Power generation using waste material from the processing of agricultural crops can be a viable biomass energy source. However, there is scant data on their burning properties and this work presents flame speed and explosibility data for two agricultural waste materials: corn cobs (CC) and peanut shells (PS). The parameters were measured on the modified 1 m<sup>3</sup> dust explosion equipment. Two coarse size fractions of corn cobs and peanut shells of size less than 500  $\mu\text{m}$  were tested using the Leeds 1 m<sup>3</sup> vessel and were compared with two pulverized coal samples. This is typical of the size fraction used in pulverized coal power stations and of pulverized biomass currently used in power generation. The explosion parameters minimum explosible concentration (MEC), rate of pressure rise (dP/dt), deflagration index ( $K_{st}$ ), peak to initial pressure rise ( $P_m/P_i$ ), turbulent and laminar flame speeds were determined using a calibrated hemispherical disperser in the 1 m<sup>3</sup> vessel. MEC were measured in the range of 0.6-0.85 (based on 0% ignition probability) in terms of burnt equivalence ratio,  $\phi_{\text{burnt}}$ , which were comparable to the coal samples. The measured  $K_{st}$  (25-

60 bar m/s) and turbulent flame speeds (~1.3 m/s) were lower than for coal, which was a reflection of the lower calorific value. These results showed that these crop residues are technically feasible power plant fuels to burn alongside coal or as a renewable biofuel on their own.

Keywords: *Explosibility, Flame propagation, Biomass Energy*

## **1. Introduction**

Agricultural waste crop residues are a renewable and economical fuel for low carbon power generation (Saeed et al., 2014). Agricultural countries like Pakistan have the potential to exploit these local agricultural waste materials as renewable fuels for power generation and this will help its rural development. Saeed et al. (2015d) proposed that power plants of about 10MW<sub>e</sub> could be built based on the agricultural wastes in a 10km radius around the plant. It was estimated that utilization of crop wastes have the potential to fulfil 76% of the electricity demand of Pakistan (Saeed et al., 2015c). These agricultural waste biomass fuels have higher moisture and ash content as compared to woody biomass and this will influence their combustion properties (Saeed et al., 2014). Thermal treatments in combination with pelletization will improve the fuel quality (Saeed et al., 2015a) and ease of handling (Kaliyan, 2008). The residues studied in this work were corn cobs and peanut shells. These are major crops in Pakistan and were sourced and milled in Pakistan. Fig. 1 shows that both of these crops have a consistent or increasing growth from 2009 and are thus available each year for continual energy generation.

