Illustration of a simple route to generate strong carbon-13 NMR signals that are detectable for several minutes

Soumya S. Roy\textsuperscript{a}, Philip Norcott\textsuperscript{a}, Peter J. Rayner\textsuperscript{a}, Gary G. R. Green\textsuperscript{b} and Simon B. Duckett\textsuperscript{a}

\textbf{Abstract:} Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI) suffer from low sensitivity and limited nuclear spin memory lifetimes. While hyperpolarization techniques increase sensitivity there is also a desire to increase relaxation times to expand the range of applications addressable by these methods. Here we demonstrate a route to create hyperpolarized magnetization in $^{13}$C nuclear spin pairs that last much longer than normal lifetimes by storage in a singlet state. By combining molecular design and low-field storage with para-hydrogen derived hyperpolarization we achieve more than three-orders of signal amplification relative to low-field storage with para-hydrogen derived hyperpolarization we achieve more than three-orders of signal amplification relative to equilibrium Zeeman polarization and an order of magnitude extension in state lifetime. These studies use a range of specifically synthesized pyrazidine derivatives and dimethyl $p$-tolyl phenyl pyridazine is the most successful, achieving a lifetime of ca 190 s in low-field which leads to a $^{13}$C-signal that is visible for 10 minutes.

While carbon is one of the most abundant elements in nature, its nuclear magnetic resonance (NMR) active form carbon-13 is present at just a $\sim$1.1% level which, when coupled with its low magnetogyric ratio, results in low detectability. Consequently, $^{13}$C magnetic resonance imaging (MRI) produces a negligible response when compared to proton measurement in the body which is facile due to high water content and high sensitivity. $^{13}$C detection does, however, benefit from potentially long relaxation times when compared to those of the proton.

A number of methods, commonly known as hyperpolarization, exist that can increase NMR sensitivity in nuclei such as $^{13}$C and are being used to overcome these issues.\textsuperscript{[15-18]} These approaches artificially increase the associated spin population differences between the energy levels that are probed. For example, Golman \textit{et al.} reported a para-hydrogen ($p$-$H_2$) induced nuclear polarization (PHIP)\textsuperscript{[13-14]} study which achieved the rapid in vivo detection of a $^{13}$C-MRI response in 2001.\textsuperscript{[19]} Two years later, they described the results of a similar study using dissolution dynamic nuclear polarization (DPN),\textsuperscript{[20]} where a normally inaccessible response was seen in vivo. Bhattacharya \textit{et al.} have since incorporated $p$-$H_2$ into sodium 1-$^{13}$C acetylene dicarboxylate to facilitate the collection of an arterial $^{13}$C-MRI image of a rat brain.\textsuperscript{[21]} More recently, a DNP derived $^{13}$C-MRI response with chemical shift resolution has been shown to distinguish different metabolic flux between normal and tumor cells in humans.\textsuperscript{[22-26]} These studies illustrate the potential benefits to human health if such methods were to become widely accessible and hence establish the need for a rapid, low cost delivery method for long-lived $^{13}$C hyperpolarization.

In this article, we demonstrate that the goal of rapidly producing a long-lived $^{13}$C hyperpolarized response can be met by applying the signal amplification by reversible exchange (SABRE) effect.\textsuperscript{[15-16]} In SABRE, a catalyst reversibly binds $p$-$H_2$ and the substrate to transfer dormant spin order from $p$-$H_2$ into the substrate via the scalar-coupling framework, as shown in Scheme 1. We use this approach here to hyperpolarize a series of coupled $^{13}$C spin-pairs in a range of pyrazidine derivatives, a motif that exhibits pharmacological activity.\textsuperscript{[15-16]} Polarization is then stored in specially created singlet spin order to enable a response to be seen several minutes later. While a range of nicotinamide and pyridazine based substrates have been shown to deliver long-lived $^{13}$C hyperpolarization,\textsuperscript{[17-18]} and analogous $^{15}$N based singlets have been created by Warren and co-workers\textsuperscript{[19]} we believe the $^{13}$C responses reported here are significant due to the growing use of $^{13}$C-MRI for in vivo study.

