ABSTRACT

Background
When human milk is not available for feeding preterm infants, protein hydrolysate rather than standard cow's milk formulas (with intact proteins) are often used because they are perceived as being tolerated better and less likely to lead to complications. However, protein hydrolysate formulas are more expensive than standard formulas, and concern exists that their use in practice is not supported by high-quality evidence.

Objectives
To assess the effect of feeding preterm infants with hydrolysate formula (versus standard cow's milk formulas) on the risk of feed intolerance, necrotising enterocolitis, and other morbidity and mortality in preterm infants.

Search methods
We used the standard Cochrane Neonatal search strategy including electronic searches of the Cochrane Central Register of Controlled Trials (CENTRAL; 2017, Issue 4), Ovid MEDLINE, Ovid Embase, and the Cumulative Index to Nursing and Allied Health Literature (CINAHL) (to April 2017), as well as conference proceedings and previous reviews.

Selection criteria
Randomised and quasi-randomised controlled trials that compared feeding preterm infants with protein hydrolysate versus standard (non-hydrolysated) cow's milk formula.

Data collection and analysis
Two review authors assessed trial eligibility and risk of bias and extracted data independently. We analysed treatment effects as described in the individual trials and reported risk ratios and risk differences for dichotomous data, and mean differences for continuous data, with respective 95% confidence intervals (CI). We used a fixed-effect model in meta-analyses and explored potential causes of heterogeneity in sensitivity analyses. We assessed quality of evidence at the outcome level using the GRADE approach.
Main results

We identified 11 trials for inclusion in the review. All trials were small (total participants 665) and had various methodological limitations including uncertainty about methods to ensure allocation concealment and blinding. Most participants were clinically stable preterm infants of gestational age less than about 34 weeks or birth weight less than about 1750 g. Fewer participants were extremely preterm, extremely low birth weight, or growth-restricted. Most trials found no effects on feed intolerance assessed variously as mean prefeed gastric residual volume, incidence of abdominal distention or other concerning gastrointestinal signs, or time taken to achieve full enteral feeds (meta-analysis was limited because studies used different measures). Meta-analysis found no effect on the risk of necrotising enterocolitis (typical risk ratio 1.10, 95% CI 0.36 to 3.34; risk difference 0.00, 95% CI -0.03 to 0.04; 5 trials, 385 infants) (low quality evidence; downgraded for imprecision and design weaknesses).

Authors’ conclusions

The identified trials provide only low quality evidence about the effects of feeding preterm infants with protein hydrolysate versus standard formula. The existing data did not support conclusions that feeding with protein hydrolysate affects the risk of feed intolerance or necrotising enterocolitis. Further large, pragmatic trials are needed to provide more reliable and precise estimates of effectiveness and cost-effectiveness.

PLAIN LANGUAGE SUMMARY

Hydrolysed formula for preterm infants

Review question: does feeding preterm infants with cow’s milk formula containing predigested (hydrolysed) proteins rather than whole proteins improve digestion and reduce the risk of severe bowel problems?

Background: preterm infants often find cow’s milk formula more difficult to digest than human milk, and cow’s milk formula may increase the risk of severe bowel problems for preterm (born before their due date) infants. If preterm infants are fed with cow’s milk formula (when human milk is unavailable), then using a formula in which the protein is already partially digested (called hydrolysed) rather than a standard formula (with intact proteins) might reduce the risk of these problems. However, hydrolysed formulas are more expensive than standard formulas, and may have specific side effects not seen with standard formulas. Given these concerns, we have reviewed all the available evidence from clinical trials that compared these types of formula for feeding preterm infants.

Study characteristics: in searches of medical databases up to April 2017, we found 11 trials; most were small (involving 665 infants in total) and had methodological weaknesses.

Key results: the data from these trials provided no strong or consistent evidence that feeding preterm infants with hydrolysed formula rather than standard formula improved digestion or reduced the risk of severe bowel problems.

Conclusions: the currently available evidence suggested that feeding preterm infants with hydrolysed formula (rather than standard formula) during their initial hospital admission has no important benefits or harms. However, this finding is not yet conclusive, and larger and better quality trials are needed to provide evidence to help clinicians and families make informed choices about this issue.
### SUMMARY OF FINDINGS FOR THE MAIN COMPARISON

**Hydrolysed compared to non-hydrolysed formula for feeding preterm infants**

**Patient or population:** feeding preterm infants  
**Setting:** neonatal unit  
**Intervention:** hydrolysed formula (protein hydrolysate)  
**Comparison:** non-hydrolysed formula

* The basis for the assumed risk (e.g. the median control group risk across studies) is provided in footnotes. The corresponding risk (and its 95% confidence interval) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI).

CI: confidence interval; RCT: randomised controlled trial; RR: risk ratio.
**BACKGROUND**

Hydrolysed cow’s milk formulas, originally developed for infants with cow’s milk protein allergy or intolerance, are used as enteral feeding alternatives for preterm infants for whom human milk is unavailable. These formulas contain hydrolysed rather than intact proteins, and may also differ from standard cow’s milk formulas in carbohydrate, lipid, and micronutrient type and content (Oldaeus 1997). Their use as a sole or supplemental enteral feed source for preterm infants has increased since the late-1990s, particularly in high-income countries, because they are perceived as being tolerated better, and less likely to lead to complications, than standard cow’s milk formulas (Zuppa 2005). However, hydrolysed formulas are more expensive than standard formulas, and concern exists that their use in practice is not supported by high quality evidence (Foucard 2005).