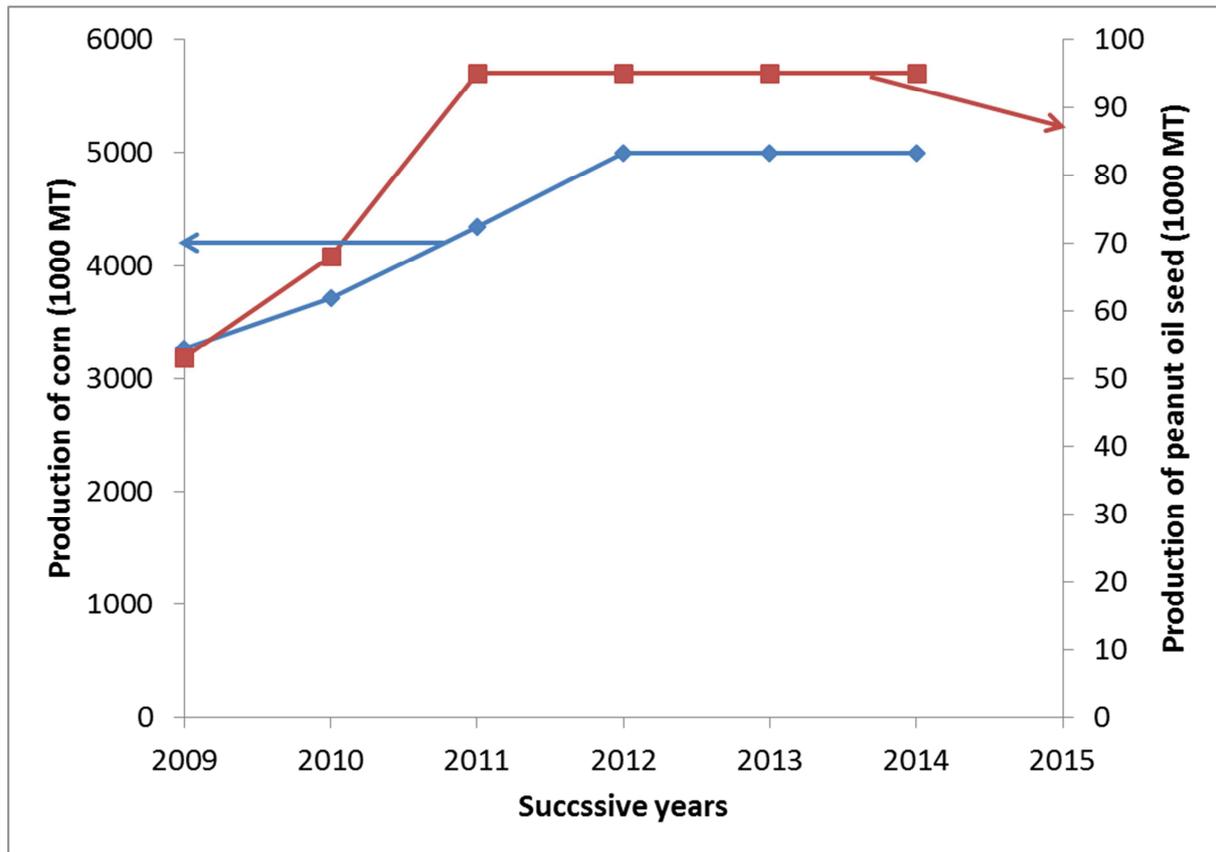

Figure 1: Production of selected crops in Pakistan for the successive years (Indexmundi, 2015)

Feeding of these compact fuel pellets in the silos results the generation of fines that carry fire and explosion risks. In electric power generation these fuels are used in pulverized form and therefore milled prior to their combustion. This pulverized state of fuel is very reactive due to more exposed area which gives a rapid volatile release and fast burning. The propagation of flames in mixed pulverised biomass and air is crucial to the design of combustion systems for burning these fuels. These biomass fuels in pulverised form have an explosibility risk, which also involves a flame propagating through a pulverised biomass and air mixture and thus is the same process as occurs in stabilised flames (Andrews and Phylaktou, 2010, Eckhoff, 2003).

Table 1: Recent biomass dust fire/explosion incidents

<b>Date</b>	<b>Type</b>	<b>Plant</b>	<b>Summary</b>
July 17, 2015	Fire + expl.	Bosley Mill Macclessfield, UK	<ul style="list-style-type: none"> <li>➤ Powerful explosion and fire resulting in the collapsing of the building.</li> <li>➤ 4 deaths and 20 injured.</li> </ul>

Sept. 03, 2013	Fire + expl.	Rotokawa wood pellet plant,	<ul style="list-style-type: none"> <li>➤ Fire and explosion originated inside the silo and duct system.</li> <li>➤ No injuries were reported.</li> </ul>
April 09, 2013	Fire	Charleston Pellet plant	<ul style="list-style-type: none"> <li>➤ Fire caught by the pellets started in the pellet plant</li> <li>➤ No injuries were reported.</li> </ul>
April 05, 2013	Fire	Dewys Manufacturing in MARNE, Mich.(WOOD)	<ul style="list-style-type: none"> <li>➤ Five fire departments were called to Dewys Manufacturing in Marne after a fire.</li> <li>➤ The fire started in a dust collecting unit in the building. No one was hurt and the fire did not spread to any other part of the structure.</li> </ul>

There have been many incidents of fire/explosion in the biomass plants and similar grain storage facilities, on average one incident was reported every day (Abbasi and Abbasi, 2007). Some of recent incidents of biomass fire/explosions are summarized in Table 1 (Industrial-Fire-World, 2015).

Utilization of the biomass as feed-stock for power generation plants partially with coal or independently involves many problems that need to be addressed (Tumuluru et al., 2011).

Consistency in the availability of the selected biomass reserves is of prime importance and this is better for biomass pellets and best for torrefied biomass. Also the balance of the harvest of biomass with consideration of their growth time has to be maintained for

environmental sustainability. Most woody biomass takes up to a hundred years for their growth and a large proportion of wood is used as construction material in industry. A major sustainability criteria is that the annual harvest of wood is the inverse of the full growth time, which is generally 1-2% for wood. This is similar to the amount of trash in forest which currently has no value. However, crop residues are different in that and in countries like Pakistan more than one crop a year can be produced. All of the non-food part of the crops is then available each year as waste biomass (Saeed et al., 2015c). However, they have limited production with some share of these crop wastes used for cattle feed.

A disadvantage of agricultural waste biomass is the high ash content, which acts as an inert mass and lowers the flame temperature and creates slag and corrosion problems in boilers. Saeed et al. (2014) showed that milling agricultural waste biomass concentrated the ash in the finer fraction which are more reactive. The ash in agricultural waste crop residues can be minimized by water and/or acid washing. Milling of agricultural waste fibrous biomass is also a problem area and burning of larger particles sizes would enable lower cost utilization of these materials. However, due to the high volatile content of biomass they do not need to be as fine milled as coal (Tumuluru et al., 2011) to be equally reactive and this will be shown in this work.

