## ABSTRACT

We report the first UV laser photodissociation spectra (4.0-5.8 eV) of gas-phase deprotonated adenosine 5'-triphosphate, diphosphate and monophosphate anions. The photodepletion spectra of these anions display strong absorption bands across the region of 4.6-5.2 eV, consistent with excitation of a primarily adenine-centred  $\pi$ - $\pi^*$  transition. The spectra appear insensitive to the charge of the species (i.e. the spectrum of  $[\text{ATP-2H}]^{2-}$  closely resembles that of  $[\text{ATP-H}]^-$ ), while the spectral profile is affected to a greater extent by the variation of the molecular structure, i.e. the  $[\text{AMP-H}]^-$  and  $[\text{ADP-H}]^-$  photodepletion spectra display similar profiles while the  $[\text{ATP-H}]^-$  spectrum is distinctive. The photodepletion cross-section also decreases for the ATP anions compared to both the AMP and ADP anions, reflecting a high intrinsic photostability of ATP versus both AMP and ADP. A range of photofragments are produced across the 4.0-5.8 eV spectral range for all of the ATP analogues studied. These fragments are primarily associated with fragmentation on the ground-state electronic surface, indicative of a statistical decay process where ultrafast decay is followed by ergodic dissociation. However, while the photofragments observed following photoexcitation of the monoanionic species,  $[\text{AMP-H}]^-$  to  $[\text{ADP-H}]^-$  to  $[\text{ATP-H}]^-$  are entirely consistent with statistical decay, an additional group of photofragments are observed for the dianionic species,  $[\text{ADP-2H}]^{2-}$  and  $[\text{ATP-2H}]^{2-}$ , that we associate with electron detachment, and subsequent fragmentation of the resulting electron-detached photofragment. TDDFT calculations are presented to support the interpretation of the experimental data, and confirm that the electronic structure of the adenine moiety is relatively unperturbed by varying the overall charge.

## 1. Introduction

The ultrafast photophysical and photochemical processes that occur in DNA following UV excitation have been the subject of intense investigation, since the absorption of UV radiation can lead to biological damage, including mutations and strand breaks.<sup>1,2</sup> Such photodamage processes display low quantum yields, however, due to the operation of non-radiative decay mechanisms that enable nucleobases to dissipate the harmful electronic excitation into more benign thermal energy. Much effort has been expended into obtaining a molecular-level understanding of these processes, with a particular focus both experimentally and theoretically on adenine.<sup>3-8</sup>

Gas-phase experiments provide a useful complement to solution-phase measurements, since they can often provide more detail and allow a more straightforward comparison between experiment and theory. Instrumental developments linking electrospray ionisation with UV laser spectroscopy provided a route to extend earlier gas-phase experiments on the simple nucleobases to the more complex oligonucleotides.<sup>9-16</sup> For example, Marcum et al. have used photodissociation spectroscopy to study photodamage in isolated mononucleotides,<sup>10</sup> and Chatterley et al. have used time-resolved photoelectron imaging spectroscopy to explore the ultrafast dynamics of the nucleotide and selected oligonucleotides of adenine.<sup>11</sup> One of the key questions raised by these studies is the extent to which the native negative charge carried by a deprotonated oligonucleotide can affect the intrinsic photophysics and photochemistry of the adenine moiety.

In this work, we present the first gas-phase UV laser photodissociation spectra of a series of deprotonated anions of adenosine 5'-triphosphate (ATP), diphosphate (ADP) and monophosphate (AMP), illustrated in Scheme 1. Adenosine 5'-triphosphate plays the central role in the storage and distribution of energy in cells, and is also of key importance in signal

1  
2  
3 transduction via the production of 3',5'-cyclic adenosine monophosphate (cAMP).<sup>17</sup> Although  
4  
5 ATP is an important biological molecule, our focus in this work is on using the  
6  
7 ATP/ADP/AMP series of molecules as a facile test system to investigate the effect of  
8  
9 changing the charge state on the UV photochemistry of adenine nucleobase. The question of  
10  
11 how an adjacent negative charge influences the UV photophysics of a nucleobase is also of  
12  
13 fundamental relevance to the correct interpretation of a number of recent laser experiments  
14  
15 on molecular clusters that include nucleobases, e.g. iodide ion-nucleobase clusters and  
16  
17 platinum complex anion-nucleobase clusters.<sup>18-21</sup> Importantly, Compagnon et al. identified a  
18  
19 strong bathochromic shift in the electronic excitation of tryptophan on going to the  
20  
21 monoanionic deprotonated species.<sup>22</sup> This shift was attributed to the impact of an adjacent  
22  
23 excess negative charge on the tryptophan chromophore. The experiments performed here  
24  
25 allow us to investigate whether this is a general phenomenon or an effect specific to the  
26  
27 tryptophan system.