**Description of the condition**

Human breast milk is recommended as the best form of enteral nutrition for preterm infants (AAP 2012). Breast milk proteins, carbohydrates, fats, and micronutrients have been optimised by evolution for neonatal digestion and absorption. Breast milk contains many non-nutrient factors including immunoglobulins and lactoferrin that promote intestinal adaptation and maturation, improve enteral feed tolerance, and protect against infection and inflammatory disorders (Agostoni 2010; Arslanoglu 2013). When sufficient human breast milk is unavailable, cow’s milk-based formulas are used for feeding preterm infants, either as the sole enteral diet or as a supplement to human breast milk (Klingenberg 2012). Feeding preterm infants with standard cow’s milk formulas rather than human breast milk is, however, associated with higher rates of feed intolerance and necrotising enterocolitis (Quigley 2014). Feed intolerance and interruption of enteral feeds is a major contributor to cumulative nutrient deficits and postnatal growth restriction in very preterm infants (Embleton 2001; Cooke 2016). Slow postnatal growth is associated with neurodevelopmental impairment in later childhood and with poorer cognitive and educational outcomes (Brandt 2003; Embleton 2013a; Leppanen 2014). Necrotising enterocolitis affects about 5% of very preterm infants. Infants who develop necrotising enterocolitis experience more infections, have lower levels of nutrient intake, grow more slowly, have longer durations of intensive care and hospital stay, and are more likely to die or be disabled than gestation-comparable infants who do not develop necrotising enterocolitis (Morgan 2011; Pike 2012; Yee 2012).

**Description of the intervention**

Standard cow’s milk formulas can be grouped broadly as ‘term’ formulas (designed for term infants; nutrient content based on the composition of mature breast milk) and nutrient-enriched ‘preterm’ formulas (designed for preterm or low birth weight infants; energy-enriched and variably protein- and mineral-enriched) (Fewtrell 1999). Concern exists that standard cow’s milk formulas (either ‘term’ or ‘preterm’) are poorly tolerated, especially by very preterm infants, because the immature infant’s gastrointestinal tract is less efficient than that of term infants at digesting intact cow’s milk proteins and fats (Ewer 1994; Lindberg 1998).

**Hydrolysed formulas**

‘Hydrolysed’ protein formulas, containing protein digested chemically (acid/alkali) or enzymatically (protease) to oligopeptides, are often used for feeding preterm infants, especially infants with feed intolerance or clinical features (such as episodic apnoea, oxygen desaturation or bradycardia) that are attributed to gastro-oesophageal reflux, or following gastrointestinal surgery or necrotising enterocolitis (Zuppa 2005).

Several brands of hydrolysed formulas (both ‘term’ and ‘preterm’) are available commercially and these are grouped broadly depending on degree of hydrolysis:

- extensively hydrolysed: residual free amino acids and peptides with molecular weights less than 1.5 kDa to 3.0 kDa;
- partially hydrolysed: residual peptides with molecular weights of 3.0 kDa to 10.0 kDa.

This distinction is mainly relevant to the putative hypo-allergenic properties of hydrolysed formulas and there are limited data regarding its functional relevance to preterm infants. Formulas also vary by the predominant protein source (casein versus whey-casein) as well as by carbohydrate (lactose, maltodextrin) and fat (cow, vegetable) type and content (BNFC 2016).

**How the intervention might work**

Although developed as hypo-allergenic alternatives to standard cow’s milk formulas for infants at risk of cow’s milk protein intolerance or allergy, the evidence for this effect in term infants is very weak (Boyle 2016; Osborn 2017). In preterm infants, hydrolysed formulas are mostly used for their perceived benefits in reducing the risk of feed intolerance and necrotising enterocolitis. When human milk is unavailable, hydrolysed formulas may be used empirically (starter formula) or therapeutically to improve feeding tolerance or reduce gastro-oesophageal reflux. The possible mechanisms for these effects include accelerated gastric emptying and intestinal transit, more efficient enteric peptide digestion, and stimulation of small intestinal enzymatic and motilin activity (Mihatsch 2001b; Zuppa 2005). If better feed tolerance reduces the time taken to establish full enteral feeding in very preterm infants, this may reduce the adverse infectious or metabolic consequences of prolonged exposure to parenteral nutrition.

Several potential adverse effects of hydrolysed formulas are recognised. Osmolality increases when protein is hydrolysed into smaller peptides, and these higher osmolarity fluids delivered to the small...
intestine may increase the risk of necrotising enterocolitis. Furthermore, if bioactive proteins such as immunoglobulin or lactoferrin are hydrolysed, this may reduce their putative benefits in reducing the risk of infection or necrotising enterocolitis. It is possible that some peptides created by artificial hydrolysis have diminished or harmful functional activities (Embleton 2013b). Concern about micronutrient bioavailability in hydrolysed formulas also exists, particularly whether bone minerals are less well absorbed in the absence of intact casein proteins (Zuppa 2005).

**Why it is important to do this review**

Given the potential for protein hydrolysate formulas (rather than standard cow’s milk formulas) to improve enteral feed tolerance and prevent adverse outcomes in preterm infants, we undertook a systematic review of the randomised trial data to help to inform practice and research.

**OBJECTIVES**

To assess the effect of feeding preterm infants with hydrolysed formula (versus standard cow’s milk formulas) on the risk of feed intolerance, necrotising enterocolitis, and other morbidity and mortality in preterm infants.

