), and X-rays were taken as part of routine clinical care or OI natural history protocols. Lateral vertebral morphometry was assessed using the Genant score.

**Bone tissue characteristics: Bone Histomorphometry, quantitative Backscattered Electron Imaging (qBEI) and Raman Microspectroscopy**

Trans-iliac bone biopsies were taken in patients 2, 4 and 7 (when naïve to BP therapy) and repeated in P7 after one year of BP therapy. Double-labeling with tetracycline for dynamic measurement of bone formation was performed in P2 and P7. Sample preparation and histomorphometric analyses were performed using standard procedures. Bone mineralisation density distribution (BMDD), reflecting the calcium content of bone matrix, was measured in trabecular and cortical bone by qBEI as described previously.

Raman microspectroscopy was used to evaluate the properties of the trabecular bone mineral and organic matrix as a function of 4 tissue ages: i) between the 2nd fluorescent label and the mineralizing front (1-3 day-old bone), ii) between the two fluorescent labels (4-20 day-old bone), iii) immediately behind the 1st fluorescent label (over 20 day-old bone), and, iv) the geometrical centre of trabeculae (older bone tissue). At each tissue age, the mineral/matrix ratio, nanoporosity (a surrogate of tissue water), glycosaminoglycan, lipid and pyridinoline content were determined, as previously described. Results from bone histomorphometry, qBEI and Raman analysis were compared to paediatric reference data.
Molecular Studies

Genomic DNA was extracted using standard protocols. For P1-6, clonal sequencing using SureSelect target enrichment (Agilent Technologies) and the Illumina MiSeq platform was performed using a custom designed gene panel. Sequence analysis using a custom bioinformatics pipeline based on open source workflow by the Broad Institute [http://www.broadinstitute.org/gatk/guide/best-practices](http://www.broadinstitute.org/gatk/guide/best-practices) was undertaken using a minimum threshold of 30-fold read depth for exonic sequence and intron/exon boundary. Variants identified were filtered against polymorphism lists and assessed using the Association for Clinical Genetic Science Best Practice Guidelines (http://www.acgs.uk.com). For P7 and P8, the maternal TMEM38B mutation was detected by NGS using a recessive OI panel (CTGT, Allentown, PA, USA). Subsequently, the paternal mutation was detected by deletion analysis[^13].

Cell Culture

Primary osteoblast (OB) cultures were established from surgical bone chips of normal control and P7, as previously described[^24]. To induce osteoblast differentiation, confluent cells were cultured for 30 days in αMEM, supplemented with 10% fetal bovine serum, 1% pen-strep, 25 μg/mL L-ascorbic acid, 10^{-8} M dexamethasone and 2.5 mM 2-glycerophosphate.

Bone marrow-derived primary osteoclast (OC) cultures were generated from femora of 8-week BL/6 mice as previously described[^25]. Cultures were assessed for an OC phenotype by the presence of multinucleated Tracp5-positive stained cells (Sigma).

Analysis of Gene Expression
Total RNA was extracted from patient OB and mouse OC cultures at the indicated time points using TriReagent (Molecular Research Center) according to the manufacturer’s protocol, then treated with DNA-free (Life Technologies). Gene transcript levels of cell differentiation markers were quantitated by real-time RT-PCR following reverse-transcription using a High Capacity cDNA Archive Kit and Taqman Assays on Demand (Suppl. Information 1). Relative expression of genes of interest was measured in triplicate and normalized to 2 reference genes (ACTB, B2M, Actb, and B2m).

RESULTS

Molecular Studies

P1-6 originated from three apparently unrelated Pakistani families seen in our centre or something similar and presented with increased bone fragility and osteoporosis. Sanger sequencing confirmed that all probands were homozygous for the same c.507G>A mutation in exon 4 of TMEM38B. This mutation replaces tryptophan169 with a STOP codon (p.W169X). All obligate carrier parents were heterozygous for the mutation (Suppl. Figure 1).

P7 and P8 were born to unrelated American parents of British/Scottish and British/German origin and found to be compound heterozygous for the previously reported deletion encompassing TMEM38B exons 1 and 2 and a novel c.63dupT, which directly introduces a premature termination codon (p.D22X). Their father carries the deletion and their mother the c.63dupT allele. Both genotypes lead to a TMEM38B null molecular outcome in fibroblast and osteoblast (OB) cultures of our patients.