## 35 2. Methods

36  
37 Gas-phase UV photodepletion and photodissociation experiments were conducted in an  
38  
39 AmaZon quadrupole ion-trap mass spectrometer, which was modified for conducting laser  
40  
41 experiments as described in detail previously.<sup>20</sup> UV photons were produced by an Nd:YAG  
42  
43 (10 Hz, Surelite) pumped OPO (Horizon) laser, giving ~1 mJ across the range 215-345 nm.  
44  
45 The laser step size employed was 1 nm. Photofragmentation experiments were run with an  
46  
47 ion accumulation time of 100 ms. A fragmentation time of 100 ms was employed, so that  
48  
49 each mass-selected ion packet interacted with one laser pulse. Moreover, due to the fact that  
50  
51 the ions are continually circulating within the ion cloud, the probability of multiphoton  
52  
53 excitation of an ion is very low. This was verified by conducting laser power studies across  
54  
55 the scanned spectral range, which showed that ion photodepletion was linear with respect to  
56  
57  
58  
59  
60

1  
2  
3 laser power, consistent with single photon absorption. The photodepletion intensity (PD) of  
4  
5 the clusters and the photofragment production (PF) have been calculated using equations 1  
6  
7 and 2 and are presented as a function of the photon energy.  
8  
9

10  
11 Photodepletion Intensity =  $\frac{\text{Ln}\left(\frac{\text{Int}_{\text{OFF}}}{\text{Int}_{\text{ON}}}\right)}{\lambda \times P}$  [1]  
12  
13

14 Photofragmentation Production =  $\frac{\left(\frac{\text{Int}_{\text{Frag}}}{\text{Int}_{\text{OFF}}}\right)}{\lambda \times P}$  [2]  
15  
16

17 Where  $\text{Int}_{\text{ON}}$  and  $\text{Int}_{\text{OFF}}$  are the peak intensities with laser on and off,  $\text{Int}_{\text{Frag}}$  is the fragment  
18  
19 intensity with laser on,  $\lambda$  is the excitation wavelength (nm) and P is the laser pulse energy  
20  
21 (mJ). Equation [1] includes a natural logarithm in line with common practice for calculating  
22  
23 photodepletion (See Ref [22]), while no natural logarithm is included in Equation [2]. This  
24  
25 practice is adopted because some photofragment intensities can be low, which would lead to  
26  
27 unintuitive negative values for photofragment production if a natural logarithm was used.  
28  
29 Solution-phase UV absorption spectra (aqueous solution,  $3 \times 10^{-5}$  mol dm<sup>-3</sup>) were recorded  
30  
31 using a Shimadzu 1800 UV spectrophotometer with a 1 cm UV cuvette, using distilled water  
32  
33 as a baseline.  
34  
35  
36

37  
38 Higher-energy collisional dissociation (HCD) was performed to investigate the ground state  
39  
40 fragmentation characteristics of the  $[\text{AXP}-n\text{H}]^{n-}$  (X = M, D, T and  $n = 1, 2$ ) anions. An  
41  
42 Orbitrap Fusion Tribrid mass spectrometer (Thermo Fisher Scientific) with an ESI source  
43  
44 was employed for these experiments, run in the negative ion mode. The HCD fragmentation  
45  
46 technique as implemented on the Orbitrap mass spectrometer provides tandem mass  
47  
48 spectrometry, similar to triple quadrupole fragmentation.<sup>23</sup> The instrument was operated at a  
49  
50 flow rate of 20  $\mu\text{L}/\text{min}$  and with the following parameters: spray voltage -2453V; sweep gas  
51  
52 flow rate, 0; sheath gas flow rate, 35; aux gas flow rate, 10; ion transfer tube temperature, 325  
53  
54 °C; vaporizer temperature, 150 °C; MS<sup>1</sup> detector, Ion Trap; MS<sup>1</sup> scan range, 50–600; MS<sup>1</sup>  
55  
56 maximum injection time, 100 ms; MS<sup>1</sup> automated gain control (AGC) target, 100,000; MS<sup>2</sup>  
57  
58  
59  
60

1  
2  
3 detector, Ion trap; MS<sup>2</sup> AGC target, 100,000; MS<sup>2</sup> maximum injection time, 100, S-lens RF  
4  
5 level, 60 V (10 V for the dianions). The HCD collisional energy was varied between 0 and 45  
6  
7 %, and the intensity of the ion in percentage was calculated.  
8  
9

10 Solutions of ATP ( $1 \times 10^{-5}$  mol dm<sup>-3</sup>) in deionised water were introduced to the mass  
11  
12 spectrometer through electrospray ionisation using a nebulising gas pressure of 10.0 psi, an  
13  
14 injection rate of 250  $\mu$ L/hr, a drying gas flow rate of 8.0 L min<sup>-1</sup>, and a capillary temperature  
15  
16 of 180°C. ATP was purchased from Sigma Aldrich and used without purification. We  
17  
18 anticipate that the ATP analogues will be deprotonated on the phosphate side chains. This  
19  
20 point is discussed further in Ref. 24.  
21  
22

23  
24 Density functional theory (DFT) was used to calculate vertical detachment energies (VDEs)  
25  
26 of the [AMP-H]<sup>-</sup>, [ADP-H]<sup>-</sup>, [ATP-H]<sup>-</sup>, [ADP-2H]<sup>2-</sup> and [ATP-2H]<sup>2-</sup> anions. Calculations  
27  
28 were performed at the M06-2X/6-311++G\*\* level as implemented in Gaussian 09.<sup>25</sup> The  
29  
30 method used to obtain the optimized structures is described in detail in the Supporting  
31  
32 Information.  
33  
34

