Summary (149 words of referenced text):
The climate impact of aerosols is highly uncertain owing primarily to their poorly quantified influence on cloud properties. During 2014-15, a fissure eruption in Holuhraun (Iceland) emitted huge quantities of sulphur dioxide, resulting in significant reductions in liquid cloud droplet size. Using satellite observations and detailed modelling, we estimate a global mean radiative forcing from the resulting aerosol-induced cloud brightening for the time of the eruption of around \(-0.2\) W.m\(^{-2}\). Changes in cloud amount or liquid water path are undetectable, indicating that these aerosol-cloud indirect effects are modest. It supports the
idea that cloud systems are well buffered against aerosol changes as only impacts on cloud
effective radius appear relevant from a climate perspective, thus providing a strong constraint
on aerosol-cloud interactions. This result will reduce uncertainties in future climate
projections as we are able to reject the results from climate models with an excessive liquid
water path response.

Main Text: (3103 words of referenced text, including concluding paragraph)

1. The 2014-15 eruption at Holuhraun (486 words of referenced text):

Anthropogenic emissions that affect climate are not just confined to greenhouse gases.
Sulphur dioxide and other pollutants form atmospheric aerosols that can scatter and absorb
sunlight and can influence the properties of clouds, modulating the Earth-atmosphere energy
balance. Aerosols act as cloud condensation nuclei (CCN); an increase in CCN translates into
a higher number of smaller, more reflective cloud droplets that scatter more sunlight back to
space (the ‘first’ indirect effect of aerosols). Smaller cloud droplets decrease the efficiency
of collision-coalescence processes that are pivotal in rain initiation, thus aerosol-influenced
clouds may retain more liquid water and extend coverage/lifetime (the ‘second’ or ‘cloud
lifetime’ indirect effect). Aerosols usually co-vary with key environmental variables making
it difficult to disentangle aerosol-cloud impacts from meteorological variability.

Additionally, clouds themselves are complex transient systems subject to dynamical
feedbacks (e.g. cloud top entrainment/evaporation, invigoration of convection) which
influence cloud response. These aspects present great challenges in evaluating and
constraining aerosol-cloud interactions (ACI) in General Circulation Models (GCM), with particular contentious debate surrounding the relative importance of these feedback
mechanisms.

Nonetheless, anthropogenic aerosol emissions are thought to cool the Earth via indirect
effects, but the uncertainty ranges from -1.2 to -0.0 W.m⁻² (90% confidence interval) due to
i) a lack of characterization of the pre-industrial aerosol state, and ii) model parametric
and structural errors in representing cloud responses to aerosol changes\textsuperscript{16,18,20,21}. It is estimated that uncertainty in the pre-industrial state can account for approximately 30% of total ACI uncertainty\textsuperscript{18,21} while representation of chemistry-aerosol-cloud processes in models is responsible for the remaining 70% uncertainty\textsuperscript{16,21}. Recently, a framework to break down uncertainties in the causal chain from emission to radiative forcing showed that the sources of uncertainty within different GCMs differ greatly\textsuperscript{16}.

Volcanic eruptions provide invaluable natural experiments to investigate the role of large-scale aerosol injection in the Earth system\textsuperscript{22-26}. There have been several Icelandic volcanic eruptions over recent years; Eyjafjallajökull erupted in 2010, Grímsvötn in 2011 and Holuhraun in 2014-15. At its peak, the 2014-15 eruption at Holuhraun emitted ~120 kt of sulphur dioxide (SO$_2$) per day into the atmosphere, a rate some four times higher than all 28 European Union member states or over a third of global emission rates. Iceland became in effect a continental-scale pollution source of SO$_2$; SO$_2$ is readily oxidised via gas- and aqueous-phase reactions, producing a massive aerosol plume in a near-pristine environment where clouds should be most susceptible to aerosol concentrations\textsuperscript{16,18,27}.

We advance upon preliminary observational assessments of the impact of the 2014-15 eruption at Holuhraun\textsuperscript{28,29} through an extensive observational analysis that includes a statistical evaluation of the significance of the observed spatial distribution of the cloud perturbations to untangle the impacts of aerosol/meteorological impacts. We then assess the simulation from a range of different climate models and assess the performance against available observations. Finally, we show that observations of a volcanic plume (Mt. Kilauea, Hawaii) in an entirely different meteorological regime exhibit similar overall impacts.