Clinical and Radiological Phenotype

Penetrance of clinical OI features was highly variable (Table 1). P1 and P6 presented
antenatally with bowed femora. P1-7 had sustained a significant low trauma fracture by 2 years of age, whilst P8 had no fractures. Two individuals were short (height < -2 SDs) and overweight. P5 had non-progressive bilateral nephrocalcinosis of unknown origin detected at birth. P7 has relative macrocephaly (58cm, 98th centile) with normal brain MRI, facial appearance and dentition. His clinical OI phenotype was severe whilst his brother (P8) was asymptomatic. All had normal calcium and phosphate metabolism, only P2 had consistently elevated alkaline phosphatase (ALP) levels.

Cognitive Development

P1 and P2 developed motor skills appropriately but have delayed speech and language development. P2 has a concomitant diagnosis of autistic spectrum disorder. Cognitive development is normal in P3-8.

Radiological Findings

Long bone radiographs of all patients demonstrated low bone mass (Suppl. Figure 2). P1,2,4 and 6 required femoral rodding (Table 1). Interestingly, P1 whose radiographs at birth showed femoral bowing with mid-shaft cortical thickening, developed widespread periosteal reactions (‘cloaking’) of all long bones at 2 months of age. A follow-up skeletal survey at 22 months of age showed resolving periosteal reaction, coxa vara and low bone mass (Suppl. Figure 2 A-C, E, F, H, I). In contrast, P7 has extremely thin long bones (Suppl. Figure 2 N, O). P1 had 4-5 Wormian bones around the lambdoid suture at age 2 months.

Spine and Respiratory

P1 had multiple vertebral compression fractures at age 2 months which showed incomplete reshaping by 22 months (Suppl. Figure 2 A, D, G). P2 had multiple vertebral compression fractures at presentation aged 12 years (Suppl. Figure 2 J). To date, four patients (50%) have
developed scoliosis, which is progressive and deforming in P5 and P7 and led to spinal rodning of P5 at age 15 years, following which he has severe restrictive lung disease. P7 developed moderate lower airway obstruction with air trapping at age 22 years (Table 1).

**Cardiovascular Health**

Three patients (P3,5,7) displayed cardiac pathology. P3 presented aged 14 years with secondary amenorrhea, significant weight gain (BMI 32kg/m²) and hirsutism. She had impaired glucose tolerance (120 min glucose 10.4mmol/L post oral glucose load), acanthosis nigricans, and fatty liver on ultrasound. She was started on metformin and later on a combined ethinylestradiol/cyproterone acetate contraceptive pill (COCP), on which her hirsutism, weight gain and periods improved. Aged 16 years, she had an extensive anterior myocardial infarction secondary to a thrombus in the left anterior descending coronary artery. Her COCP was discontinued. P5 had a large congenital secundum atrial septal defect and a perimembraneous ventricular septal defect. He developed heart failure, requiring surgery aged 2 months. P7’s echocardiogram aged 21 years revealed tricuspid regurgitation with an anatomically normal valve. At age 27, asymmetric septal hypertrophy of the left ventricle and mild aortic root dilation were detected. Cardiovascular lipid profile was normal in all eight individuals. Echocardiogram and ECG were normal in P1,2,4-6,8.

**Muscle Phenotype**

P1-3 and P6, their unaffected siblings, and P7 and P8 have no evidence of myopathy. P4 has muscular hypotonia, which was fully investigated. Her EMG showed a denervating pattern with no suggestion of muscle myopathic activity. Muscle biopsy also showed no evidence of congenital myopathy, metabolic or storage disorder or mitochondrial cytopathy. Serum lactate, basic mitochondrial DNA screen and MRI brain were normal. She walks upright with a Trendelenburg gait. Her brother, P5, also has moderate hypotonia associated with delayed
motor milestones, and only walked without support at 3 years of age.