37

### 38 **3. Results and Discussion**

#### 39 *i. Photodepletion Spectra*

40  
41  
42 The photodepletion spectra of the [AMP-H]<sup>-</sup>, [ADP-H]<sup>-</sup>, [ATP-H]<sup>-</sup>, [ADP-2H]<sup>2-</sup> and [ATP-  
43  
44 2H]<sup>2-</sup> anions are displayed in Figure 1. (We label these species as [AXP-*n*H]<sup>*n-*</sup> where X = M,  
45  
46 D, T and *n* = 1,2.) These spectra can be considered as gas-phase absorption spectra, in the  
47  
48 limit where fluorescence is not a significant decay channel following electronic excitation.<sup>26</sup>  
49  
50 The spectra are all similar in that they display broad absorption features between ~4.6-5.2 eV,  
51  
52 with the photodepletion cross section remaining considerable (or increasing) towards the  
53  
54 high-energy limit of the scans. We note that the photodepletion intensity of ATP is markedly  
55  
56  
57  
58  
59  
60

1  
2  
3 smaller than the photodepletion intensities of AMP and ADP, indicating that the ATP anions  
4 are inherently more photostable than the AMP and ADP analogues. To test that the  
5 photodepletion spectra correspond to single-photon absorption spectra, laser-power  
6 dependent photodepletion measurements (0.5 to 1.5 mJ) were conducted at 4.9 eV, close to  
7 the maxima of the broad absorption maxima bands. Figure 2 displays these power-dependent  
8 measurements, which are linear across this range, confirming that photoexcitation under the  
9 experimental conditions employed here (100 ms fragmentation time, 1.0 mJ pulse energy) is  
10 a one-photon process.  
11  
12  
13  
14  
15  
16  
17  
18  
19

20  
21 Figure 3 presents the aqueous absorption spectra of solutions of ATP recorded at a range of  
22 pHs (between 1 and 12) for comparison with the gas-phase spectra. Despite the change in  
23 pH, these solution-phase absorption spectra are remarkably similar, displaying a prominent  
24 absorption between 4.6 and 5.2 eV ( $\lambda_{\text{max}} \sim 4.75$  eV), followed by a strongly increasing  
25 absorption profile towards the high-energy limit of the scan. The  $\lambda_{\text{max}} \sim 4.75$  eV absorption  
26 band has been associated with the  $\pi\text{-}\pi^*$  transition centred on the adenine moiety,<sup>6,7,27,28</sup> and  
27 this feature dominates the spectra irrespective of the fact that the various ATP solutions will  
28 contain mixtures of differentially deprotonated ATP, ADP and AMP species.<sup>29</sup>  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39

40 Returning to the gas-phase photodepletion spectra (Figure 1), we therefore assign the broad  
41 absorptions observed between  $\sim 4.6\text{-}5.2$  eV as arising from the same, predominantly adenine-  
42 centred  $\pi\text{-}\pi^*$  transition that appears with  $\lambda_{\text{max}} \sim 4.75$  eV for the solution-phase ATP species.<sup>29</sup>  
43  
44  
45  
46 It is evident that this absorption is relatively insensitive to whether the species carries a single  
47 or a double negative charge (e.g. the  $[\text{ATP-H}]^-$  spectrum closely resembles that of the  $[\text{ATP-}$   
48  $2\text{H}]^{2-}$  spectrum). Although the photodepletion spectra of all of the  $[\text{AXP-}n\text{H}]^{n-}$  anions are  
49 broadly similar, the spectra are modified by whether the adenosine species carries a mono-,  
50 di- or triphosphate tail. This is most evident for the  $[\text{ATP-}n\text{H}]^{n-}$  species which have spectra  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 that display a considerably more sharply increasing absorption profile towards high energy  
4  
5 compared to the ADP and AMP species. We note that the strong absorption towards the  
6  
7 high-energy tail we observe here mirrors the spectral profile of solution-phase ATP (Figure  
8  
9  
10 3).

11  
12 It is instructive to consider where the photodepletion spectra appear with respect to the  
13  
14 electron detachment energies of the  $[\text{AXP-}n\text{H}]^{n-}$  anions. Photoelectron spectra of the  
15  
16 dianionic species have been recorded by Schinle et al.,<sup>30</sup> but since we have no experimental  
17  
18 electron affinities for the monoanions, we calculated electron affinities for all of the species  
19  
20 studied here and use them as a complete set of values, where relative values should be  
21  
22 reliable. These calculated VDEs are included in Table 1. For the monoanions,  $[\text{AXP-H}]^-$ , the  
23  
24 VDEs all lie above the high-energy limit of the scans, indicating that the electronic transitions  
25  
26 observed in Figures 1a-1c lie well below the electron detachment continuum. The situation is  
27  
28 slightly different for the dianionic species,  $[\text{ADP-2H}]^{2-}$  and  $[\text{ATP-2H}]^{2-}$ , which we predict to  
29  
30 have vertical detachment energies of 3.10 and 4.11 eV. However, the threshold for electron  
31  
32 detachment is only reached around  $\sim 5.3$  and 6.0 eV,<sup>30</sup> respectively, when the repulsive  
33  
34 coulomb barrier (RCB) for electron detachment is exceeded.<sup>31,32</sup> Therefore, the dianion  
35  
36 photodepletion spectra also lie predominantly below the electron detachment continuum,  
37  
38 although there is likely to be some photodetachment below these energies associated with  
39  
40 electron tunnelling through the RCB.<sup>31,32</sup>  
41  
42  
43  
44  
45

46 While the overall spectral profile is similar for all of the  $[\text{AXP-}n\text{H}]^{n-}$  anions, it is evident that  
47  
48 there are differences between the spectral profiles. One prominent example of this is the way  
49  
50 that the ATP species (Figures 1c and 1e) display a much more strongly increasing  
51  
52 photodepletion cross-section to high-energy. To further explore the differences in the  
53  
54 photodepletion spectra and the decay pathways that follow photoexcitation,<sup>33</sup> we will  
55  
56  
57  
58  
59  
60

investigate the spectral profile for the photofragment production spectra that accompany the photodepletion spectra in Section 3iii.