\textbf{Scheme 1} Schematic depiction of the SABRE hyperpolarization technique. IMes $\equiv$ 1,3-bis(2,4,6-trimethylphenyl)imidazol-2-ylidene.

The term singlet ($|S\rangle = (|\alpha\beta\rangle - |\beta\alpha\rangle)/\sqrt{2}$) that is used here represents the spin-zero magnetic alignment of a coupled spin-1/2 system whose conversion into the associated triplet states ($|T_0\rangle = (|\alpha\beta\rangle + |\beta\alpha\rangle)/\sqrt{2}$; $|T_1\rangle = |\alpha\alpha\rangle$; $|T_{-1}\rangle = |\beta\beta\rangle$) is symmetry-forbidden. Consequently, any population difference that can be created between these singlet and triplet forms is expected to relax more slowly than the usual time constant $T_1$.\textsuperscript{[20]} The symmetry properties that make such states long-lived also make them challenging to generate and probe.\textsuperscript{[20,21]} Levitt and co-workers have demonstrated a number of strategies to do this in a range of chemically inequivalent spin systems\textsuperscript{[22-26]} and have achieved a lifetime of over 1 hour in an optimized chemical system at low-field.\textsuperscript{[27]} However, when a substantial chemical shift difference exists between these spin-pairs, the application of a spin-lock, or sample-shuttling to low field, is necessary to extend state lifetime.\textsuperscript{[22,28-29]} This effect has recently been illustrated by monitoring the effect of solvent dependent chemical shift changes.\textsuperscript{[17-18]} Warren and co-workers have...
reported a parallel approach that exploits magnetic inequivalence to create related singlet states.\textsuperscript{[21, 30-33]} Hence while SABRE has been shown to create hyperpolarized \textsuperscript{1}H and \textsuperscript{15}N derived singlets there is a need to expand these methods to \textsuperscript{13}C given the success of DNP.\textsuperscript{[8-11]} However, \textsuperscript{13}C-SABRE itself has though currently seen limited application\textsuperscript{[24]} and reported efficiency gains are relatively low. We develop here a molecular design strategy for use with SABRE and radio frequency (rf) excitation to achieve greater than 2\% net \textsuperscript{13}C polarization in a long-lived form.

In this study, we employ magnetic and chemical inequivalence effects through the synthesis of specific substrates where their carbon-4 and carbon-5 sites are \textsuperscript{13}C enriched as detailed in Scheme 2 (full synthetic strategy and characterization data are available in the supporting information, Section S1-3). The Type-1 form agents exhibit chemically equivalent but magnetic inequivalent \textsuperscript{13}C spin-pairs ($\delta \neq 0$) and have local $C_2$ symmetry. The Type-2a form is constructed such that $R^1$ and $R^2$ are chemically different and a small chemical shift difference results between the \textsuperscript{13}C spin-pair ($\delta \neq 0$). Chemical inequivalence is also derived by remote substitution, at $R^3$ and $R^4$, in the Type-2b agents of Scheme 2. Whilst these synthetic strategies allow access to two distinct classes of molecular system, our results illustrate that both are equally viable.

In order to explore the singlet states of these systems their NMR properties must first be analyzed. The Type-1 substrate, 1, of Table 1 reflects an AA'XX' type spin system (Figure 1a) and produces the \textsuperscript{13}C NMR spectrum shown in Figure 1b. This trace illustrates the effect of magnetic inequivalence, but does not immediately yield the individual carbon-proton couplings ($J_{CCH}$ and $J_{CC}$) necessary to create a singlet state by the method of Warren\textsuperscript{[21]} as the peak-to-peak separations reflect the mean value of the \textsuperscript{13}C-$H$ J-couplings (5.25 Hz = ($J_{CCH} + J_{CC}$)/2). By employing a $J$-synchronized experiment,\textsuperscript{[23, 30, 32]} it is possible to show the difference in these J-couplings is 3.1 Hz (see Section S5 in the supporting information). We harness this difference in coupling ($J_{CCH}$) to popolate the singlet state via rf pulse sequencing as detailed in Figure 1c. Table 1 details the chemical structures of Type-1 agents 1-3 that are examined here. A value of zero for $J_{CCH}$ means that it is not possible to induce interconversion between the singlet and triplet forms via rf pulses (eg. see Section S5).\textsuperscript{[20]}