**Clinical and radiological phenotype of heterozygous carriers**

Parents of affected patients had no history of fractures, were generally healthy, with normal bone density (BMD) where measured (Z-scores: 0.7 to -0.3, n=4). Parents of P7/8 were fully assessed. Their father, age 59 years, has macrocephaly (59cm, >95th centile), moderate hip laxity, degenerative changes in mid-thoracic vertebrae, normal BMD (Z-score +0.1), and occupational high-frequency hearing loss bilaterally. Echocardiogram shows concentric left ventricular hypertrophy, mildly dilated ascending aorta, and mild mitral and aortic regurgitation with normal valvular anatomy. Their mother, age 56 years, has type I DM and Graves Disease, short stature and normal head circumference. Radiographs show mild central compressions of lower thoracic and lumbar vertebrae, with normal BMD (Z-score -0.3). Calcifications were noted in the abdominal aorta on X-rays, with annular calcification of mitral and aortic valves. She has mild mid-frequency sensorineural hearing loss bilaterally.

**Bone mineral density and response to BP treatment**

Proband lumbar spine BMD Z-scores varied widely, ranging from normal (P3,4) to osteopenic (P6,8) to decreased (P2,5,7 with mean median Z-score -3.3 [range -4.77 to -2.0]) in individuals old enough to be measured (P2-8, Table 2). Four patients were treated with BPs. DXA scans before and after treatment (n=3) revealed substantial increase in BMD Z-score of 3, 1.7 and 1.17 SD (median +1.7), respectively. Patients with BMD Z-scores within the normal range have not required BP treatment to date.

**Evaluation of trans-iliac bone biopsies**

**A) Bone histomorphometry (Table 3)**

The main histomorphometric features in the trans-iliac biopsy samples (P2,4,7) were
predominance of low bone mass, normal to reduced OB numbers and very low resorption. Backscattered electron images demonstrate bone volumes (BV/TV) below -1SD in P4 (Figure 1C) and below -4SD (-82% from normal) in P7 (Figure 1D). Whilst BV/TV could not be assessed in P2, many thin and partially isolated trabecular features were viewed in the cancellous compartment (Figure 1A, B). Trabecular surfaces (in P2 and P7) were covered by an abnormally extended and thin osteoid layer resulting in a substantial increase in osteoid surface (OS/BS) and osteoid volume (OV/BV) (Table 3). Unlike OI caused by collagen-gene mutations, neither OB nor OC indices were increased in affected patients. In fact, OB surface (Ob.S/BS) and mineralizing surface (MS/BS) were within normal range or decreased (P4). Interestingly, despite the low amount of trabecular bone, intense fluorescent double labels were detected in cortical bone (Figure 1E, P7). P2 had focal areas of osteoid accumulation which explains the elevated mineralization lag time (Mlt) and the low adjusted apposition rate (aj.AR). In all patients, OC and bone resorption indices were markedly decreased to less than 20% of healthy controls. Bone cortex had a normal thickness, lamellar pattern, and normal haversian canals.

**B) qBEI (Table 4)**

Trabecular bone:

In P2 and P7, the average bone matrix mineralization was normal, rather than elevated as in OI type I bone. The matrix portion with low mineralization (CaLow) was slightly above both the healthy reference and OI type I ranges. In contrast, P4 had a BMDD curve that was shifted towards higher matrix mineralization (Figure 1F) with increased CaMean, CaPeak and CaHigh values, consistent with low turnover revealed on histomorphometry. In all patients, the portion of fully mineralized CaHigh was markedly lower (53-84%) than in OI type I.

Cortical bone:
The CaMean and CaPeak of P2 and P4 were within the normal range, although again P4 showed increased CaHigh. In contrast, P7’s cortical bone matrix before BP treatment was much less mineralized than control bone, even less than his trabecular bone (CaMean: -7%, and -10% respectively). Concomitantly, there was a 3-fold increase of CaLow reflecting the large portion of bone undergoing primary mineralization. The high cortical bone apposition was mirrored by strong tetracycline labeling on endo–and intracortical surfaces (Figure 1E). After one year of BP therapy, his cortical CaMean and CaPeak increased and CaLow decreased substantially, reflecting increasing tissue age due to the anticatabolic therapy.