**METHODS**

**Criteria for considering studies for this review**

**Types of studies**

Randomised or quasi-randomised controlled trials, including cluster-randomised controlled trials.

**Types of participants**

Preterm (less than 37 weeks’ gestation) newborn infants who received cow’s milk formula as their sole or supplemental enteral diet.

**Types of interventions**

Hydrolysed cow’s milk formula versus standard (non-hydrolysed) cow’s milk formula or another type of hydrolysed cow’s milk formula. Formula was to be allocated as at least 20% of intended enteral diet for at least two weeks to allow measurable effects on growth rates and episodes of feed intolerance. Trials should have compared formulas with similar energy and protein levels (i.e. hydrolysed ‘preterm’ formula versus non-hydrolysed ‘preterm’ formula, or hydrolysed ‘term’ formula versus non-hydrolysed ‘term’ formula).

We planned separate comparisons of trials that assessed:

- empirical use of hydrolysed formulas;
- indicated (therapeutic) use of hydrolysed formulas to treat infants with feed intolerance, gastro-oesophageal reflux (and associated apnoea, desaturation or bradycardia), or following gastrointestinal surgery or necrotising enterocolitis (as defined by the primary investigators).

**Types of outcome measures**

**Primary outcomes**

- Number of infants with at least one episode of feed intolerance that resulted in cessation or reduction in enteral feeding (enteral feeds reduced or ceased for more than four hours), or mean number of episodes of feed intolerance during trial period, or both.
- Infants with at least one episode of necrotising enterocolitis (modified Bell stage 2/3) (Walsh 1986) (unless indicated use following necrotising enterocolitis).

**Secondary outcomes**

- Time to full enteral feeding independent of parenteral fluids (days).
- Growth: time to regain birth weight, and subsequent rates of weight (grams/kilogram/day), length (millimetre/week), and head growth (millimetre/week) during hospital admission.
- Duration of hospital admission (days).
- Measures of bone mineralisation:
  - serum alkaline phosphatase level at 36 to 40 weeks’ postmenstrual age or
  - bone mineral content assessed post-term by dual energy x-ray absorptiometry (DEXA) or
  - clinical or radiological evidence of rickets on long-term follow-up.
- Late-onset invasive infection diagnosed more than 72 hours after birth as determined by culture from a normally sterile site: cerebrospinal fluid, blood, bone or joint, peritoneum, pleural space or central venous line tip; or findings on autopsy examination consistent with invasive microbial infection.
- Mortality: all-cause until 28 days and during hospital admission.
- Neurodevelopmental outcomes assessed by a validated test after 12 months’ post-term: neurological evaluations, developmental scores and classifications of disability, including auditory and visual disability.
- Allergy or atopy diagnosed after 12 months’ post-term: asthma, eczema, allergic rhinitis or conjunctivitis, food allergy,
allergic sensitisation (skin prick, or specific or total immunoglobulin E level) (Boyle 2016).

Search methods for identification of studies

Electronic searches
We searched the Cochrane Central Register of Controlled Trials (CENTRAL, 2017, issue 4), Ovid MEDLINE (1946 to April 2017), Ovid Embase (1974 to April 2017), Ovid Maternity & Infant Care Database (1971 to April 2017), and CINAHL (1982 to April 2017) using a combination of the following text words and MeSH terms described in Appendix 1. We limited the search outputs with the relevant search filters for clinical trials as recommended in the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011). We did not apply any language restrictions.

We searched ClinicalTrials.gov and the World Health Organization’s International Trials Registry and Platform (www.who.int/ictrp/en/) for completed or ongoing trials.

Searching other resources
We examined reference lists in previous reviews and included studies. We searched the proceedings of the annual meetings of the Pediatric Academic Societies (1993 to 2016), the European Society for Paediatric Research (1995 to 2016), the Royal College of Paediatrics and Child Health (2000 to 2017) and the Perinatal Society of Australia and New Zealand (2000 to 2016). Trials reported only as abstracts were eligible if sufficient information was available from the report, or from contact with the authors, to fulfil the inclusion criteria.

Data collection and analysis
We used the standard methods of Cochrane Neonatal.

Selection of studies
We screened the title and abstract of all studies identified by the search strategy and two review authors independently assessed the full articles for all potentially relevant trials. We excluded those studies that did not meet all the inclusion criteria and we stated the reason for exclusion. We discussed any disagreements until consensus was achieved.

Data extraction and management
Two review authors (DN and WM) extracted data independently using a data collection form to aid extraction of information on design, methodology, participants, interventions, outcomes and treatment effects from each included study. We discussed any disagreements until we reached a consensus. If data from the trial reports were insufficient, we contacted the trialists for further information.

Assessment of risk of bias in included studies
We used the criteria and standard methods of Cochrane Neonatal to assess the methodological quality of any included trials. Two review authors (DN and JKA) assessed risk of bias across key domains (Appendix 2) and resolved disagreements in consultation with a third review author (WM). We requested additional information from the trial authors to clarify methodology and results when necessary. We did not exclude trials on the basis of risk of bias, but we did plan to conduct sensitivity analyses if applicable to explore the consequences of synthesising evidence of variable quality (Higgins 2011).