### 2. Impact of the eruption on clouds (2140 - 20 = 2120 words of referenced text):

Following the lifecycle of sulphur from emission, our initial analysis concentrates on the coherence of SO$_2$ detected by the Infrared Atmospheric Sounding Interferometer (IASI) sensor (Supplementary M1) and the HadGEM3 GCM that is constrained by observed
temperatures and winds (i.e. nudged, Supplementary M2). IASI retrievals use the discrete spectral absorption structure of SO$_2$ to determine concentrations$^{30}$. Comparisons of IASI SO$_2$ observations from explosive volcanic eruptions against model simulations have proven valuable in the past$^{31,32}$. The processing procedure for quantitative comparison between IASI and HadGEM3 data uses only data that are spatially and temporally coherent (Supplementary M3).

There is considerable uncertainty in the quantitative emission of SO$_2$ from the 2014-15 eruption at Holuhraun. A previous study$^{28}$ assumed a constant emission rate of 40 kt[SO$_2$]/day based on initial estimates of degassing. As our standard scenario (STAN) we use an empirical relationship between degassed sulphur and TiO$_2$/FeO ratios and lava production derived from Icelandic basaltic flood lava eruptions$^{33}$ which suggests significantly higher emissions during the early phase of the eruption in September, but we also investigate a simulation where a constant 40 ktSO$_2$/day is released (40KT scenario). The model simulations and IASI retrievals of column SO$_2$ are shown in Figure 1 (40KT emission scenario shown in Supplementary S1).

***Insert Figure 1 here***

The distribution and the magnitude of the column loading of SO$_2$ detected by IASI are similar to those derived from HadGEM3, showing that the GCM nudging scheme and the assumed altitude of the emissions in the STAN scenario (surface to 3 km) reproduces the week to week spatial variability and magnitude of observed column SO$_2$ (SI-SO2_animation.mp4).

While the spatial distribution of sulphate aerosol optical depth ($AOD$) caused by the eruption can be determined easily in the model (Supplementary Fig. S2.1), detection of the aerosol plume over the north Atlantic in the MODIS data is hampered by the mutual exclusivity of aerosol and cloud retrievals. The predominance of cloudy scenes makes accurate detection of the aerosol plume in monthly-mean MODIS data extremely challenging (Supplementary S2).
Nonetheless, despite lacking observations of AOD, we can look for evidence of perturbations caused by aerosols on cloud properties. We examine the perturbation to retrieved cloud top droplet effective radius ($r_{eff}$) in September and October 2014 using collection 051 monthly mean data from MODIS AQUA (MYD08, Supplementary M4) over the period 2002-2014. MODIS AQUA data are not subject to the degradation in performance of the sensors at visible wavelengths that has recently been documented for the MODIS TERRA\textsuperscript{34} sensor (Supplementary S3). We present a summary of the change in $r_{eff}$, $\Delta r_{eff}$, for October 2014 compared to the long term 2002-2013 mean in Figure 2a. A full analysis of the year-to-year variability in $\Delta r_{eff}$ is presented in Supplementary S4.

***Insert Figure 2 here***

There is clear evidence of a signal in $\Delta r_{eff}$ in October (Figures 2a) and September (Supplementary Fig. S5.1a). Pixels that are statistically significantly different from the 2002-2013 climatological mean at 95% confidence occur over the entire breadth of the north Atlantic. The spatial distribution of $\Delta r_{eff}$ is governed by the prevailing wind conditions that advect the volcanic plume and are quantitatively similar to those noted in Collection 006 MODIS data\textsuperscript{29}.

Figures 3a show the corresponding $\Delta r_{eff}$ derived from the model in October (for September, Supplementary Fig. S5.2a). The observations and modelling show obvious similarities in spatial distribution. In addition to the spatial coherence in $\Delta r_{eff}$, the changes in the model of -1.21 µm (September) and -0.68 µm (October) are within 30% of MODIS $\Delta r_{eff}$ of -0.98 µm (September) and -0.97 µm (October) for the domain shown in Figure 2.