We also prepared agents 4-8 which reflect a series of Type-2 molecular systems. Their spin system is illustrated in Figure 1d, while Figure 1e shows the \textsuperscript{13}C NMR spectrum of agent 5 in methanol-$d_4$. In this case, the partially resolved 1.05 Hz ($\Delta \delta^2/2\text{J}_{CC}$) splitting signifies that a strongly coupled \textsuperscript{13}C spin-pair results when $R^1$ and $R^2$ are deuterated phenyl and para-tolyl groups respectively.

In order to explore the singlet states of these systems their NMR properties must first be analyzed. The Type-1 substrate, 1, of Table 1 reflects an AA’XX’ type spin system (Figure 1a) and produces the $^{13}$C NMR spectrum shown in Figure 1b. This trace illustrates the effect of magnetic inequivalence, but does not immediately yield the individual carbon-proton couplings ($J_{CCH}$ and $J_{CC}$) necessary to create a singlet state by the method of Warren\textsuperscript{[21]} as the peak-to-peak separations reflect the mean value of the $^{13}$C-$H$ J-couplings (5.25 Hz = ($J_{CCH} + J_{CC}$)/2). In this case, the partially resolved 1.05 Hz ($\Delta \delta^2/2\text{J}_{CC}$) splitting signifies that a strongly coupled $^{13}$C spin-pair results when $R^1$ and $R^2$ are deuterated phenyl and para-tolyl groups respectively.

![Scheme 2](image)

**Scheme 2** The molecular systems studied here are of Type-1, which reflect a chemically equivalent but magnetically distinct $^{13}$C spin-pair (1), or Type-2a and Type-2b, which reflect chemically inequivalent $^{13}$C spin-pairs ($R^1 \neq R^2 \neq R^3$).
we achieved a $T_S$ of 90 ± 3 s in high field which increases to 165 ± 18 s in low-field. Table 1 summarizes these values for agents 1-8 and confirms that this strategy allows the creation of long-lived singlet states in these molecules. $^2$H-labeled 7 contained the optimal molecular environment of the series, delivering a low-field $T_S$ of 186 ± 18 s.

Table 1. $^{13}$C (3) SABRE signal enhancement (c) over the corresponding thermal measurement at 9.4 T after transfer at the indicated field (G), net polarization (P, %) and $T_S$ and $T_C$ lifetimes (s) of substrate 1-8 in high field (HF: 9.4 T) and low field (LF: ~10 mT). The $J$-coupling between the $^{13}$C spin-pair was found to be ~58.5 ± 2 Hz in all cases. The $\Delta J_{CD}$ values for Type-1 substrates, and the chemical shift difference ($\delta\nu$) for Type-2 substrates are noted.

$^a$ For 2, the $^{13}$C-$^2$H couplings are too small to exploit the M2S sequence to prepare the singlet. For 4, the singlet state lifetime proved low due to the $^{13}$C-deuterium coupling which provides a route to scalar relaxation. $^b$ In 8, the chemical shift difference between the $^{13}$C pairs is similar to the $J$-coupling constant in high field and a low lifetime results but in low field this extends to 45 s. In contrast, agents 5, 6, and 7 operate well in both low and high field, exhibiting lifetimes in excess of 150 s in low field.