*ii. Collision-Induced Dissociation*

Higher-energy collisional dissociation (HCD) was performed for the series of  $[\text{AXP-}n\text{H}]^{n-}$  ( $X = \text{M, D, T}$  and  $n = 1, 2$ ) anions to fully characterise their ground electronic-state fragmentation behaviour. The HCD fragmentation curves are displayed in Figure 4. Inspection of the fragmentation curves shows that a number of larger molecular fragments are produced only over a limited energy range, with fragmentation into smaller ionic species becoming dominant at higher collision energies. One example is provided by the  $[\text{ADP-H}]^-$  anion (Figure 4b) which fragments with production of  $[\text{cAMP-H}]^-$  only between 10-35% HCD, and also the corresponding dianion,  $[\text{ADP-2H}]^{2-}$  (Figure 4d) which produces the  $[\text{AMP-H}]^-$  fragment only between 0-28% HCD. Although there have been previous collision-induced dissociation (CID) measurements conducted on the  $[\text{ATP-2H}]^{2-}$  and  $[\text{ADP-2H}]^{2-}$  dianions (low-energy CID),<sup>24</sup> and the  $[\text{AMP-H}]^-$  monoanion (higher-energy CID),<sup>34</sup> this is the first time that a comparable set of CID profiles have been obtained for the  $[\text{AXP-}n\text{H}]^{n-}$  series.

In the previous CID measurements of the  $[\text{AMP-H}]^-$  anion by Ho and Kebarle,<sup>34</sup> an absolute measurement of centre of mass collision energy was obtained through absolute calibration. Comparison of the current results for  $[\text{AMP-H}]^-$  (Figure 4a) with these earlier measurements,<sup>34</sup> allows us to obtain an approximate calibration of the HCD fragmentation curves presented in Figure 4. From this comparison, it appears that the 4-6 eV energy range (i.e. the photon range employed in our laser experiments, and hence the maximum amount of energy that would be available to fragment the ground state surface anions) corresponds to the 20-38% range on the HCD fragmentation plots (Figure 4).

1  
2  
3  
4  
5  
6 *iii. Photofragmentation Mass Spectra*  
7

8  
9 Figure 5 displays the photofragment mass spectra obtained for photoexcitation of the [AXP-  
10 nH]<sup>n-</sup> anions at 4.9 eV, close to the peaks of the photodepletion spectra. (A list of the  
11 prominent photofragments observed is included in Table 2.) Photofragments associated with  
12 fission of the phosphate side chain are common, e.g. PO<sub>3</sub><sup>-</sup> and HP<sub>2</sub>O<sub>6</sub><sup>-</sup>. For [ATP-2H]<sup>2-</sup>  
13 (Figure 5e), the PO<sub>3</sub><sup>-</sup> photofragment is observed with the accompanying monoanion in  
14 photofragmentation of the dianionic species, consistent with a photoinduced ionic  
15 fragmentation process,<sup>10,23,32</sup> e.g.  
16  
17  
18  
19  
20  
21  
22  
23

25  
26  
27 Deprotonated adenine, [A-H]<sup>-</sup> is seen as a prominent photofragment for [AMP-H]<sup>-</sup>, [ADP-H]<sup>-</sup>  
28 , and [ADP-2H]<sup>2-</sup> (Figures 5a, 5b and 5d). It should be noted that although we refer to this  
29 fragment as deprotonated adenine, it could equivalently be described as A<sup>-</sup>, i.e. the anionic  
30 nucleobase formed upon rupture of the CN glycosidic bond.<sup>34</sup> The [A-H]<sup>-</sup> anion has been  
31 observed as a stable photofragment in several recent studies of clusters that include adenine.<sup>20</sup>  
32 Intriguingly, [A-H]<sup>-</sup> it is not observed as a significant intensity photofragment for either of  
33 the ATP anions (Figures 5c and 5e). Electron detachment is observed for both of the  
34 dianionic species (Figures 5d and 5e), e.g.  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44