Measures of treatment effect
We analysed the treatment effects in the individual trials using Review Manager 5 (RevMan 2014) and reported risk ratio (RR) and risk difference (RD) for dichotomous data and mean difference (MD) for continuous data, with respective 95% confidence intervals (CI). We determined the number needed to treat for an additional beneficial outcome (NNTB) or an additional harmful outcome (NNTH) for analyses with a statistically significant difference in the RD.

Unit of analysis issues
The unit of analysis was the participating infant in individually randomised trials and the neonatal unit (or subunit) for cluster-randomised trials. For cluster-randomised trials, we planned to undertake analyses at the level of the participant while accounting for the clustering in the data using the methods recommended in the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011).

Dealing with missing data
Where data were missing, and could not be derived as described, we approached the analysis of missing data as follows.
- We contacted the original study investigators to request the missing data.
- Where possible, we imputed missing standard deviations (SDs) using the coefficient of variation (CV) or calculated from other available statistics including standard errors, CIs, t values and P values.
- If the data were assumed to be missing at random, we analysed the data without imputing any missing values.
- If this could not be assumed, then we planned to impute the missing outcomes with replacement values, assuming all to have a poor outcome. We planned sensitivity analyses to assess
any changes in the direction or magnitude of effect resulting from data imputation.

Assessment of heterogeneity
Two review authors assessed clinical heterogeneity, with a meta-analysis conducted only when both authors agreed that study participants, interventions and outcomes were sufficiently similar. We examined the treatment effects of individual trials and heterogeneity between trial results by inspecting the forest plots. We calculated the I² statistic for each analysis to quantify inconsistency across studies and described the percentage of variability in effect estimates that may be due to heterogeneity rather than to sampling error. If we detected moderate or high heterogeneity (I² greater than 50%), we would explore the possible causes (e.g. differences in study design, participants, interventions or completeness of outcome assessments).

Assessment of reporting biases
If more than 10 trials were included in a meta-analysis, we planned to examine a funnel plot for asymmetry.

Data synthesis
We used the fixed-effect model in Review Manager 5 for meta-analyses (as per Cochrane Neonatal recommendations) (RevMan 2014). Where moderate or high heterogeneity existed, we planned to examine the potential causes in subgroup and sensitivity analyses.

Quality of evidence
We assessed the quality of evidence for the main comparisons at the primary outcomes level using the GRADE approach, as outlined in the GRADE handbook (Schünemann 2013; see Appendix 3). Two review authors independently assessed the quality of the evidence for outcomes identified as critical or important for clinical decision-making (feed tolerance and incidence of necrotising enterocolitis). We considered evidence from randomised controlled trials as high quality but downgraded the evidence one level for serious (or two levels for very serious) limitations based upon the following: design (risk of bias), consistency across studies, directness of the evidence, precision of estimates and presence of publication bias. We used the GRADEpro GDT Guideline Development Tool to create a 'Summary of findings' table to report the quality of the evidence.

Subgroup analysis and investigation of heterogeneity
We planned subgroup analyses by:
- gestational age at birth: very preterm (less than 32 weeks) infants versus infants born at 32 weeks or later;
- indication (for therapeutic use): post-surgery versus post-necrotising enterocolitis versus feeding intolerance or gastro-oesophageal reflux;
- extent of protein hydrolysis (as defined by manufacturers): extensively versus partially hydrolysed formula.

Sensitivity analysis
We planned sensitivity analyses to determine if the findings were affected by including only studies of adequate methodology (low risk of bias), defined as adequate randomisation and allocation concealment, blinding of intervention and measurement, and less than 10% loss to follow-up.

RESULTS

Description of studies
Results of the search
From the preliminary search, we identified 1405 records, including three records from other sources. After removing duplicates, we screened 805 separate records against titles and abstracts for relevance. Among these, we excluded 782 articles outright. We shortlisted 21 articles for full-text assessment, with two articles identified as on-going trials (ACTRN12613000481774; Yin 2015). We included 11 trials (Characteristics of included studies table) and excluded seven studies (Characteristics of excluded studies table). See Figure 1.
Figure 1. Study flow diagram.

1405 records identified through database searching

3 additional records identified through other sources

805 records after duplicates removed

782 records excluded; 2 records ongoing studies

805 records screened

7 full-text articles excluded, with reasons; 3 articles awaiting classification

21 full-text articles assessed for eligibility

11 studies included in qualitative synthesis

9 studies included in quantitative synthesis (meta-analysis)
One trial is awaiting further data (Del Moral 2017), and two trials await English language translation to allow assessment of eligibility for inclusion (Dobryansky 2015; Luo 2016).

Included studies

We included 11 trials (Huston 1992; Schweizer 1993; Raupp 1995; Pauls 1996; Picaud 2001; Riezzo 2001; Mihatsch 2002; Szajewska 2004; Maggio 2005; Florendo 2009; Baldassarre 2017). Most of the included trials were undertaken during the 1990s and 2000s by investigators in neonatal units in Europe (mainly Germany and Italy) and North America. For further details, see Characteristics of included studies table.

Participants

In total, 665 infants participated in the included trials. Most participants were clinically stable preterm infants of gestational age less than about 34 weeks or birth weight less than about 1750 g. Few participants were extremely preterm, extremely low birth weight or growth-restricted. Most of the trials specifically excluded infants with congenital anomalies, or gastrointestinal or neurological problems.