A series of SABRE experiments were then undertaken to see if it was possible to create hyperpolarized longitudinal spin order within the $^{13}$C manifold of agents 1-8 (Table 1). This involved taking methanol-$d_4$ solutions that contained 20 mM of the substrate, and 5 mM of the IMes catalyst. $^2$H$_2$ gas was bubbled through the solution for 20 s in low field and the sample transferred into the NMR spectrometer for further analysis. Figure 2 highlights the results of this process, with the level of $^{13}$C polarization reaching ~2% as compared to the corresponding thermal polarization of only 0.0008% at 9.4 T in the case of agent 1 after relayed transfer from $^1$H-$^{13}$C at 30 G (see Section S6). No H/D-exchange is observable on the timescale of the SABRE experiment. The relayed transfer process was then examined as a function of the magnetic field experienced by the sample, and three maxima were observed, at ~10 mG (using µ-metal shield), ~30 G, and ~100 G. Simulation revealed the ~10 mG maxima is associated with direct hydride-carbon spin-spin transfer via the $^4J_{\text{CH}}$ and $^5J_{\text{CH}}$ couplings in the catalyst. The remaining maxima appear to result from relayed transfer via the agents $^1$H response (see Section S4).

When agent 2 is examined the $^2$H labels should prevent the relayed response operating and restrict transfer to the ~10 mG field range. Under these conditions a strong $^{13}$C signal is seen. However, upon moving from 10 G to 150 G, $^{13}$C and $^1$H SABRE enhanced signals are observed in the $^1$H and $^{13}$C frequency ranges. These results reveal readily detectable contributions from the $^1$H$^2$H$^{13}$C isotopolog, which is present at 1%, through the observation of a $^{13}$C response that contains a $J_{13}^{13}$ splitting of 5.4 Hz. This reflects one of the challenges faced when work with hyperpolarization in so far as low-concentration species can be readily detected. Agents 3 and 5-8 also require direct polarization transfer as there is no suitable relayed transfer pathway and again work well between 1 mG and 20 mG. These $^{13}$C hyperpolarization data are summarized in Table 1 and (Section S5). Polarization levels approaching 2% are readily achieved, which would be expected to increase further through catalyst optimization. We then transferred the resulting $^{13}$C hyperpolarization into singlet order via the methods described earlier. The efficiency of singlet conversion in all successful cases was found to be in the range of 50-80%.

![Figure 2](image_url)
creation when stored in a low-field region. In the case of 7, hyperpolarized signals were detectable for well over 10 mins.

Figure 3. Hyperpolarized 13C singlet state decay (log10 scale) as a function of low-field storage time (\(t_{\text{WLL}}\)) for agents 1, 5-8. Results are summarized in Table 1.

In summary, we have demonstrated that a series of novel agents can be prepared which contain two adjacent 13C labels in addition to two nitrogen based lone pairs which make them suitable for SABRE. Despite the weak J-coupling that exists between the hydride ligands and the targeted 13C sites we achieve a hyperpolarized response at the 2% level. This hyperpolarization has then been efficiently converted into singlet spin order within the two 13C labels by rf excitation with a low-field storage time \(t_{\text{WLL}}\) of \(\sim 190\) s being the result for deuterated dimethyl p-tolyl phenyl pyridazine. This process has been exemplified for both magnetic and chemical inequivalence. Our method provides a fast and low-cost technique to create 13C hyperpolarization in a reversible fashion with very little waste. Because of the simplicity of this approach we envisage that this strategy will be adopted more widely to hyperpolarize related tracers. We are currently seeking to improve on the purity of these states in order to test the in vivo detection of these agents.

A fast, cost-effective method to increase carbon-13 NMR sensitivity by 3 orders of magnitude is detailed for a series of pyridazine derivatives. When the resulting polarisation is stored as long-lived singlet order, the resulting hyperpolarized $^{13}$C NMR signals remain detectable for up to 10 minutes.

Illustration of a simple route to generate strong carbon-13 NMR signals that are detectable for several minutes.