46  
47  
48  
49 This is despite the fact that this photoexcitation energy, although greater than the adiabatic  
50 electron affinity, is still considerably below the electron detachment onsets associated with  
51 exceeding the RCB (see Section 3i).  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 As described in Section 3ii, a series of HCD experiments were conducted on the  $[\text{AXP-nH}]^{n-}$   
4  
5 anions to establish which ionic fragments are produced on the ground state surface following  
6  
7 collisional excitation. Table 2 presents a comparison of the major photofragments obtained  
8  
9 with a photoexcitation energy of 4.9 eV, along with the anionic fragments obtained with an  
10  
11 HCD centre-of-mass collision energy of 24%, i.e. a similar energy to the laser photon energy.  
12  
13 For systems where photoexcitation is followed by rapid decay back to the ground-state  
14  
15 surface and subsequent ergodic (statistical) dissociation, the photofragments are expected to  
16  
17 mirror the HCD fragments produced when an amount of energy equivalent to the photon  
18  
19 energy is deposited in the ground-state system.<sup>9,10</sup> Inspection of Table 2 reveals that the  
20  
21 major 4.9 eV photofragments largely mirror the major 24% HCD fragments, consistent with a  
22  
23 predominantly statistical decay process. For the dianionic systems, all the fragments  
24  
25 observed in the HCD experiment are seen as photofragments, along with a small number of  
26  
27 additional photofragment species e.g.  $[\text{cADP}]^-$  from  $[\text{ADP-2H}]^{2-}$ .<sup>35</sup> It appears that  
28  
29 photofragmentation represents a slightly softer fragmentation process than HCD, since larger  
30  
31 fragments such as  $[\text{cADP}]^-$  can be seen in photofragmentation but are absent in HCD,  
32  
33 presumably due to secondary fragmentation of primary CID fragments that are produced with  
34  
35 high internal energy. We note that while similar sets of photofragments and HCD fragments  
36  
37 are observed for all of the ATP analogues, the relative intensities (of a set of fragments  
38  
39 produced by a single  $[\text{AXP-nH}]^{n-}$  species in photofragments *versus* HCD) vary more on  
40  
41 going to longer phosphate chain length and to higher charge. For the dianionic systems, this  
42  
43 observation can largely be attributed to the electron-detachment decay pathway of a multiply-  
44  
45 charged anion being accessed via photoexcitation in addition to adenine-centred  $\pi$ - $\pi^*$   
46  
47 transitions.  
48  
49  
50  
51  
52  
53

54  
55 The observation that all of the  $[\text{AXP-nH}]^{n-}$  anions produce a group of photofragments that  
56  
57 mirrors the CID fragments indicates that each of the  $[\text{AXP-nH}]^{n-}$  anions follow broadly  
58  
59  
60

1  
2  
3 similar decay pathways following photoexcitation at 4.9 eV, irrespective of the charge state  
4 or the phosphate chain length. This picture is consistent with the photodepletion spectra  
5 discussed above, and with the known photophysics of adenine (i.e. ultrafast decay with  
6 subsequent ergodic dissociation),<sup>5-9</sup> and thus again indicates that the adenine moiety is largely  
7 unaffected across the [AXP-nH]<sup>n-</sup> series.  
8  
9

10  
11  
12  
13  
14 Table 3 compares the photofragment mass spectra observed following photoexcitation at 5.6  
15 eV with the ionic fragments produced upon HCD at 36% collision energy. The propensity  
16 for production of lower mass fragments (e.g. PO<sub>3</sub><sup>-</sup> and H<sub>2</sub>PO<sub>4</sub><sup>-</sup>) can be seen to increase, as  
17 both the laser excitation energy and the collision excitation energy increase. As for the 4.9  
18 eV photoexcitation data presented above, similar fragmentation patterns are observed for both  
19 laser excitation and collisional excitation, indicating that a largely ergodic dissociation  
20 process is also occurring at high-energy, along with the additional multiply-charged anion  
21 photofragment pathways.

#### 33 34 35 36 *iv. Photofragment Action Spectra*

37  
38  
39 Figure 6 displays the photofragment action spectra (4.0-5.8 eV) for production of some  
40 photofragments of the [AXP-nH]<sup>n-</sup> anions. For the [AMP-H]<sup>-</sup> anion (Figure 6a), the major  
41 photofragments PO<sub>3</sub><sup>-</sup> and H<sub>2</sub>PO<sub>4</sub><sup>-</sup> are produced smoothly through the main photodepletion  
42 band ( $\lambda_{\text{max}} \sim 5.0$  eV), and then increase strongly in intensity towards the high-energy tail of the  
43 spectrum. The [A-H]<sup>-</sup> anion displays a similar profile, although production of this  
44 photofragment peaks slightly lower in energy ( $\sim 4.85$  eV), and increases less strongly towards  
45 the high-energy limit. This difference in the band shapes for production of the [A-H]<sup>-</sup>  
46 photofragment compared to the PO<sub>3</sub><sup>-</sup> and H<sub>2</sub>PO<sub>4</sub><sup>-</sup> pair of photofragments explains the shape of  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 the overall photodepletion spectrum (Figure 1a), where a step is visible at  $\sim 4.85$  eV  
4  
5 associated with production of the  $[A-H]^-$  photofragment peaking at this excitation energy.  
6  
7