Interventions

All the trials assessed the empirical use of protein hydrolysate formulas; none assessed indicated use. Trials varied according to brand of formula studied. All trials except one assessed a "preterm" (nutrient-enriched) hydrolysed formula; Schweizer 1993 assessed a "term" hydrolysed formula. Most trials used a whey-casein-based hydrolysate. Two trials used a predominantly casein-based hydrolysate (Huston 1992; Riezzo 2001). Most studies assessed a partially hydrolysed formula. Three trials use an extensively hydrolysed formula (Schweizer 1993; Mihatsch 2002; Baldassarre 2017). One (three-arm) trial randomly allocated infants to receive a partially hydrolysed formula, an extensively hydrolysed formula, or a standard preterm formula (Szajewska 2004). Control diets were preterm non-hydrolysed formulas in all except Riezzo 2001 where the control diet was a standard term formula. No trials compared hydrolysed cow's milk formula versus another type of hydrolysed cow's milk formula. Trial participants received the intervention or control formulas on commencing enteral feeds either as a sole diet or a supplement when mother's own milk was not available or insufficient. One trial specifically excluded participants post hoc if mother's own milk formed more than 10% of enteral intake (Mihatsch 2002). In general, trial feeds were allocated for several weeks (at least two weeks), or until participating infants reached a specified weight (typically about 1.8 kg).

Outcomes

The outcomes reported most commonly were feed intolerance (reported in various ways but often without accompanying numerical data), growth parameters during the study period or until hospital discharge, and adverse events (including mortality and necrotising enterocolitis). None of the trials reported long-term growth and neurodevelopmental outcomes.

Excluded studies

We excluded seven studies (Rigo 1994; Rigo 1995; Mihatsch 1999; Mihatsch 2001a; Agosti 2003; Corvaglia 2013; Logarajaha 2015). The reasons for exclusion are described in the Characteristics of excluded studies table.

Risk of bias in included studies

Quality assessments are detailed in the Characteristics of included studies table and summarised in Figure 2.
Figure 2. Risk of bias summary: review authors' judgements about each risk of bias item for each included study.

**Allocation**
Three trials reported adequate allocation concealment methods (sealed, numbered envelopes; central randomisation in blocks) and were at low risk of bias (Szajewska 2004; Maggio 2005; Florendo 2009). None of the remaining trials reported sufficient details to assess if or how allocation concealment was achieved.

**Blinding**
Four trials reported blinding of investigators, and carers or parents (Schweizer 1993; Maggio 2005; Florendo 2009; Baldassarre 2017). It is probable that the other trials were not blinded as the reports did not describe any methods that might achieve this.

**Incomplete outcome data**
Most trials were likely to be at low risk of bias because of incomplete assessment of the trial cohort. In one trial, the investigators recruited 129 infants initially then excluded 42 participants post hoc because they had received more than 10% of their enteral intake as human milk (Mihatsch 2002).

**Selective reporting**
We were unable to assess reliably whether selective reporting occurred as we did not have protocols or other indicators of prespecified outcomes for any of the trials.

**Other potential sources of bias**
We did not identify any other potential sources of bias in the reports.

**Effects of interventions**
See: Summary of findings for the main comparison

**Empirical use of protein hydrolysate versus standard formula (Comparison 1)**

1. **Feed intolerance (Outcome 1.1)**
Two trials reported numerical data on the incidence of feed intolerance (Maggio 2005; Florendo 2009; Baldassarre 2017). Meta-analysis found no statistically significant effect (typical RR 2.71, 95% CI 0.29 to 25.00; typical RD 0.02, 95% CI -0.03 to 0.08) (I² not applicable) (Analysis 1.1). The other trials did not report any numerical data but described their findings narratively. These found no differences in measures of gastric residual volumes (Pauls 1996; Mihatsch 2002), frequency of regurgitation (Riezzo 2001), or vomiting or diarrhoea (Szajewska 2004). Raupp 1995 reported that “both formulas were well tolerated.” The remaining trials did not report any measures of feed intolerance (Huston 1992; Schweizer 1993; Picaud 2001).

2. **Incidence of necrotising enterocolitis (Outcome 1.2)**
Meta-analysis of data from five trials (385 infants) found no difference (typical RR 1.10, 95% CI 0.36 to 3.34; typical RD 0.00, 95% CI -0.03 to 0.04) (I² = 0%) (Analysis 1.2; Figure 3).
Figure 3. Forest plot of comparison: 1 Hydrolysed versus non-hydrolysed formula, outcome: 1.2 Necrotising enterocolitis.

The other trials did not report this outcome, although in most it seems likely that none of the participants developed necrotising enterocolitis.

The quality of evidence for the primary outcomes was low because of methodological limitations in the included trials (including uncertainty about allocation concealment and blinding), and imprecision of effect size estimates (Summary of findings for the main comparison).

3. Time to full enteral feeding (Outcome 1.3)

Most trials did not report time to full enteral feeds (Huston 1992; Raupp 1995; Riezzo 2001; Szajewska 2004; Maggio 2005; Florendo 2009).

Mihatsch 2002 reported that the median time to full enteral feeding was shorter in the intervention group (10 days versus 12 days in the control group).

Four trials reported no difference:

- Schweizer 1993: 24 days versus 25 days (SD not reported);
- Pauls 1996: no data reported;
- Picaud 2001: 16 (SD 8) days versus 17 (SD 8) days (MD -1.00 days, 95% CI -8.36 to 6.36);
- Baldassarre 2017: 11 days versus 10 days (SD not reported)

4. Growth: time to regain birth weight, and subsequent rates of growth during hospital admission (Outcomes 1.4 to 1.6)

Four trials did not report any growth data (Pauls 1996; Riezzo 2001; Szajewska 2004; Baldassarre 2017). The other trials reported some data on growth parameters during the study period or until hospital discharge, but most did not provide sufficient data for inclusion in the meta-analysis (Huston 1992; Schweizer 1993; Raupp 1995; Mihatsch 2002).