***Insert Fig 3 here***
There are similarities between the MODIS and HadGEM3 probability distribution functions (Figures 2b and 3b) with a shift to smaller $r_{\text{eff}}$ for the year of the eruption. Almost all high values of $r_{\text{eff}}$ (i.e. $r_{\text{eff}} > \sim 16$ µm for MODIS and $r_{\text{eff}} > \sim 11$ µm for HadGEM3) are absent in 2014 suggesting that clouds with high $r_{\text{eff}}$ are entirely absent from the domain in both the observations and the model. There are obvious discrepancies in the absolute magnitude of $r_{\text{eff}}$ between MODIS and HadGEM3. MODIS retrievals of $r_{\text{eff}}$ from the MYD06 product in liquid water cloud regimes have been shown to be significantly larger than those derived from other satellite sensor products, mainly due to the algorithm’s use of a different primary spectral channel relative to other products\textsuperscript{35,36}. Nevertheless, $\Delta r_{\text{eff}}$ is in encouraging agreement as this quantity, along with changes in cloud liquid water path ($LWP$), needs to be accurately represented if aerosol-cloud interactions are to be better quantified. As with $r_{\text{eff}}$, there are similarities between the MODIS and HadGEM3 for $\Delta LWP$ (Figure 2c-d and Figure 3c-d), however, evidence of a clear signal due to the volcano is neither observed or modelled. Additionally, we also found that perturbations in the monthly mean cloud fraction from MODIS are negligible, both in September and October as previously reported\textsuperscript{29}. It is incumbent on any study attributing $\Delta r_{\text{eff}}$ to volcanic emissions to prove the causality beyond reasonable doubt, i.e. that the changes are not due to natural meteorological variability. The meteorological analyses in Supplementary S6 suggest that, while in September 2014 the southern part of the spatial domain shown in Figure 2 is somewhat influenced by anomalous easterlies bringing pollution from the European continent over the easternmost Atlantic Ocean and hence influencing $r_{\text{eff}}$, the perturbations to $r_{\text{eff}}$ during October 2014 are entirely of volcanic origin. MODIS and HadGEM3 show a similar spatial distribution and magnitude for October for the perturbation in cloud droplet number concentration ($\Delta N_d$), but a smaller $\Delta N_d$ in MODIS than in HadGEM3 for September 2014 (Supplementary S7.2). Once $r_{\text{eff}}$ is reduced, the autoconversion process whereby cloud droplets grow to sufficient size to form precipitation
may be inhibited, leading to clouds with increased liquid water path. The cloud optical depth, $\tau_{\text{cloud}}$, is related to $r_{\text{eff}}$ and $LWP$ and the density of water ($\rho$) by the approximation:

$$\tau_{\text{cloud}} \cong \frac{3LWP}{2\rho r_{\text{eff}}}$$  \hspace{1cm} (1)

We use HadGEM3 to assess the detectability of perturbations against natural variability. Two different methods are pursued using the nudged model; firstly, assessing model simulations with and without the emissions from the eruption for the year 2014 (HOL-NO_HOL-2014), and secondly assessing model simulations including emissions from Holuhraun for 2014 against simulations for 2002-2013 (HOL-NO_HOL-2002-2013). While the former method allows the ‘cleanest’ assessment of the impacts of the eruption (as the meteorology is effectively identical and meteorological variability is removed), the second method allows assessment of the statistical significance against the natural meteorological variability. This provides an assessment that is directly comparable to observations and can be used to effectively isolate signal from noise (Supplementary S7).

***Insert Figure 4 here***

Figure 4 shows that $\Delta AOD$, $\Delta N_d$, and $\Delta r_{\text{eff}}$ are statistically significant at 95% confidence across the majority of latitudes. The fact that the simulations from [HOL-NO_HOL-2014] and [HOL-NO_HOL-2002-2013] are similar for these variables again indicates that the impacts of natural meteorological variability on these variables is small (i.e. NO_HOL-2014 $\approx$ NO_HOL-2002-2013). For $\Delta LWP$, no statistically significant changes are evident at either 95% or 67% confidence, suggesting that meteorological variability provides a far stronger control on cloud $LWP$ than aerosol (Supplementary S7.3). With $\Delta LWP$ being due to meteorological noise, $\Delta \tau_{\text{cloud}}$ is driven by $\Delta r_{\text{eff}}$ and Figure 4e suggests that the perturbations to $\tau_{\text{cloud}}$ north of around 67°N/57°N, which are significant at the 95%/67% confidence level, are due to the 2014-15 Holuhraun eruption. Our simulations suggest that Top of Atmosphere changes in
short wave radiation ($\Delta T_{\text{OASW}}$) are unlikely to be detectable at 95% or even 67% confidence when compared to natural variability. More details supporting this assertion are given in Supplementary S7.5 which uses satellite observations of the Earth’s radiation budget.