Biomass is primarily composed of cellulose, hemicellulose and lignin that decompose upon exposure to heat. Pyrolysis components involve free and bound moisture, tar, incondensable gases, char and ash contents. The bound moisture is collected in the tar that can be separated from bio-oil (Bridgwater et al., 1999). These are composed of complex compounds such as furfural, levoglucosan, phenol, 1,4:3,6-dianhydro- $\alpha/\beta$ -d-glucopyranose, acetic acid etc. Further fractionation results in the formation of simple gases like CO, CO<sub>2</sub>, CH<sub>4</sub>, H<sub>2</sub> and other C<sub>x</sub>H<sub>x</sub> (Wang et al., 2014). The characterization of these volatiles is dependent on the particle size distribution, heating rate and the heating temperature. Higher heating rate with

higher temperature increases the production of hydrogen due to more decomposition of lignin that releases more hydrogen (Neves et al., 2011). These pyrolysis gases play an important role in the flame propagation due to substantial amount of volatiles that dominate the combustion with relatively low char yields and char combustion. Also the low activation energies for their volatiles release rate make them more reactive than coal samples (Saeed et al., 2016a). Biomass can be either co-fired with coal or burnt on its own (Sami et al., 2001).

The velocity of the dust/air mixture from the mill to the burner must be higher than the burning velocity otherwise there can be a flashback into the supply tube and mill. However, the velocity cannot be too high or the flame stability will be poor and these aspects of burner design need to know the burning velocity of the pulverized biomass/air mixture. These parameters are also critical in the explosion protection design procedures.

## 2. Experimental Methods

Ultimate analysis was performed on a Flash 2000 Thermal Scientific Analyser in which a small amount of sample was burned in pure oxygen at 1800°C and converted to the respective combustion gases CO<sub>2</sub>, H<sub>2</sub>O, NO<sub>2</sub> and SO<sub>2</sub>. These combustion gases were passed through a chromatographic column using a helium carrier gas, where they were separated and quantified using a thermal conductivity detector (TCD). Oxygen found by the missing mass and was not directly analysed. The elemental analysis as shown in Table 2 and was used for the determination of molar ratios of hydrogen and oxygen relative to carbon, H/C and O/C, on a dry ash free basis (daf) that were used for the calculation of the stoichiometric air to fuel ratio.

A Shimadzu 50 Thermo-gravimetric analyser (TGA) was used to determine the water, volatile, fixed carbon and ash content. The weight loss in nitrogen was determined as a function of temperature. The weight loss to 110°C and 910°C was the water and volatile content respectively. Air was then substituted for nitrogen and the weight loss was the fixed

carbon content. The remaining weight as a proportion of the initial weight was the ash content. Bomb calorimetry was used to measure the gross calorific values of the samples. A Malvern Mastersizer 2000 was used to measure the size distribution and cumulative size of the samples. SEM analysis was performed using a Carl Zeiss EVO MA15 scanning electron microscope for surface morphology..

A modified ISO 1m<sup>3</sup> vessel, shown in Figure 2, was used for the determination of the pulverised biomass reactivity in terms of the deflagration parameter  $K_{st}$  ( $=dP/dt_{max}V^{1/3}$ ) and the turbulent flame speed,  $S_T$ . The standard 1m<sup>3</sup> dust explosion equipment operates by inserting the dust to be tested in an external 5L pot that is separated from the main vessel by a fast acting valve. This pot with the dust was pressurised to 20 bar prior to the test. The pot is connected to a 'C' ring with an array of holes that is designed to disperse the dust and air. The main vessel is partially evacuated, so that when the compressed air is added, the pressure is a standard atmosphere. The flow of air through the holes in the C ring creates turbulence as well as dispersing the dust. Turbulence decays rapidly with time after the end of injection and the results of this test depend on the turbulence present at ignition. This is controlled by the time delay between the external compressed air arriving in the vessel (determined from the rise in pressure of the vessel) and ignition of the mixture. In the standard C ring method this delay is 0.6s. The authors have used turbulent and laminar gas explosions in this vessel to show that the turbulence created with 0.6s delay gave a factor of 4 enhancement of the flame speed (Sattar et al., 2014).

A 2 D array of thermocouples were placed for measurement of flame speeds that will also show whether the flame is propagating uniformly and spherically, as assumed in the definition of  $K_{st}$ . This turbulent flame speed can be converted into a laminar flame speed by dividing by the above turbulence factor of 4 and then converted into the laminar burning velocity using expansion ratio, as determined by the measured peak to initial pressure ratio

(Sattar et al., 2014). Unfortunately, the standard “C” ring injector does not work for pulverised coarse woody biomass, as the particles are compressed in the delivery tube and do not emerge from the injection holes. This occurs even where the woody biomass is sieved to  $<63\ \mu\text{m}$ , as size and SEM analysis of these particles shows that cylinders of diameter  $<63\ \mu\text{m}$  occur with lengths much greater and these block in the “C” ring. Several modifications were investigated, but for particles with sieved sizes  $>63\ \mu\text{m}$ , as used in power stations and as occur in pellet store dusts, no method using the external pot to place the dust could be operated with coarse biomass dusts.