Time to regain birth weight

One trial reported days to regain birth weight (Schweizer 1993). This trial found no difference (10 days in the intervention group versus 9 days in the control group; SD not reported).

Weight gain

Three trials reported rates of weight gain over the study period or until hospital discharge (Picaud 2001; Maggio 2005; Florendo 2009). Meta-analysis showed that weight gain was slower in the infants fed with hydrolysed formula (MD -3.02 g/kg/day, 95% CI -4.66 to -1.38) (Analysis 1.4; Figure 4).
Length change

Meta-analysis of data from two trials (97 infants) found no difference in length change (MD -0.04 mm/week, 95% CI -1.24 to 1.15) (Analysis 1.5).

Head circumference growth

Meta-analysis of data from two trials (97 infants) found no difference in head circumference growth (MD 0.27 mm/week, 95% CI -0.39 to 0.94) (Analysis 1.6).

5. Duration of hospital admission

None of the trials reported the duration of hospital admission.

6. Measures of bone mineralisation (Outcome 1.7)

Two trials reported measures of bone mineralisation (Raupp 1995; Florendo 2009). Neither trial, nor a meta-analysis of data from both trials, showed a difference in serum alkaline phosphatase level at 36 to 40 weeks’ postmenstrual age (MD 16.6 IU/L, 95% CI -34.1 to 67.4) (Analysis 1.7; Figure 5). None of the trials reported bone mineral content assessed post-term or clinical or radiological evidence of rickets on long-term follow-up.

7. Late-onset invasive infection (Outcome 1.8)

Only one trial reported the incidence of late-onset invasive in-

fection (Baldassarre 2017). There was no difference in the incidence of microbiologically confirmed bacteraemia (typical RR 1.50, 95% CI 0.27 to 8.34; typical RD -0.03, 95% CI -0.11 to...
8. Mortality
None of the trials reported the incidence of mortality.

9. Neurodevelopmental outcomes
None of the trials reported neurodevelopmental outcomes.

10. Allergy or atopy diagnosed after 12 months’ post-term
(Outcome 1.8)
One trial assessed allergy or atopy (Szajewska 2004). The trial found no difference in the incidence of “any allergic disease” (atopic dermatitis, gastrointestinal symptoms, wheezing) at 12 months (RR 0.62, 95% CI 0.27 to 1.42; RD -0.13, 95% CI -0.36 to 0.10) (Analysis 1.9).

Subgroup analyses
- Gestational age at birth: very preterm (less than 32 weeks) infants versus infants born at 32 weeks or later: subgroup data not available.
- Indication (for therapeutic use): postsurgery versus post-necrotising enterocolitis versus feeding intolerance or gastro-oesophageal reflux: not applicable as all trials assessed empirical use.
- Extent of protein hydrolysis (as defined by manufacturers): data for subgroup analysis sufficient for necrotising enterocolitis (outcome 1.2) only. Three trials used a partially hydrolysed preterm formula (Raupp 1995; Pauls 1996; Florendo 2009). Two trials used an extensively hydrolysed formula (Mihatsch 1999; Baldassarre 2017). Meta-analysis found no evidence of a subgroup effect (test for subgroup differences: \( \chi^2 = 0.75, \text{df} = 1 (P = 0.39), I^2 = 0\% \)) (Figure 3).

Indicated use of protein hydrolysate versus standard formula (Comparison 2)
We found no trials comparing protein hydrolysate versus standard formula.

Discussion

Summary of main results
These data from 11 small randomised controlled trials provided only low quality evidence about how feeding preterm infants (typically stable infants of gestational age less than 34 weeks at birth) with protein hydrolysate rather than standard cow’s milk formula affects the risk of feed tolerance, necrotising enterocolitis or other adverse outcomes. Limited data did not indicate any important effects on growth, although a meta-analysis of data from three trials suggested that weight gain was slower in infants fed with protein hydrolysate compared with isocaloric preterm formula. There are currently no data available to assess the effects on growth and neurodevelopmental outcomes beyond the initial hospital admission.

Overall completeness and applicability of evidence
These findings should be interpreted and applied cautiously. The primary outcome, feed intolerance, was reported in various ways, and together with the paucity of numerical data, this precluded meta-analysis. Trials generally reported that feeding with protein hydrolysate did not affect measures such as the prefeed gastric residual volume or the need to cease enteral feeding. Similarly, few trials reported the impact of the intervention on the time to achieve full enteral feeding, and the trials that did report this outcome found no statistically significant or clinically important effects. Although a meta-analysis of five trials (385 participants) found no effect on the risk of necrotising enterocolitis, there were insufficient data to exclude a more modest but still important effect size. The lower bound of the 95% CI was consistent with a 3% absolute risk reduction (i.e. one fewer infant developing necrotising enterocolitis for every 33 infants who received protein hydrolysate formula). Because necrotising enterocolitis is a relatively rare outcome, affecting about 5% of very preterm infants, much larger trials would be needed to provide a more precise estimate of the effect of feeding with protein hydrolysate versus standard formula (Yee 2012).