8 Figure 6b displays the photofragment action spectra for  $[ADP-H]^-$ . This set of photofragment  
9  
10 action spectra show the advantage of recording the photofragment action spectra, compared  
11  
12 to just the photodepletion spectrum (Figure 1b), since they clearly reveal that two distinct  
13  
14 fragmentation processes occur across the spectral region investigated. Production of the  
15  
16  $[cAMP-H]^-$  photofragment peaks strongly at 4.7 eV, dropping to zero above 5.6 eV, while the  
17  
18  $[A-H]^-$  photofragment peaks close to 5.25 eV, probably due to the  $[cAMP-H]^-$  fragmenting  
19  
20 into  $[A-H]^-$  with maximum cross section around this energy. The distinctive profile of the  
21  
22  $[cAMP-H]^-$  photofragment between 4.7-5.6 eV closely mirrors the production of this ion at  
23  
24 only a limited range of HCD energies (Figure 4b), and is strong evidence that this  
25  
26 photofragment is produced through a statistical decay process. The  $HP_2O_6^-$  photofragment  
27  
28 appears to be produced concurrent with both of the  $[cAMP-H]^-$  and  $[A-H]^-$  photofragments.  
29  
30  
31

32  
33  $HP_2O_6^-$  and  $[cADP]^-$  are observed as the major photofragments for the  $[ATP-H]^-$  monoanion  
34  
35 (Figure 6c). Both photofragments are produced with identical profiles across the 4.0-5.0 eV  
36  
37 region, although the  $[cADP]^-$  fragment is produced much less strongly than the  $HP_2O_6^-$   
38  
39 fragment above 5.0 eV. This behaviour again mirrors the HCD results for this anion (Figure  
40  
41 4c), with production of  $HP_2O_6^-$  increasing towards high collision energy, while the intensity  
42  
43 of the  $[cADP]^-$  fragment tails off, again probably due to the  $[cADP]^-$  fragmenting into  $HP_2O_6^-$   
44  
45  
46  
47  
48

49 Figure 6d displays the photofragment action spectra for the fragments produced from the  
50  
51  $[ADP-2H]^{2-}$  dianion. These spectra show similar profiles, although the  $PO_3^-$  fragment and the  
52  
53  $H_3P_2O_7^-$  both show an increasing production profile towards high energy. The  $H_3P_2O_7^-$  and  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 [cADP]<sup>-</sup> fragments also display a similar profile, with an onset around 4.3 eV and a  
4  
5 maximum around close to the maximum of the electron detachment fragment, [ADP-2H]<sup>-</sup>.  
6  
7

8 It is intriguing that the [ATP-2H]<sup>-</sup> electron detachment fragment is produced so strongly  
9  
10 through the 4.4-5.2 eV region (Figure 6e), since this energy is considerably below the  
11  
12 expected electron detachment threshold (Section 3i). It appears that the excited state accessed  
13  
14 in this region is able to couple efficiently to an electron detachment coordinate that  
15  
16 circumvents the repulsive coulomb barrier. This phenomenon is not unique to the [ATP-  
17  
18 2H]<sup>2-</sup> dianion, since in a recent photoelectron spectroscopy study of Pt(CN)<sub>4</sub><sup>2-</sup>-nucleobase  
19  
20 clusters, delayed electron detachment signals were observed when the adenine cluster was  
21  
22 irradiated at 266 nm (4.66 eV). This appeared to be due to excitation of long-lived adenine-  
23  
24 centred excited states that can effectively couple to the electron detachment continuum.<sup>36</sup>  
25  
26  
27

28 To summarize, the [AXP-nH]<sup>n-</sup> anions produce a range of different photofragments across the  
29  
30 4.0-5.8 eV range. In general, production of the smaller fragment ions, e.g. H<sub>2</sub>PO<sub>4</sub><sup>-</sup>, PO<sub>3</sub><sup>-</sup> and  
31  
32 HP<sub>2</sub>O<sub>6</sub><sup>-</sup>, increases towards the high-energy region of the spectrum, and the overall patterns for  
33  
34 production of photofragments as a function of excitation energy mirrors those observed using  
35  
36 high-energy collisional excitation. The energy redistribution process involved in ergodic  
37  
38 dissociation following fast internal conversion back to the ground state may not exactly  
39  
40 match the energy transfer (and subsequent energy redistribution) that occurs upon higher-  
41  
42 energy collision induced dissociation. However, the close relationship between  
43  
44 photofragments and collisional fragments observed here, strongly indicates that the [AXP-  
45  
46 nH]<sup>n-</sup> anions do undergo rapid conversion back to the electronic ground state following  
47  
48 photoexcitation, as would be expected for a system with a largely adenine-centred  
49  
50 chromophore, as would be expected for a system with a largely adenine-centred  
51  
52 chromophore.

2  
3 *v. Time-dependent density functional theory calculations*  
4

5  
6 To gain further insight into the nature of the electronic excitations involved in  
7 photoexcitation of the [AXP-nH]<sup>n-</sup> anions across the 4-6 eV range, time-dependent density  
8 functional theory (TDDFT) calculations were performed. Full details of these calculations,  
9 along with the full results are presented in Section S3 of the supporting information. The  
10 TDDFT calculations were able to accurately predict the general form of the photodepletion  
11 spectra, with each anion displaying a broad absorption between 4.4-5.6 eV, followed by an  
12 increasing absorption profile to high photon energy. In general, the main electronic  
13 transitions originated from orbitals with electron density on both the adenine and the  
14 phosphate group(s), indicating extensive orbital mixing across the molecular framework. The  
15 dominant transition in the region of the maximum (~5.0 eV) of the 4.4-5.6 eV absorption  
16 band was found to be associated with the expected  $\pi$ - $\pi^*$  transition on adenine.  $n$ - $\pi^*$  and  $\sigma$ -  
17 based transitions are also common, particularly in the high-energy excitation regions.