The principle of an externally based dust driven in by compressed air had to be abandoned and instead, the Hartmann method was used whereby the dust was placed inside the vessel in a chamber and dispersed with a blast of air. A hemispherical container was secured on the floor of the vessel, as shown in Figure 3, that was 0.4m diameter with a volume of 17L and could contain 3.5 kg of biomass particles with bulk density of  $200\ \text{kg}/\text{m}^3$ . This was used with compressed air from a 10L external volume at 20 bar pressure. The air was fed via a pipe, the same size as the “C” ring, to the bottom of the hemisphere and injected through a series of holes around and along the tube end, so that the same total hole area as for the “C” ring injector was used. Calibration of the injection system showed that an ignition delay of 0.5s was required to give the same explosibility indices for cornflour and Colombian coal as the standard ISO  $1\ \text{m}^3$  design. This method of dispersion of the dust also gave a spherical flame. Calibration of the turbulence in this arrangement, as outlined above for the standard C ring, gave a turbulence factor of 4.7.

Figure 2: Modified 1 m<sup>3</sup> dust explosion vessel

Figure 3: Hemispherical disperser

It was observed in the 1 m<sup>3</sup> dust explosion vessel, shown in Figure 2, that about half of the nominal starting mass remained unburnt after the flame propagation in the hemisphere or on

the bottom of the vessel (Sattar et al., 2012a, Sattar et al., 2012b). The composition of this unburnt mass was shown that of the unburnt original biomass with minimal change in composition. The unburnt mass was extracted using a vacuum cleaner into a filter bag and weighed. The equivalence ratio of the tests was corrected for the mass unburnt and is referred to as the burnt mass equivalence ratio,  $\phi_{burnt}$ . This included a correction for the proportion of the unburnt mass plus the ash from the burnt biomass.  $\phi_{burnt}$  is the actual concentration involved in the propagation of flame calculated using the Eqs 1 and 2.

$$\text{Actual burnt mass} = \frac{\text{Injected mass} - \text{Vessel residue}}{1 - \text{Ash fraction}} \quad (1)$$

$$\text{Burnt equivalence ratio, } \phi_{burnt} = \frac{\left(\frac{\text{Air}}{\text{Fuel}}\right)_{\text{Stoichiometric}}}{\left(\frac{\text{Air}}{\text{Fuel}}\right)_{\text{Actual}}} \quad (\text{by mass}) \quad (2)$$

### 3. Corn Cob and Peanut Shell Characterisation

Two crop residues ‘Corn cob’ (CC) and ‘Peanut shell’ (PS) were investigated as they are typical of waste agricultural products in Pakistan. These agricultural residue samples were milled at source in Pakistan and it was this milled sample that was used in the explosions after sieving to  $<500\mu\text{m}$ . The TGA proximate and elemental analysis of the two samples and of two coal samples for comparison are shown in Table 2. The two coal samples used for comparison were milled and sieved to  $<63\mu\text{m}$  and this is the main reason that they were more reactive as is shown in the results.

Table 2 shows that corn cobs and peanut shells have a high ‘N’ and ash content which are undesirable, but both levels are about half those for coal. The differences in the stoichiometric A/F ratio have to be taken into account in the burner control for these fuels, a much higher mass flow of biomass is required compared to coal to deliver the same energy to the furnace. Table 1 also shows that these crop residues have higher volatile content and

lower fixed carbon content compared to coal. In addition to higher volatiles, the rate of release of volatiles were faster than in the coal samples and occurred at lower temperatures, as shown by the TGA results in Figure 4. Two peaks for the release of volatiles for the corn cobs sample was caused by the decomposition of outer soft hemicellulose at the lower temperature and the decomposition of cellulose and lignin at the higher temperature. The calorific value was lower for corn cobs than peanut shells. Higher volatiles and their higher rate of release make corn cobs more reactive than peanut shells.

Table 3 shows the elemental and TGA analysis of the post explosion residues for the most reactive concentration, in comparison to their respective raw samples. For the corn cob post explosion residues, the composition was very close to the original raw material for all parameters measured. In contrast, the post explosion residues from the peanut shell dust explosions were significantly different. The biggest difference was the increase in ash, which is expected as the ash from the material that burns should accumulate with the residue alongside the material injected that did not burn. If only about 50% of the original material burns then the ash in the deposits should be about double that in the raw material and this occurs for the PS residues. The lack of an increase in ash content for the CC is difficult to explain. The PS residues had a significant decrease in volatiles and increase in fixed carbon together with a decrease in O content.

Table 2: Chemical Characterisation of selected crop residues in comparison to coals (Huéscar

Medina et al., 2015)

This indicates some low temperature pyrolysis has occurred, with similar results to torrefaction. Why these two biomass behaved differently is not known. However, the post explosion residue is concluded to be predominantly the same as that of raw biomass.

