This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the author guidelines.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the ethical guidelines, outlined in our author and reviewer resource centre, still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Glycosidases are hydrolytic enzymes that catalyze the hydrolysis of oligosaccharides and glycoconjugates. Glycosidases are involved in a broad array of human pathologies and are therefore promising therapeutic targets. Activity-based protein profiling (ABPP) provides an effective tool for the analysis of enzyme composition, expression and activity, and can assist in the discovery of enzyme inhibitors. ABPP relies on the addition of a mechanism-based inhibitor to the sample of interest, which reacts with the catalytic machinery of the target enzyme in a covalent and irreversible manner. The inhibitor carries a reporter tag and is termed an activity-based probe (ABP). As the first example on the development of ABPP, Cravatt and co-workers have described irreversible fluorophosphonate based ABPs which display high reactivity towards a wide range of serine hydrolases (SH). These ABPs were used to reveal active SH composition and expression level in various tissues, and as well in the development of highly specific and potent inhibitors against, for instance, monoacylglycerol lipase in a competitive ABPP setting. Cyclophellitol, first isolated from Phellinus sp., is a covalent irreversible retaining β-glucosidase inhibitor. The configurational isomers, galacto-cyclophellitol (2) and manno-cyclophellitol (3) are inactivators for β-galactosidases and β-mannosidases, respectively, and their selectivity arises from their absolute configurations. We have previously reported several cyclophellitol based ABPs for selective glycosidase profiling. For example, treatment of mouse tissue lysates with acyl ABP 4 resulted in tissue-specific fluorescent labelling of the three retaining β-glucocerebrosidases (GBA1, 2 and 3) and lactase-phlorizin hydrolase (LPH) without non-specific cross-labelling. Later studies revealed that alkyl ABP 5 also effectively labels these retaining β-glucosidases. While the selectivity of these probes is an attractive value, it also impedes the study of multiple enzyme classes with a single probe, as for example can be done by the broad-spectrum SH ABPs developed by Cravatt and co-workers. Therefore, the development of broad spectrum glycosidase ABPs would be of interest. Since the substrate specificity of glucosidases, mannosidases and galactosidases is dependent on the carbohydrate hydroxyl configuration at C2 and C4 (axial or equatorial), removal of these hydroxyls may abolish active site preference. We therefore synthesized four deoxygenated ABPs and we set out to establish whether these compounds would be effective for instance, monoacylglycerol lipase in a competitive ABPP setting.

Fig. 1. (a) Structures of cyclophellitols 1-3, selective covalent and irreversible retaining glycosidase inhibitors. (b) Selective β-glucosidase ABPs 4-5, 4-deoxy ABPs 6-7 and 2,4-deoxy ABPs 8-9.
ABPs indiscriminate towards glucosidases and galactosidases (and for 8-9, mannosidases).

The synthesis of compounds 6-9 was achieved from key intermediates 12 and 15, which were further functionalized to 2,4-deoxy ABPs following similar synthetic transformations (c). Reagents and conditions i) PMBCl, 2-aminomethyl diphenylborinate (10 mol%), K₂CO₃, KI, MeCN, 60 °C, 95%; ii) TsCl, pyridine, 60 °C, 90%; iii) LIAH₄, THF, reflux, 86%; iv) HCl (10%), DCM/CH₂Cl₂, 86%; v) 1. (+)-IpcB₃(allyl)borane, THF, -90 °C; 2. Grubbs II [5 %], DCM, reflux, 77%, dr 86:14; vi) BzCl, Et₃N, DMAP, DCM, 84%; vii) CSA, MeOH, DCM, 94%.

The synthesis of deoxygenated ABPs required two different synthetic strategies (a and b) to afford key intermediates 12 and 15, which were functionalized to ABPs 6-9 following similar synthetic transformations (c). Reagents and conditions i) PMBCl, 2-aminomethyl diphenylborinate (10 mol%), K₂CO₃, KI, MeCN, 60 °C, 95%; ii) TsCl, pyridine, 60 °C, 90%; iii) LIAH₄, THF, reflux, 86%; iv) HCl (10%), DCM/CH₂Cl₂, 86%; v) 1. (+)-IpcB₃(allyl)borane, THF, -90 °C; 2. Grubbs II [5 %], DCM, reflux, 77%, dr 86:14; vi) BzCl, Et₃N, DMAP, DCM, 84%; vii) CSA, MeOH, DCM, 94%.