C) Raman Microspectroscopy

Mineral/matrix and mineral maturity/crystallinity ratios were within reference range of healthy children. Nanoporosity was decreased (at younger tissue ages in P2,7 and oldest in P4), compared to healthy controls and even lower than classical OI bone. Relative glycosaminoglycan content at the oldest tissue age was decreased in P2,4 and increased in P7 compared to healthy children. Lipid content was lower in P2 and P7 compared to healthy children. Finally, pyridinoline content was comparable to OI type I bone, being higher than normal at the two younger tissue ages, and normal at older ones (Suppl. Table 5).

Osteoblast and osteoclast studies

Cultured osteoblasts from P7 showed reduced expression of early markers of differentiation (RUNX, SP7, COL1A1, SPARC), an increase in later markers, including those related to mineralisation (ALP, OPN, IBSP, BGLAP, DMP) and also delayed SOST expression (Figure 2). The normal RANKL/OPG profile suggests normal functioning of the major extrinsic OC stimulation system. To explain the low bone resorption on patient bone histomorphometry, we examined osteoclasts from murine cultures, since cultures of patient osteoclasts were not
available. We determined whether Tric-b and its coupled [Ca^{2+}] channel Itp3 were expressed in differentiated murine osteoclasts, as well as the potential for redundancy by Tric-a and its coupled Ryr3 [Ca^{2+}] channel in this cell type\(^{26}\). The results confirm marked predominant expression of the ER TRIC-B channel over TRIC-A (10-15-fold in mature OC), and the IP_{3}R3 [Ca^{2+}] efflux channel over RyR3 (≈ 25-fold), respectively (Figure 2, bottom panels).

**DISCUSSION**

The null mutations in TMEM38B that cause type XIV OI disturb the kinetics of ER calcium flux and impact the function of multiple proteins in the ER\(^{13}\). We previously demonstrated in TMEM38B-null cells that type I collagen post-translational modification is altered in a distinct pattern for OI, with decreased helical and increased telopeptide lysyl hydroxylation compared to the helical overmodification that is a hallmark of autosomal dominant classical OI and recessive defects in procollagen prolyl 3-hydroxylation. Procollagen in TMEM38B-null cells is also misfolded and substantially degraded intracellularly, underlying reduced collagen secretion. Here, we present our extensive investigations of the type XIV OI phenotype, and distinctive bone tissue characteristics and bone cellular defects arising from defective ER calcium flux kinetics.

First, the phenotype of our eight probands with TMEM38B null mutations had quite variable penetrance, ranging from barely detectable to severe skeletal characteristics. One patient (P8) had no fractures, normal height and osteopenia although his sibling (P7) was the most severely affected patient in our set. Development of scoliosis and hearing loss was variable, and 3 patients had normal height. We also observed previously unreported features such as vertebral fractures with spontaneous reshaping, periosteal cloaking, coxa vara and abnormal dentition. Periosteal cloaking similar to our observation in P1 appears to be present on
radiographs of other patients with OI type XIV and in another report of OI of unknown etiology. Such generalised cloaking may represent a response to healing long bone fractures and has not been reported in classical OI. Cardiac abnormalities of different etiologies were observed in 3/8 patients, and in both carrier parents of P7 and P8. P4 and P5 have muscular hypotonia. However, muscle and myocardial cells express much more TRIC-A than the ubiquitous TRIC-B, although TRIC-B deficiency may indirectly affect these tissues via increased ER stress. Tric-a and Tric-b double KO mice die in-utero due to cardiac arrest, indicating a shared role of these channels in Ca\(^{2+}\) signalling in embryonic cardiomyocytes. In addition, even Tric-b +/- mice are susceptible to stress-induced heart failure, which potentially puts the cardiac findings of P7’s heterozygous parents in a different light. Until more evidence becomes available, monitoring cardiovascular risk factors in affected patients may be required. In addition, the lack of significant respiratory abnormalities in our patients contrasts the Tric-b KO mouse model which shows respiratory defects with abnormal IP\(_3\)R-mediated Ca\(^{2+}\) release in airway epithelial cells. Finally, in view of parental consanguinity, we cannot confidently attribute cognitive impairment in P1 and P2 to a TMEM38B effect in neuroepithelial tissue.