Data on growth parameters are limited, as are data on other adverse outcomes. Furthermore, uncertainty remains about longer-term impact on growth or development. As concerns exist that hydrolysed proteins may be utilised less efficiently than intact proteins by preterm infants, and that concomitant mineral uptake may be lower, trials that assess the effects on both short- and long-term growth and body composition (including bone health) may help to inform policy and practice (Senterre 2016).

Another major applicability limitation of this review is that all the included trials were undertaken at healthcare facilities in high-income countries, and none in low-income countries. Therefore, this evidence may be of limited applicability to practices in resource-limited settings where, globally, most preterm and low birth weight infants are cared for (Imdad 2013).

All the included trials assessed the effect of empirical (primary) use of protein hydrolysate for feeding preterm infants. We found no trials that assessed the indicated use of protein hydrolysate versus standard formula for preterm infants with feed intolerance, gastrointestinal reflux (and associated apnoea, desaturation or bradycardia), or following gastrointestinal surgery or necrotising enterocolitis. Although indicated use of protein hydrolysate is common,
Quality of the evidence

The GRADE assessments indicated that the quality of evidence for the primary outcomes was 'low' because of methodological limitations in the included trials (including uncertainty about allocation concealment and blinding), and imprecision of effect size estimates (Summary of findings for the main comparison). Most of the included trials were funded or supported by the manufacturers of the formulas being assessed but the funders were not involved in trial design or analysis. However, there remains some concern that formula manufacturers may promote study findings involved in trial design or analysis. There remain some limitations in the included trials (including uncertainty about allocation concealment and blinding), and imprecision of effect size estimates (Summary of findings for the main comparison).

Potential biases in the review process

It is possible that our findings were subject to publication and other reporting biases. We attempted to minimise this by screening the reference lists of included trials and related reviews and searching the proceedings of major international perinatal conferences to identify trial reports that were not (or were not yet) published in full form in academic journals. The meta-analyses that we performed did not contain sufficient trials to explore symmetry of funnel plots as a means of identifying possible publication or reporting bias.

Authors’ conclusions

Implications for practice

This review provides only low quality evidence regarding any benefits or harms of feeding preterm infants with protein hydrolysate versus standard formula. Although there are no trial data to suggest an effect on the risk of feed intolerance or necrotising enterocolitis, the total number of infants studied was small (665 infants) and the data that could be abstracted from published studies for inclusion in meta-analyses were limited.

Implications for research

Further, high-quality randomised controlled trials are needed to assess the benefits and safety of protein hydrolysate versus standard cow’s milk formulas for feeding very preterm infants when maternal breast milk is insufficient or not available. Trials could assess primary (empirical) use and secondary (indicated) use in infants with feed intolerance or gastro-oesophageal reflux, or following gastrointestinal surgery or necrotising enterocolitis. Trials should aim to ensure the participation of extremely preterm, extremely low birth weight or growth-restricted infants so that subgroup analyses can be planned for these infants at higher risk of necrotising enterocolitis. Given that protein hydrolysate preterm formulas is more expensive than standard preterm formula, trials could justifiably include a cost-benefit analysis.

Acknowledgements

We thank the corresponding authors of included trials for providing further information on methods and outcomes.

Selective reporting (reporting bias)  All outcomes | Unclear risk | Protocol not available. |
Other bias  All outcomes | Unclear risk | Funder: Nestle (manufacturer of the trial formula). |

**Riezzo 2001**

**Methods**  RCT.

**Participants**  Preterm infants (n = 36).

**Interventions**  Partially hydrolysed casein preterm formula* (n = 18).
Standard (whey-casein) formula* (n = 18).

**Outcomes**  Proportion of infants who had > 1 episode of regurgitation or vomiting per day

**Notes**  Department of Pediatrics, Neonatology Section, University of Bari, Bari, Italy
Trial date: 2000.
Energy content of hydrolysed formula (80 kCal/100 mL) higher than control standard term formula (68 kCal/100 mL). Because this did not report growth rates (the reason for specifying similar energy levels in comparison formulas), we made a consensus decision to include the trial

Appendix 2. Risk of bias

- Random sequence generation: we categorised the method used to generate the allocation sequence as:
  - low risk of bias: any random process (e.g. random number table; computer random number generator; coin tossing; shuffling of cards or envelopes; throwing of dice; drawing of lots; minimisation (may be implemented without a random element; this is considered equivalent to being random));
  - high risk of bias: any non-random process (e.g. sequence generated by odd or even date of birth; date (or day) of admission; sequence generated by hospital or clinic record number; allocation by judgement of the clinician; allocation by preference of the participant; allocation based on results of a laboratory test or series of tests; allocation based on availability of the intervention);
  - unclear risk of bias: insufficient information about the sequence generation process to permit judgement.

- Allocation concealment: we categorised the method used to conceal the allocation sequence as:
  - low risk of bias: randomisation method described that would not allow investigator/participant to know or influence the intervention group before eligible participants entered the study (i.e. central allocation, including telephone, web-based, and pharmacy-controlled randomisation; sequentially numbered drug containers of identical appearance; sequentially numbered, opaque, sealed envelopes);
  - high risk of bias: open random allocation schedule (i.e. list of random numbers); assignment envelopes used without appropriate safeguards (e.g. if envelopes were unsealed or non-opaque or were not sequentially numbered); alternation or rotation; date of birth; case record number; any other explicitly unconcealed procedure;
  - unclear risk of bias: randomisation stated but no information provided on method used.