We have shown that HadGEM3 is capable of representing observations of aerosol-cloud interactions with a reasonable representation of the perturbation to $r_{\text{eff}}$ but minimal perturbation to $LWP$. To demonstrate the practical value of the study, we repeat the simulations with other models. First, we use HadGEM3 but using the older single moment CLASSIC aerosol scheme instead of the new two-moment UKCA/GLOMAP-mode scheme. We also perform calculations with the NCAR Community Atmosphere Model (CAM5-NCAR) and the atmospheric component of an intermediate version of the Norwegian Earth System Model (CAM5-Oslo), driven using nominally the same emissions and plume top height. CAM5-NCAR has been used previously in free-running mode to provide an initial estimate of the radiative forcing of the 2014-15 Holuhraun eruption, but as in the HadGEM3 simulations we run CAM5-NCAR and CAM5-Oslo in nudged mode to simulate the meteorology during the eruption as closely as possible. Figure 5 shows a comparison of $\Delta r_{\text{eff}}$ and $\Delta LWP$ derived from HOL$_{2014}$-NO$_{2014}$ simulations from HadGEM3, HadGEM3-CLASSIC, CAM5-NCAR, CAM5-Oslo and MODIS for October. We chose October as the contribution from continental Europe pollution to cloud property anomalies has been shown to be small (Supplementary S4-6-7; Supplementary S8 shows the impacts on cloud properties in September).

***Insert Figure 5 here***

It is immediately apparent from the first column of Figure 5 that HadGEM3 using UKCA, CAM5-NCAR, and CAM5-Oslo are able to accurately model the impact on $\Delta r_{\text{eff}}$, while HadGEM3-CLASSIC produces an impact that is too strong when compared to the MODIS observations owing to the single moment nature of the aerosol scheme (Supplementary S9).
For $\Delta LWP$, as we have seen from the multi-year analysis of MODIS (Supplementary Fig. S7.3), the meteorological variability is the controlling factor. Even with meteorological variability suppressed in these [HOL 2014 - NO HOL 2014] results, HadGEM3 using UKCA shows only a very limited increase in $LWP$ (Fig. 5f), HadGEM3-CLASSIC and CAM5-Oslo show a progressively more significant response whereas CAM5-NCAR shows a much larger response (Fig. 5h).

It is insightful to examine the influence of the eruption on precipitation in both observations and models using a similar analysis (Supplementary S10). We observe that there is little impact on precipitation indicating that the cloud system readjusts to a new equilibrium with little impact on either $LWP$ or precipitation. The larger response in CAM5-NCAR ($\Delta LWP > 16 \text{ g.m}^{-2}$) is not supported by the MODIS observations where the 2002-2013 domain mean standard deviation in $\Delta LWP$ is ~4.5 g.m$^{-2}$. Thus, we are able to use the eruption to evaluate the models: HadGEM3 using UKCA and CAM5-Oslo perform in a manner consistent with the MODIS observations while HadGEM3-CLASSIC and CAM5-NCAR do not. Moreover, the fact that changes in $LWP$ are not detectable above natural variability suggests that aerosol-cloud interactions beyond the impact on $r_{eff}$ are small (i.e. net second indirect effects are small).

The effective radiative forcing (ERF) from the event may be estimated from the difference between the top of atmosphere net irradiances from simulations including and excluding the volcanic emissions. The global ERF from HadGEM3 over the September-October 2014 period is estimated at -0.21 W.m$^{-2}$. Tests using an offline version of the radiation code reveal that the presence of overlying ice-cloud weakens the ERF by approximately 20% (Supplementary S11).