#### 4. Particle size distribution of the milled biomass

Table 4 shows the particle size distribution of the raw biomass (sieved to <500 $\mu$ m) and the post explosion residues. The two size distributions were very similar, again indicating that the residue was predominantly the original raw biomass. There was an increase in the proportion of fines and a decrease in the proportion of coarse material in the residues for both biomasses. However, for CC the surface average size decreased in the post explosion residue whereas for the PS the surface averaged size increased in the post explosion residue, but the changes were relatively small.

Table 4: Chemical characterization of the post explosion residues in comparison to their raw samples

Materials	d (10%)	d (50%)	d (90%)	Surface weighted	% Fraction
				mean	<100 $\mu$ m
Corn cob	45.0	372.6	777.8	98.1	19
Post explosion corn cob	48.4	239.6	668.3	92.1	22
Peanut shell	24.3	176.1	698.5	63.5	39
Post explosion peanut shell	32.4	180.9	648.6	75.3	35

Table 4 shows that the raw biomass size distributions as milled were relatively coarse with over 50% of the mass >373 $\mu$ m for CC and >176 $\mu$ m for PS. The distribution of sizes in the samples and residues are shown in the SEM images in Figure 5. There is no evidence in the size distribution or in the SEM images of the raw biomass and their residues, that only the fines burn in the explosion, as also proved by the minor difference of the % fraction <100 $\mu$ m in Table 4. The conclusion is that the fines and coarse material burn approximately with equal effectiveness and this was not expected.

SEM images, in Figure 5, of molten layers of the burnt mass showed the formation of some cenospheres, so there was some pyrolysis of the biomass. In the corn cob sample, more molten layers were observed in the post explosion residues than the peanut shell sample. The soft structure of corn cob facilitating the efficient release of volatiles is also supported by the volatile release plot in Figure 4. Also smoldering of the biomass was experienced during milling of the corn cob sample, but not for the peanut shell sample.

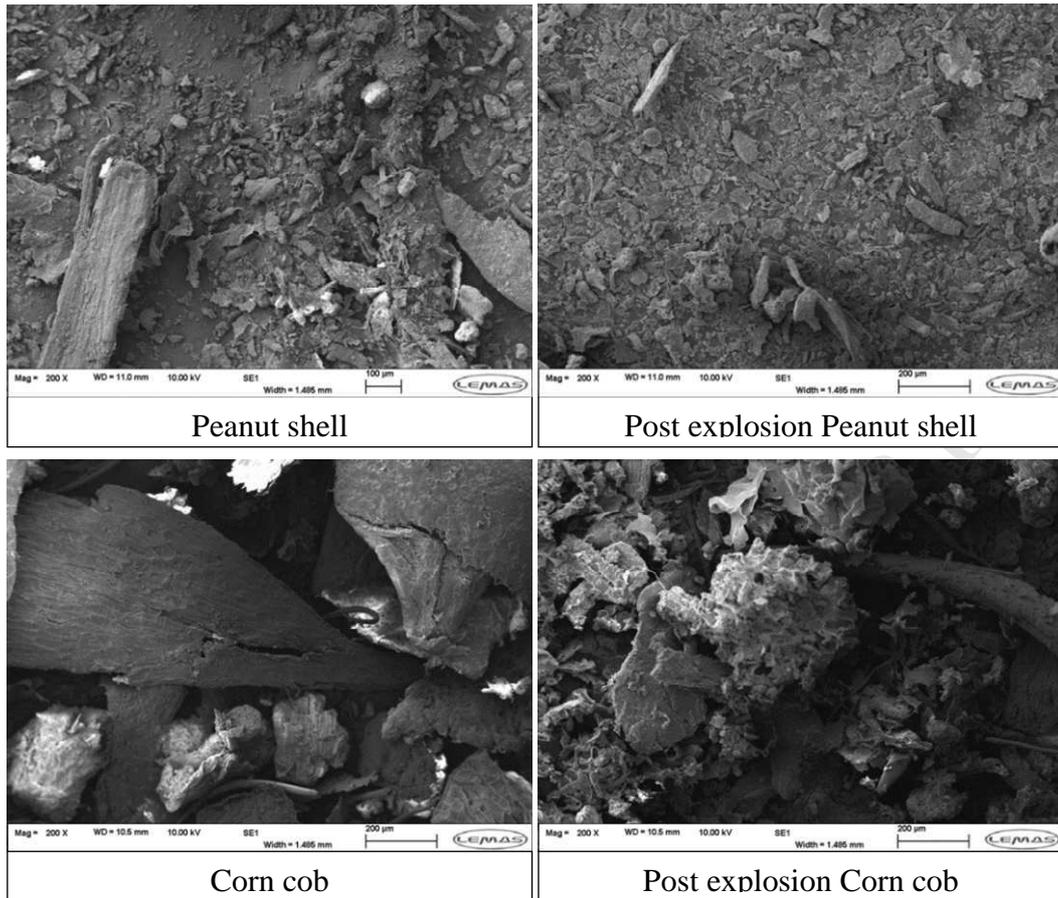

Figure 5: Scanning Electron Microscopy of the post explosion residues in comparison to their respective samples