32

33 Comparing the calculated spectra and the component electronic excitations for pairs of anions  
34 with the same molecular framework but different excess negative charges (e.g. [ATP-2H]<sup>-</sup>  
35 versus [ATP-2H]<sup>2-</sup>), indicates that there is little change in the excitation energies or extinction  
36 coefficients of the main electronic excitations with variation in excess charge. For the  
37 adenine-centred chromophoric molecules studied here, we therefore conclude that there is no  
38 substantial bathochromic shift associated with negative charges existing in close proximity to  
39 the nucleobase.<sup>22</sup>

1  
2  
3 Nielsen *et al.* studied the photodestruction of [AMP-H]<sup>-</sup> at 266 nm (4.66 eV),<sup>9</sup> and found that  
4  
5 the excited state lifetime was 16 μs, with the major part of photofragmentation occurring by  
6  
7 an ergodic process. The photofragment identities associated with excited state decay could  
8  
9 not be identified in that experiment due to instrumental limitations. However, the set of  
10  
11 photofragments of [AMP-H]<sup>-</sup> observed in the current study (i.e. PO<sub>3</sub><sup>-</sup>, H<sub>2</sub>PO<sub>4</sub><sup>-</sup> and [A-H]<sup>-</sup>)  
12  
13 with 4.9 eV excitation are entirely consistent with photofragmentation occurring *via* an  
14  
15 ergodic process since the photofragments are identical to the major HCD fragments observed  
16  
17 with a similar collisional excitation energy.  
18  
19

20  
21 The ultrafast dynamics of adenine following 4.66 eV photoexcitation was also investigated  
22  
23 by Verlet and co-workers via time-resolved photoelectron imaging of the deprotonated 3'-  
24  
25 deoxy-adenosine-5'-monophosphate nucleotide, and its di- and trinucleotides.<sup>11,12</sup> These  
26  
27 experiments revealed that the dynamics of the base are relatively insensitive to the  
28  
29 surrounding environment, and led to the conclusion that the decay mechanism primarily  
30  
31 involves internal conversion from the initially populated <sup>1</sup>π-π\* states to the ground states.  
32  
33 These results again mirror the results found in this study, across the 4.4-5.2 eV absorption  
34  
35 band. In another related work, Weber and co-workers studied the photodissociation  
36  
37 spectroscopy of a series of deprotonated nucleotides, including deprotonated 2'-deoxy-  
38  
39 adenosine-5'-monophosphate.<sup>10</sup> Their results are again largely consistent a photodecay  
40  
41 mechanism that involves rapid electronic relaxation followed by unimolecular fragmentation  
42  
43 on the vibrationally hot ground-state surface.  
44  
45  
46  
47  
48

49 The results presented herein complement these earlier results, since they demonstrate how the  
50  
51 ATP anions appear to share much of the photophysical properties that were observed  
52  
53 previously. Photoexcitation across the 4-5.8 eV region appears to largely follow the expected  
54  
55 adenine-centred excitation followed by rapid relaxation via a conical intersection and  
56  
57 subsequent ground-state statistical decay. The TDDFT calculations provide a picture of  
58  
59  
60

1  
2  
3 electronic excitations that contain significant adenine-centred  $\pi$ - $\pi^*$  character, but are  
4  
5 delocalized across the entire molecular framework, possibly facilitating statistical decay.  
6  
7 One interesting point of note in comparing the ATP experiments conducted with the deoxy-  
8  
9 nucleotides studied by Verlet and Weber is that the presence of two OH groups on the ribose  
10  
11 in the ATP analogues, means that the anions are able to maintain a hydrogen-bond network  
12  
13 across the molecular ion (see Section S1 of the supporting information for calculated  
14  
15 geometric structures). Such molecular structures have recently been identified to facilitate  
16  
17 ultrafast decay mechanisms,<sup>7</sup> and appear likely to be a key factor in the overall photostability  
18  
19 of ATP.  
20  
21

22  
23  
24 It is interesting to consider the results of the current work in the context of the  
25  
26 photodetachment study of the tryptophan anion conducted by Compagnon and co-workers.<sup>22</sup>  
27  
28 They found via experiment and TDDFT calculations that the tryptophan chromophore was  
29  
30 sensitive to the presence of the excess negative charge in the anion, resulting in substantial  
31  
32 bathochromism of the main electronic excitations of up to 25 nm. No such dramatic shift is  
33  
34 observed here on going from the monanionic to dianionic species, either experimentally or in  
35  
36 the TDDFT calculations. It seems possible that this differing behaviour can be traced to the  
37  
38 very different geometric arrangements of the chromophores and excess charges in the  
39  
40 tryptophan anion compared to the  $[\text{AXP-nH}]^{n-}$  anions. Alternatively, it may be that the  
41  
42 electronic excitations of the adenine chromophore studied here are particularly insensitive to  
43  
44 environmental changes,<sup>11,12</sup> including excess charge. Nonetheless, the considerable  
45  
46 differences in bathochromism between deprotonated tryptophan and ATP are notable. Further  
47  
48 investigation of a broader range of molecular anions where excess charge is located at a  
49  
50 distance from a chromophore are desirable to clarify the generality of excess-charge induced  
51  
52 electronic transition shifts.  
53  
54  
55  
56  
57  
58  
59  
60