We also investigate whether a fissure eruption of this magnitude could have a more significant radiative impact if the timing/location of the eruptions were different (Supplementary S12). Our simulations suggest that for contrasting scenarios the global ERF would i) strengthen to -0.29 W.m$^{-2}$ (+40%) if the eruption commenced at the beginning of
June, ii) strengthen to -0.49 W.m\(^{-2}\) (+140%) if the fissure eruption had occurred in an area of South America where it could affect clouds in a stratocumulus-dominated regime, iii) strengthen to -0.32 W.m\(^{-2}\) (+55%) if the eruption had occurred in pre-industrial times when the background concentrations of aerosols was reduced\(^\text{18}\) indicating that climatic impact of fissure eruptions such as Laki\(^\text{41}\) in 1783-1784 would not have been as large if it had occurred in the present day.

Many studies\(^\text{9,11,42,43}\) suggest that cloud adjustments may be dependent upon meteorological regime, so we ask whether the cloud LWP invariance observed near Holuhraun is simply a special case. We have reproduced the cloud regimes analysis derived from satellite measurements presented in a recent study\(^\text{44}\). We find that, when examining the 2014-15 eruption at Holuhraun, we are far from examining a meteorological ‘special case’, in fact rather the opposite (Supplementary S13); we are examining a region that contains the whole spectrum of liquid-dominated cloud regimes and deducing that, overall, the impact on LWP is minimal.

To further support our conclusion, we report results from a different event (Mount Kilauea, Hawaii, Supplementary S14), which degassing rate significantly increased during June-August 2008. The outflow of the plume affected the surrounding trade maritime cumuli\(^\text{24,45,46}\), increasing the SW reflectance; the causal interpretations of this in the literature have varied\(^\text{24,46}\) affecting the surrounding trade maritime cumuli\(^\text{24,45,46}\) and increased the SW reflectance in the outflow of the plume, although with different causal interpretations\(^\text{24,46}\). Again, LWP does not vary, either in the AMSR-E data\(^\text{46}\) or in the MODIS monthly retrievals (Supplementary S14) which again suggests LWP insensitivity in the trade cumulus regime as well. Thus, for a very different meteorological environment dominated by very different cloud regimes, similar conclusions emerge.

4. Discussion and Conclusion (507 words of referenced text):
The 2014-15 eruption at Holuhraun presents a unique opportunity to investigate continental-scale aerosol-cloud climatic effects. Using synergistic observations and models driven by an empirical estimate of SO$_2$ emissions$^{33}$ we simulate spatial distributions of SO$_2$ that compare favourably with satellite observations. The HadGEM3 model is able to predict an impact from aerosol-cloud interactions of similar magnitude to the signal found in the MODIS data. Our analysis further highlights that cloud properties are largely unaffected by the eruption beyond the impact on $r_{\text{eff}}$.

We repeated the experiment with two additional GCMs and show that HadGEM3 using UKCA, CAM5-NCAR and CAM5-Oslo are able to capture the magnitude of the observed impacts on $r_{\text{eff}}$ despite the lack of explicit representation of processes such as sub-cloud updraft velocities and entrainment, enhancing our confidence in GCMs’ ability in predicting the aerosol first indirect effect. However, in line with recent work$^{16}$, modelled responses in the LWP differ significantly. The fact that cloud adjustments via LWP are not identified in the observations of the 2014-15 eruption at Holuhraun indicates that clouds are buffered against LWP changes$^{9-10,12}$, providing evidence that models with a low LWP response display a more convincing behaviour. These findings have wide scientific relevance in the field of climate modelling as, in terms of climate forcing, they suggest that aerosol second indirect effects appear small and climate models with a significant LWP feedback need reassessment$^{15-16,47}$.

Despite such massive emissions and large anomalies in $r_{\text{eff}}$, we estimate a moderate global-mean radiative forcing of -$0.21 \pm 0.08$ W.m$^{-2}$ (1 standard deviation, Supplementary S15) for September-October which equates to a global annual mean effective radiative forcing of -$0.035 \pm 0.013$ W.m$^{-2}$ (1 standard deviation) assuming that a forcing only occurs in September and October 2014. Global emissions of anthropogenic SO$_2$ currently total around 100 TgSO$_2$/year and the Intergovernmental Panel on Climate Change$^{17,47}$ suggests a best estimate for the aerosol forcing of -$0.9$ W.m$^{-2}$, yielding a forcing efficiency of -$0.009$ W.m$^{-2}$/TgSO$_2$. The emissions for September and October 2014 total approximately 4 TgSO$_2$, thus the global annual mean radiative forcing efficiency for the 2014-15 eruption at
Holuhraun yields a forcing efficiency of \(-0.0088 \pm 0.0024 \text{ W.m}^{-2}/\text{TgSO}_2\) (1 standard deviation). The similarity is remarkable, but may be by chance given the modelled sensitivity to emission location and time (Supplementary S12).