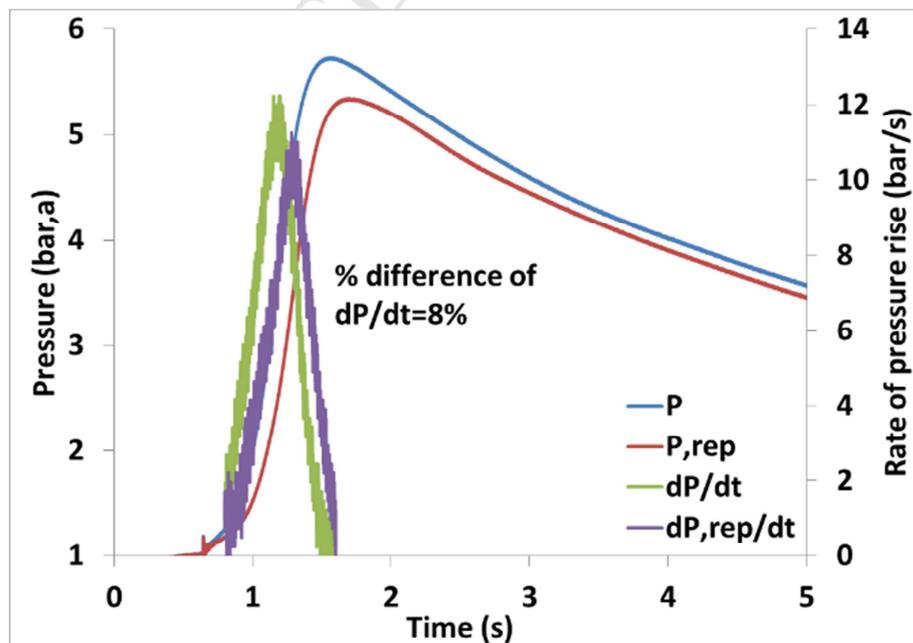

Figure 6: Repeat tests of peanut shell for same concentration of  $600 \text{ g/m}^3$

A physical model of the turbulent biomass flame front that fits the above evidence is that the explosion induced wind blows the dust ahead of the flame and eventually this dust is compressed into a layer on the walls. The flame then impinges on the wall and partially pyrolyses the outer layer, but the inner layer next to the wall remains the original biomass with the original size distribution. After the explosion this residue falls off onto the floor of the vessel (Sattar et al., 2012a, Sattar et al., 2012b, Slatter. et al., 2014). At the turbulent flame front the action of the explosion induced wind is for the fines to follow the gas flow and the coarse particles to lag behind and be enveloped in the products of reaction of the fines. The coarse material is then gasified in the hot combustion products of near stoichiometric burning of fines. This model explains why rich mixtures can burn with the generation of a high pressure, as will be shown in the results. In these biomass samples there are sufficient fines for lean mixtures to burn and to give a relatively lean MEC. However, the temperature is still sufficient to ignite the coarse particles and for lean overall mixtures they can then burn as there is surplus oxygen. For rich overall equivalence ratios the coarse particles are gasified by heating in the products of the combustion of the fines.

##### **5. Deflagration Index ( $K_{st}$ ) and Normalised explosion pressure ( $P_m/P_i$ ) Results**

Figure 6 shows two repeat tests of peanut shells that were performed at a nominal concentration of  $600 \text{ g/m}^3$ . This shows a typical pressure time record and the measurement of  $dp/dt_{max}$  by differentiation of the pressure time record. The repeatability of the test were good with 6.5% and 8% differences in  $P_m$  and  $K_{st}$  respectively. The deflagration index,  $K_{st}$ , Normalised explosion pressure,  $P_m/P_i$ , Turbulent flame speed,  $S_T$  and Laminar burning velocity results as a function of  $\phi_{burnt}$  are shown in Figures 7-10 for the two biomass samples sieved to  $<500\mu\text{m}$  in comparison with two coals milled and sieved to  $<63\mu\text{m}$ . The coal samples had higher values of  $K_{st}$  mainly due to their much smaller particle size. Corn cobs, CC, was more reactive than peanut shells, PS, with higher ' $K_{st}$ ' and ' $S_T$ ', but the higher

' $P_m/P_i$ ' for CC resulted in the maximum laminar burning velocities being lower for CC. The increase in reactivity by the change in ' $K_{st}$ ' for CC relative to PS was much larger than that based on the turbulent flame speeds. This was not expected and could be due to the measurement being based on the reactivity close to peak pressure in the explosion, whereas the flame speeds were measured in the initial near constant pressure flame propagation. The pressure rise in the explosions are shown in Figure 7 and show that despite the low reactivity of the coarse biomass, the pressure rise was high and would be completely destructive if it occurred inside an enclosure such as pellet silo or pulveriser mill or pellet manufacturing plant. Also a peak pressure close to the theoretical maximum for gas explosions indicated that complete combustion of the fine and coarse biomass had occurred.