OI type XIV bone is structurally distinct from bone with type I collagen gene defects. In the absence of TRIC-B, bone tissue has low-normal OB numbers with a low mineral apposition rate (Aj.AR) and a uniform paucity of OCs. In classical OI, even simply with type I collagen haploinsufficiency, bone turnover and cell numbers are high, but mineral apposition rate is low, implying that many OBs produce a reduced amount of matrix, which is typically hypermineralized. BMDD by qBEI in TRIC-B deficient bone is either normal or slightly right-shifted, reflecting a situation of low bone turnover that allows more time for bone packets to mineralize. Specifically P4 has a high mineralization, low turnover profile
similar to children with chronic kidney disease\textsuperscript{30}. In contrast, bone from P7, with the most severe skeletal phenotype, featured active OBs on rudimental trabeculae, a lack of OCs but normal BMDD. Strikingly, his cortex showed active primary bone formation as evidenced by intense intra- and endocortical fluorescence labeling (Figure 2E) and increased cortical CaLow. Raman microspectroscopic analysis also revealed that the ratio of mineral to matrix was not altered in TMEM38B mutant bone. However, similar to classical OI bone, nanoporosity, a surrogate of tissue water, was decreased at the three younger tissue ages compared to healthy controls\textsuperscript{22}. Consistently, the elevated pyridinoline content at the two younger tissue ages mirrors increased or accelerated trivalent cross-links formation resulting in stiffer collagen fibers, which are known to exhibit a more “brittle-like” behavior\textsuperscript{31}. Thus, bone fragility in type XIV OI is explained by low bone mass, reduced trabecular bone and nanoporosity, and high pyridinoline content. Despite low bone resorption, bone mass and cortical mineralization density increased in response to BP therapy in Type XIV OI patients. The observed shift towards higher, and less heterogeneous, cortical BMDD following one year of BP therapy is characteristic for patients with normal or lowered mineralization density\textsuperscript{16}. This is again in sharp contrast to classical OI bone where the hypermineralized, fully saturated matrix cannot further increase its density\textsuperscript{32}.

Differentiation of osteoblasts derived from iliac crest of a TMEM38B-null proband demonstrated reduced expression of RUNX2, SP7, and COL1A1. Decreased expression of these early markers of differentiation is consistent with the reduction in OB numbers shown on bone biopsy in our patients, and would exacerbate the decreased collagen secretion resulting from collagen misfolding in the ER\textsuperscript{13}. Expression of the OB differentiation marker ALP is related to calcium flux since its suppression by siRNA blocks BMP2-induced flux of [Ca\textsuperscript{2+}] from ER to cytoplasm, raising the proposal of ALP as a monitor of intracellular
calcium concentration\textsuperscript{33}. Our cell culture work suggests that this loop may also work in the reverse direction, with reduced ER calcium flux in TRIC-B deficient cells leading to a compensatory increase in osteoblast ALP expression.

Ca\textsuperscript{2+} signalling also has broad effects on pathways promoting and inhibiting mineralization. Interestingly, expression of multiple genes whose products interact with calcium and/or have roles in mineralization are altered in Type XIV OI osteoblasts, although mineralization of type XIV OI bone tissue is not abnormal. On the one hand, expression of pro-mineralization ALP\textsuperscript{34} is increased. On the other hand, there is decreased expression of osteonectin/SPARC, which initiates and promotes mineralization, and increased osteocalcin/BGLAP and OPN, which inhibit crystal growth\textsuperscript{35,36}. The SIBLING proteins BSP and OPN have generally opposing roles in promoting and opposing mineralization\textsuperscript{37}, but their concurrent increase in transcripts in TRIC-B deficient cells is unexpected, since BSP\textsuperscript{-/-} cells have increase OPN expression\textsuperscript{38}. Further, SOST expression was delayed, suggesting differentiation to osteocytes may be impaired. The complex OB gene expression pattern apparently contravenes the usual OI mechanism toward hypermineralization. Studies on the levels and interactions of these proteins in TRIC-B deficient cells and matrix should be a focus of further investigation.