Our study is not without caveats given that the observations themselves are uncertain owing to the limitations of satellite retrievals. The modelling is not completely constrained owing to the lack of detailed in-situ observations of e.g. the background aerosol concentrations and plume height. We cannot rule out that models showing small LWP sensitivity to aerosol emission behave as they do because they lack the resolution to represent fine-scale dynamical feedbacks\(^9,^{12}\). Further high-resolution modelling of the 2014-15 Holuhraun eruption is necessary to evaluate more thoroughly how processes such as autoconversion or droplet evaporation plays a role in buffering the aerosol effect\(^9,^{12},^{48},^{49}\). Bringing many of the different global models together and inter-comparing results of Holuhraun simulations is merited to provide a traceable route for reducing the uncertainty in future climate projections.

The probability distributions of absolute cloud droplet effective radius (b) and liquid water path (d) for 2014 including (blue) or excluding (gold) the Holuhraun emissions, and the 2002-2013 mean (green). Changes correspond to the deviation from the 2002-2013 mean. Stippling in a) and c) represent areas of 95% confidence level significant perturbation based on a
two-tailed Student’s t-test. Grey shading in the zonal means represent the standard deviation over 2002-2013.

**Figure 4.** Modelled perturbations from HadGEM3 using UKCA during the Sept-Oct 2014 period. Showing perturbations for a) AOD, b) N_d, c) \( \tau_{\text{eff}} \), d) LWP, e) \( \tau_{\text{cloud}} \) and f) Top of Atmosphere (ToA) net SW radiation. Zonal means are shown for the 44°N-80°N, 60°W-30°E analysis region. The shaded regions represent the natural variability in the simulations from 2002-2013. Values outside of the light grey (respectively dark grey, bottom row) shaded regions represent significant perturbations at the 95% (respectively 67%) confidence level based on a two-tailed Student’s t-test. Red lines represent HOL_2014 minus NO_HOL_2014 and blue lines represent HOL_2014 minus NO_HOL_2002-2013.

**Figure 5.** Multi-model estimates of the changes in cloud properties for October 2014. Left column shows \( \Delta \tau_{\text{eff}} \) (\( \mu \text{m} \)) and right column \( \Delta \text{LWP} \) (g m\(^{-2} \)) determined from HadGEM3 using the 2-moment UKCA/GLOMAP-mode aerosol scheme (first row), HadGEM3 using the single moment CLASSIC aerosol scheme (second row) CAM5-NCAR (third row), CAM5-Oslo (fourth row) and AQUA MODIS (last row). Note that MODIS anomalies show the aerosol impacts plus the meteorological variability while the model simulations show the impact of aerosols only (Supplementary S7).

AQUA MODIS - October 2014

**a**

Area mean = -0.99 μm

Zonal mean Δreff [μm]

Liquid cloud effective radius anomalies, Δreff [μm]

**b**

2014

2002-2013

Probabilities [%]

Liquid cloud effective radius [μm]

**c**

Area mean = 1.27 g.m⁻²

Zonal mean ΔLWP [g.m⁻²]

Liquid Water Path anomalies, ΔLWP [g.m⁻²]

**d**

2014

2002-2013

Probabilities [%]

Liquid Water Path [g.m⁻²]
Liquid cloud effective radius anomalies, $\Delta_r_{\text{eff}}$ [\(\mu m\)]

Area mean = -0.68 \(\mu m\)

Zonal mean $\Delta_r_{\text{eff}}$ [\(\mu m\)]

Liquid cloud effective radius [\(\mu m\)]

Liquid Water Path anomalies, $\Delta LWP$ [g.m\(^{-2}\)]

Area mean = 0.75 g.m\(^{-2}\)

Zonal mean $\Delta LWP$ [g.m\(^{-2}\)]

Liquid Water Path [g.m\(^{-2}\)]
Liquid cloud effective radius anomalies, $\Delta r_{\text{eff}}$ [µm]