Figures 7 and 8 show that the minimum explosible concentration (MEC) for CC and PS were 0.62 and  $0.85\phi_{burnt}$  based on 0% ignition probability respectively. The lean limit for CC and PS were higher than the Kellingley ( $\phi_{burnt}=0.48$ ) and Colombian coal samples ( $\phi_{burnt}=0.39$ ). This difference was caused by the differences in the particles size after sieving to  $<63\mu m$  for the two coal samples and  $<500\mu m$  for the two biomass samples. Table 3 shows that PS were finer than CC and both had a very wide size distribution with 50% of the mass of size  $>370\mu m$  for CC and  $180\mu m$  for PS. CC due to higher volatiles and oxygen content was more reactive than the PS sample with lean minimum explosion concentration.

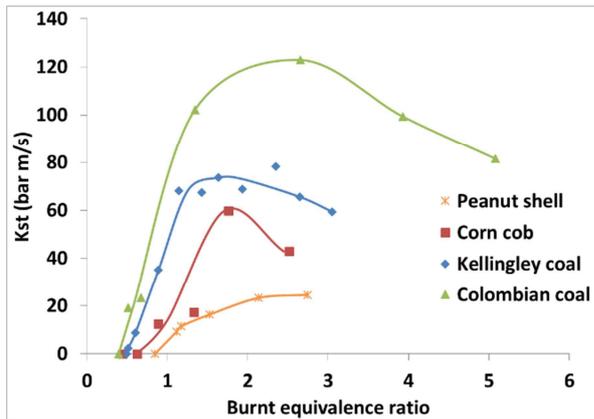

Figure 7:  $K_{st}$  v.  $\Phi_{burnt}$  for CC, PS and coal

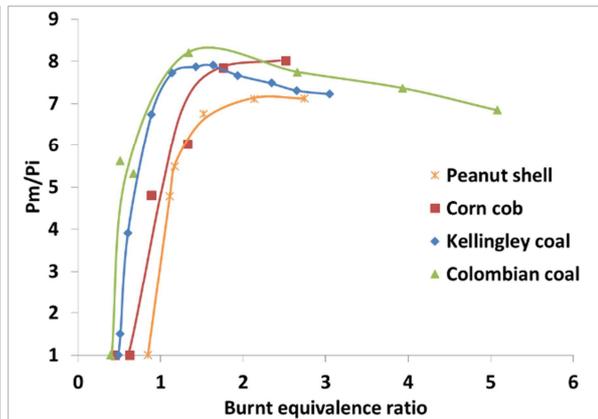

Figure 8:  $P_m/P_i$  v.  $\Phi_{burnt}$  for CC, PS and coal

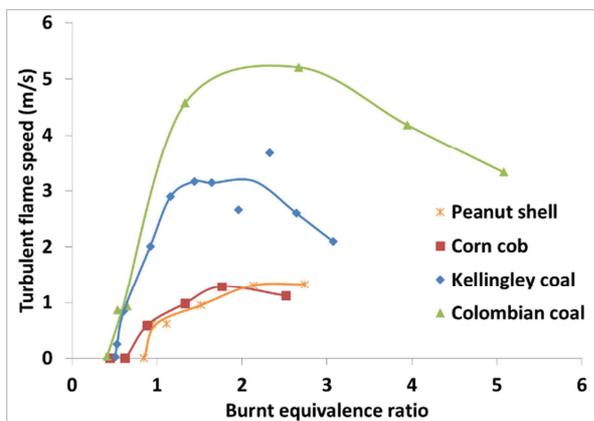

Figure 9: Turbulent flame speed,  $S_T$ , v.  $\Phi_{burnt}$

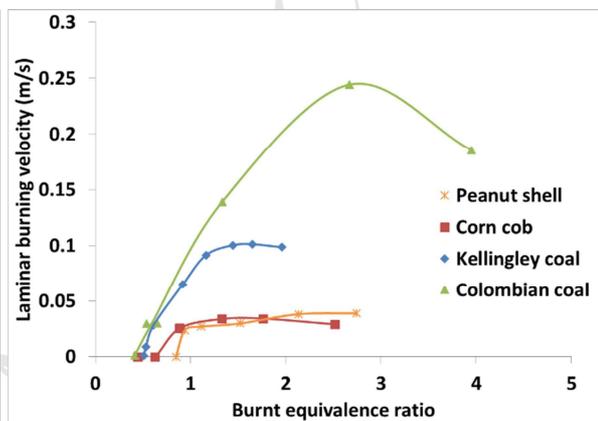

Figure 10: Laminar burning velocity v.  $\Phi_{burnt}$

The pressure rise in Figure 7 is driven by the temperature of the burnt gases and a maximum pressure ratio of '7' for PS indicates about 2100K as the burnt gas temperature. The peak pressure for CC was higher at '8' indicating a burnt gas temperature of 2400K. This higher peak pressure for CC was unexpected as Table 2 shows that the GCV was much lower. For the two coal samples the Colombian coal had a 6% higher GCV than the Kellingley coal and there was a similarly higher peak pressure.