A recent report on calvarial osteoblasts of Tric-b KO mice\textsuperscript{26} is in partial agreement with our patient findings. Differentiated KO murine osteoblasts have normal levels of type I collagen transcripts, with decreased collagen production due to intracellular degradation. As in patient cells, the early OB markers Runx2 and Osx are reduced in murine KO OBs. However, Alp, Bsp and Bglap transcripts are reduced, while Sparc is normal, suggesting greater impairment of murine OB differentiation and mineralization than in patients.
An apparent intrinsic defect in osteoclasts is yet another distinctive feature of Type XIV OI. To investigate the low numbers and activity of OC in patient bone in the context of normal osteoblast RANKL/OPG ratios, we investigated the levels of expression of the TRIC-B/IP3R and TRIC-A/RyR paired sets of channels for K$^+$ entry and Ca$^{2+}$ efflux from the ER in normal murine OCs. Our demonstration of 15-fold higher expression of TRIC-B relative to TRIC-A, and 25-fold higher expression of IP$_3$R than RyR channels support the predominance of the TRIC-B system in osteoclasts, with minimal to no redundancy of function. Combined with patient histomorphometry and in vitro OB expression profiles, our data support an intrinsic, OB-independent, OC defect in patients with TMEM38B mutations. We speculate that interference with [Ca$^{2+}$] flux kinetics in TRIC-B null OCs impairs their response to normal developmental signals, resulting in low OC numbers, and impairing bone resorption. In recent experimental data from Tric-b$^{-/-}$ mice, OC markers such as cathepsin K and Atp6v0d2 (part of the proton pump functioning in extracellular acidification for resorption), had reduced expression in newborn murine femora.

In conclusion, OI caused by TMEM38B mutations has a much wider skeletal phenotypic spectrum than previously reported, ranging from asymptomatic to severe. We describe novel skeletal features and potential extraskeletal features. Bone tissue of our patients did not reveal the characteristic OI phenotype, with high bone turnover and high BMDD. While normal BMDD has also been reported in OI caused by WNT1 mutations, WNT1-deficient patients lack the abnormalities of type I collagen post-translational modification found in OI type XIV. The paucity of OBs and OCs, the normal BMDD, and the very low nanoporosity are uniquely different from classical OI bone. Here, we further delineate the mechanism of bone fragility in TMEM38B mutant bone not only as a complex OB differentiation defect due to impaired ER Ca$^{2+}$ flux kinetics, but also likely an intrinsic OC defect. Despite the low bone
resorption, patients still respond to BP therapy with increased BMD and cortical mineralisation density. The role of TRIC-B in human OB and OC function, as well as cardiovascular or muscular health requires further study.

Figure Legends:

**Figure 1: Bone tissue characteristics**

Trans-iliac bone biopsy section of patient 2 under light microscopy (A) shows plump osteoblasts forming an unmineralized matrix (dark gray). Mineralized matrix appears light gray (Goldner’s trichrome staining represents originally mineralized bone matrix in green, and osteoid in purple). Active bone formation was very rarely sighted. Backscattered images show bone biopsy samples from Patient 2 (B), 4 (C) and 7 (D). The very low amount of trabecular bone tissue in Patient 7’s sample is consistent with his severe skeletal phenotype. Under confocal laser-scanning microscopy, fluorescent double labels are detected on intra- and endocortical bone surfaces (E, see white arrows), which does not reflect high bone remodeling but cortical bone apposition. F) Bone Mineral Matrix Density Distribution curves of cancellous bone of the 3 patients in relation to pediatric reference values20.

**Figure 2: Patient Osteoblast and Murine Osteoclast Differentiation**

Osteoblast differentiation time course (from P7) depicting relative levels of RNA transcripts for various proteins involved in collagen synthesis or bone mineralisation, measured at baseline and every 5d, for 30d. RNA transcripts included RUNX, SP7, COL1A1, ALPL (TNSALP), BGLAP (osteocalcin), SPARC (osteonectin), OPN (osteopontin), IBSP, DMP1, SOST and RANKL/OPG. Murine osteoclast differentiation cultures (bottom panels) were used to measure calcium channel expressions. Itpr3/Ryr3 are equivalent to the human ER calcium efflux channels IP3R and RyR, and Tric-b/Tric-a are equivalent to the human channels TRIC-B and TRIC-A.