- Blinding of participants and personnel: we assessed blinding of participants, clinicians and carers, and outcome assessors separately for different outcomes and categorised the methods as:
  - low risk of bias: no blinding or incomplete blinding, but review authors judged that the outcome was not likely to be influenced by lack of blinding; blinding of participants and key study personnel ensured, and unlikely that blinding could have been broken;
  - high risk of bias: no blinding or incomplete blinding, and the outcome was likely to be influenced by lack of blinding; blinding of key study participants and personnel attempted, but likely that blinding could have been broken, and the outcome was likely to be influenced by lack of blinding;
  - unclear risk of bias: insufficient information to permit judgement.

- Incomplete outcome data: we described the completeness of data including attrition and exclusions from the analysis for each outcome and any reasons for attrition or exclusion where reported. We assessed whether missing data were balanced across groups or were related to outcomes. We categorised completeness as:
  - low risk of bias: no missing outcome data; reasons for missing outcome data unlikely to be related to true outcome (for survival data, censoring unlikely to introduce bias); missing outcome data balanced in numbers across intervention groups, with similar reasons for missing data across groups; for dichotomous outcome data, the proportion of missing outcomes compared with observed event risk not enough to have a clinically relevant impact on the intervention effect estimate; for continuous outcome data, plausible effect size (difference in means or standardised difference in means) among missing outcomes not sufficient to have a clinically relevant impact on observed effect size; missing data imputed by appropriate methods;
• high risk of bias: reason for missing outcome data likely to be related to true outcome, with imbalance in numbers or reasons for missing data across intervention groups; for dichotomous outcome data, the proportion of missing outcomes compared with observed event risk enough to induce clinically relevant bias in intervention effect estimate; for continuous outcome data, plausible effect size (difference in means or standardised difference in means) among missing outcomes enough to induce clinically relevant bias in observed effect; ‘as-treated’ analysis done with substantial departure of the intervention received from that assigned at randomisation; potentially inappropriate application of simple imputation;
  o unclear risk of bias: insufficient information to permit judgement.
• Selective reporting: we assessed reporting bias due to selective outcome reporting as:
  o low risk of bias: study protocol was available, and all the study's prespecified (primary and secondary) outcomes that were of interest in the review were reported in the prespecified way; study protocol was not available, but it was clear that published reports included all expected outcomes, including those that were prespecified;
  o high risk of bias: not all the study's prespecified primary outcomes were reported; one or more primary outcomes were reported by measurements, analysis methods or subsets of data (i.e. subscales) that had not been prespecified; one or more reported primary outcomes were not prespecified (unless clear justification for their reporting was provided, such as an unexpected adverse effect); one or more outcomes of interest in the review had been reported incompletely, so that they could not be entered into a meta-analysis; the study report failed to include results for a key outcome that would be expected to have been reported for such a study;
  o unclear risk of bias: insufficient information to permit judgement.
• Other bias: we analysed bias due to problems not covered elsewhere in the table:
  o low risk of bias: study appeared free of other sources of bias;
  o high risk of bias: study had a potential source of bias related to the specific study design used; stopped early because a data-dependent study design was used; stopped early as the result of a data-dependent process (including a formal stopping rule); had extreme baseline imbalance; was claimed to be fraudulent; had some other problem;
  o unclear risk of bias: insufficient information to assess whether an important risk of bias existed; insufficient rationale or evidence to suggest that an identified problem would introduce bias.

Appendix 3. GRADE
GRADE considers that evidence from randomised controlled trials is 'high' quality but that assessment may be downgraded based on consideration of any of five areas:
• design (risk of bias);
• consistency across studies;
• directness of the evidence;
• precision of estimates; and
• presence of publication bias.

This results in an assessment of the quality of a body of evidence in one of four grades:
• High: we are very confident that the true effect lies close to that of the estimate of the effect.
• Moderate: we are moderately confident in the effect estimate: the true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different.
• Low: our confidence in the effect estimate is limited: the true effect may be substantially different from the estimate of the effect.
• Very low: we have very little confidence in the effect estimate: the true effect is likely to be substantially different from the estimate of effect.
CONTRIBUTIONS OF AUTHORS

All authors developed the protocol.

DN and WMG: screened the search outputs, assessed study eligibility, extracted and synthesised data.

DN and JK assessed risk of bias across key domains and undertook the GRADE assessment with WMG.

All authors revised the final review.

DECLARATIONS OF INTEREST

Nicholas Embleton has conducted research with support from manufacturers of infant formula including Nestec SA (Switzerland), Wyeth UK and Nutricia UK but did not receive any payment, support or benefit in kind for contribution to this review.

The other authors do not have any declarations of interest.

SOURCES OF SUPPORT

Internal sources

- University of York, UK.

External sources

- National Institute for Health Research, UK.

This report is independent research funded by a UK National Institute of Health Research Grant (NIHR) Cochrane Programme Grant (13/89/12). The views expressed in this publication are those of the authors and not necessarily those of the National Health Service, the NIHR or the UK Department of Health.

- Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, USA.

Editorial support of the Cochrane Neonatal Review Group has been funded with Federal funds from the Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, USA, under Contract No. HHSN275201100016C.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

Two trials compared formulas with different energy densities (Schweizer 1993; Riezzo 2001). These did not report growth rates (the reason for prespecifying similar energy levels) so we made consensus decision to include them in the review.