The mechanism for large size particles to react behind the flame front for rich mixtures, as discussed above, postulates that the large particles are gasified in the rich overall mixture but with a temperature generated by near stoichiometric combustion in the fine particles that burn first. The release of gasified gases, CO and hydrogen, by the large particles will cause the

pressure to increase in the chamber, not due to flame temperature increases but due to gas volume addition. If a simple assumption is made that all the mass of CC injected after  $\phi_{\text{burnt}}=1$  was converted into CO with no change in the temperature at stoichiometric, then it may be shown, using the C content of the biomass in Table 2, that the 5.5 pressure ratio at  $\phi_{\text{burnt}} = 1$  would increase to '7' at  $\phi_{\text{burnt}} = 2.5$ . This is the pressure found for PS but for CC it was '8'. This difference is probably due to the assumption of constant flame temperature, which is the temperature derived from the initial burning of the fines. As more mass is added, more fines occur and hence the temperature will rise and this is likely to account for the additional pressure ratio increase to '8' for the CC biomass.

## 6. Comparison with Previous Biomass Measurements of Flame Propagation

Table 5 compares the present work with previously published work using the same equipment as in the present work. Most of the previous work was for biomass milled and sieved to  $<63\mu\text{m}$  and this all showed a higher reactivity of the biomass due to the smaller size. Saeed et al. (2016b) have investigated a mixed wood biomass (Spruce, pine, fir - SPF) that was milled and sieved to  $<1000\mu\text{m}$  and the results are very similar to the present work for agricultural waste biomass, the main difference was the lower ash in the wood sample (Saeed et al., 2016b).

The present results show the CC and PS were slightly more reactive than the wood, in spite of the higher ash content. Saeed et al. (2016) showed that the prime correlator of the data in Table 4 was the particle size, which was different for each biomass even though the sieved size was the same.

Table 5: Comparison of the flame propagation properties of the present samples with the previous biomass measurements of Flame Propagation

Samples	$\emptyset_{\text{peak}}$ $K_{\text{st}}$	Peak Pm/Po	Peak $K_{\text{st}}$ bar m/s	Peak $S_{\text{T}}$ m/s	Peak $S_{\text{u}}$ m/s	Refs.
Corn cob<500 $\mu\text{m}$	1.8	8.0	60	1.3	0.03	This work
PS <500 $\mu\text{m}$	2.7	7.1	25	1.3	0.04	This work
Wood SPF <1000 $\mu\text{m}$	3.3	7.3	24	1.05	0.03	(Saeed et al., 2016b)
Bagasse<63 $\mu\text{m}$	2.72	8.8	103	3.79	0.11	(Saeed et al., 2015b)

Pine 1<63 $\mu\text{m}$	4.2	9.0	109	3.7	0.1	(Huéscar Medina et al., 2013)
Spruce<63 $\mu\text{m}$	1.9	8.8	81	3.4	0.09	(Huéscar Medina et al., 2014b)
US Pine 2<63 $\mu\text{m}$	2.5	9.0	105	4.5	0.11	(Huéscar Medina et al., 2014a)

## 7. Conclusions

Two agricultural waste biomass, corn cobs (CC) and peanut shells (PS), were sourced from and milled in Pakistan and their flame propagation characteristics were determined. The milled samples were sieved to <500 $\mu\text{m}$  and the size distribution showed that PS had been milled finer than the CC. In spite of this the CC were found to be more reactive with a higher  $K_{\text{st}}$  of 60 compared with 25 for PS and comparable peak  $S_{\text{T}}$  of 1.3 in the initial constant pressure region. The peak pressure was also higher for CC indicating a higher flame temperature and this was in spite of the higher GCV for PS of 19.7 MJ/kg compared with 16.7 for CC. A model for the flame front of the explosion induced wind inducing a size separation with the fine particles (<100 $\mu\text{m}$ ) propagating the flame and the coarse particles

being gasified in the hot flame gases behind the flame front. This was shown to explain most of the observed results.

### Highlights

- Agricultural wastes biomass residues as a potential fuel for extraction of energy.
- Flame propagation rate of selected corn cobs and peanut shells wastes were measured using Modified 1 m<sup>3</sup> dust explosion vessel.
- Reactivity data results like minimum explosible concentration (MEC), deflagration index (K<sub>st</sub>) and maximum pressure rise ( $P_{\max}/P_i$ ) of pulverized biomass residues were measured and compared with two previously tested coal samples.
- Coarse biomass agricultural waste propagated the flame with comparable pressure build up for the most reactive concentration.
- Agricultural wastes tested can be a good substitute of coal (partially/fully) in the coal power generation plants for the green energy.