## 5. CONCLUDING REMARKS

The photofragmentation measurements conducted on the [AXP-nH]<sup>n-</sup> series of anions indicate that the decay dynamics are consistent with photoexcitation of a largely adenine centred chromophore that undergoes ultrafast decay following photoexcitation. Both the photodepletion spectra and photofragmentation patterns indicate that the adenine moiety within the ATP anions appears to be unaffected by the charge state of the molecular system. This is an important result for clarifying the interpretation of recent experiments that have been conducted on anion-nucleobase clusters such as I<sup>-</sup>·uracil and Pt(CN)<sub>4</sub><sup>2-</sup>·adenine.<sup>18,36</sup> In further work, it would be interesting to directly monitor the inferred decay dynamics by probing the production of the various photofragments via ultrafast spectroscopy. Time-resolved photodetachment photoelectron spectroscopy provides a facile approach to such measurements,<sup>37</sup> and could be readily applied to the system studied here.

## TABLES

**Table 1: M06-2X/6-311++G\*\* calculated vertical detachment energies (VDEs) and electron detachment onset energies of the [AXP-  $n$ H]<sup>*n*-</sup> ( $n = 1,2$ ) anions.<sup>c</sup>**

| Ion                    | Calculated VDEs (eV) <sup>a</sup> | Electron Detachment Onset Energies (eV) <sup>b</sup> |
|------------------------|-----------------------------------|--|
| [AMP-H] <sup>-</sup>   | 6.04                              |  |
| [ADP-H] <sup>-</sup>   | 6.17                              |  |
| [ATP-H] <sup>-</sup>   | 6.24                              |  |
| [ADP-2H] <sup>2-</sup> | 3.10                              | 5.3  |
| [ATP-2H] <sup>2-</sup> | 4.11                              | 6.0  |

<sup>a</sup> Not zero point energy corrected.

<sup>b</sup> Calculated VDEs combined with the experimental RCB from Ref 24.

<sup>c</sup> See Section S1 of SI for details.

**Table 2: Photofragments observed following photoexcitation at 4.9 eV and higher-energy collisional dissociation (HCD) fragments obtained at 24% collisional energy for the [AXP-*n*H]<sup>*n*-</sup> (*n* = 1,2) anions.<sup>a</sup>**

| Parent ion             | Photofragments (4.9 eV)  | HCD fragments (24%)   |
|------------------------|--|---|
| [AMP-H] <sup>-</sup>   | PO <sub>3</sub> <sup>-</sup> ≈ H <sub>2</sub> PO <sub>4</sub> <sup>-</sup> , [A-H] <sup>-</sup> , [AMP-H-A] <sup>-</sup>   | PO <sub>3</sub> <sup>-</sup> , H <sub>2</sub> PO <sub>4</sub> <sup>-</sup> , [AMP-H-A] <sup>-</sup> , [A-H] <sup>-</sup>  |

<sup>a</sup> Photofragments and HCD fragments are listed in order of decreasing intensity.

## SCHEMES AND FIGURES

**Scheme 1** Chemical structures of the neutral forms of AMP, ADP and ATP.

**Figure 1** a) Photodepletion (absorption) spectra of a) [AMP-H]<sup>-</sup>, b) [ADP-H]<sup>-</sup>, c) [ATP-H]<sup>-</sup>, d) [ADP-2H]<sup>2-</sup>, and e) [ATP-2H]<sup>2-</sup> across the range 4.07 – 5.77 eV. The solid lines are five-point adjacent averages of the data points.

**Figure 2** Laser power measurements for photodepletion of the a) [AMP-H]<sup>-</sup>, b) [ADP-H]<sup>-</sup>, c) [ATP-H]<sup>-</sup>, d) [ADP-2H]<sup>2-</sup>, and e) [ATP-2H]<sup>2-</sup> anions, recorded at 4.9 eV.

**Figure 3** Aqueous absorption spectra of ATP ( $3 \times 10^{-5}$  mol dm<sup>-3</sup>) recorded at pH = 1, 2, 7 and 12.

**Figure 4** Fragment production curves for a) [AMP-H]<sup>-</sup>, b) [ADP-H]<sup>-</sup>, c) [ATP-H]<sup>-</sup>, d) [ADP-2H]<sup>2-</sup> and e) [ATP-2H]<sup>2-</sup> upon HCD between 0 and 45 % energy.

**Figure 5** Photofragment mass spectra of a) [AMP-H]<sup>-</sup>, b) [ADP-H]<sup>-</sup>, c) [ATP-H]<sup>-</sup>, d) [ADP-2H]<sup>2-</sup>, and e) [ATP-2H]<sup>2-</sup> excited at 4.9 eV. \* indicates the depleted parent ion signal.

**Figure 6** Photofragment action spectra of the major photofragments produced following photoexcitation of mass-selected a) [AMP-H]<sup>-</sup>, b) [ADP-H]<sup>-</sup>, c) [ATP-H]<sup>-</sup>, d) [ADP-2H]<sup>2-</sup>, and e) [ATP-2H]<sup>2-</sup>, across the range 4.07 – 5.77 eV. The solid lines are five-point adjacent averages of the data points.