Scheme 1: The synthesis of deoxygenated ABPs required two different synthetic strategies (a and b) to afford key intermediates 12 and 15, which were further functionalized to 2,4-deoxy ABPs 6-9 following similar synthetic transformations (c). ABPs indiscriminate towards glucosidases and galactosidases (and for 8-9, mannosidases).

The synthesis of compounds 6-9 was achieved from key intermediates 12 and 15, which were prepared as follows. The primary alcohol in diol 10 (available by chemistry developed by Madsen and co-workers, Scheme 1a) was protected as the p-methoxybenzyl ether (PMB) after which tosylation of the corresponding primary imidates (Scheme 1c), which were alkylated with an azidoalkyl spacer and detritylated afforded cyclohexene 15 (Scheme 1b), chiral aldehyde 13 (available by chemistry developed by Helmchen and co-workers) was asymmetrically allylated using Brown’s reagent and subsequently subjected to ring-closing metathesis using the Grubbs 2nd generation catalyst to give 14. Benzoylation and detritylation afforded cyclohexene 15. Both cyclohexenes 12 and 15 could be reacted with trichloroacetontitrile to afford the corresponding primary imidates (Scheme 1c), which upon treatment with N-iodosuccinimide (NIS) cyclized to afford the cyclic imidates 16 and 19 stereospecifically. Acidolysis and base treatment resulted in formation of aziridines 17 and 20, which were alkylated with an azidoalkyl spacer and deprotected to give alkyl aziridines 18 and 21, and then ligated with a reporter tag using click chemistry to afford deoxygenated ABPs 6-9 (see ESI).

The labelling efficiency and specificity towards recombinant β-glucosidases, β-galactosidases and β-mannosidases was investigated for fluorescent ABPs 6 and 8, and compared to that of β-glucosidase selective probe 5. After enzyme incubation with a range of ABP concentrations (30 minutes, 37 °C, optimal enzyme pH), recombinant Homo sapiens GBA1 is highly efficiently labelled by ABP 5, with protein bands visualized at probe concentrations as low as 10 nM (Fig. 2a). Additionally, 4-deoxy ABP 6 also labelled GBA1 efficiently, although the potency was slightly reduced, likely due to lacking hydrogen-bonding interactions within the active site residue(s) as the result of the absence of OH-4. The labelling potency of 2,4-deoxy ABP 8 proved to be drastically reduced. All bands could be competed with selective β-glucosidase inactivator 1. Also, denatured enzyme (1% SDS, 100 °C, 5 min) is not labelled by any of the probes indicating that all labelling is activity-based. As expected, binding kinetics studies revealed that 5 is a far more potent GBA1 inactivator (Kᵢ₅ = 27.51 ± 0.85 µM⁻¹min⁻¹) than 6 (Kᵢ₆ = 0.14 ± 0.08 µM⁻¹min⁻¹). Kinetic parameters for 8 could not be determined under our assay conditions reflecting its low potency. Labelling of Cellvibrio japonicus β-galactosidase from glycoside hydrolase family 35 (Cgh35A) could be detected at micromolar concentrations of 5 and 8. Interestingly, 4-deoxy ABP 6 was significantly more potent and labelled the enzyme at concentrations down to 100 nM, similar to GBA1 labelling; which is surprising given the extensive interactions of O-4, from a galacto-cyclophellitol aziridine, with the enzyme (see ESI). Indeed, kinetic parameters for 6 in Cgh35A (Kᵢ₆ = 0.16 ± 0.07 µM⁻¹min⁻¹) are comparable to that in GBA1 (kinetic parameters of 5 and 8 could not be determined under our assay conditions, due to low potency). Competition experiments indicated the labelling was activity-based, although full competition was not achieved which could indicate a fraction of non-specific binding. Lastly, we found that none of the ABPs showed significant labelling of GH2 β-mannosidase from Helix pomatia (see ESI). Indeed, it is known that OH-2 is highly important for coordination to the glycosidase catalytic nucleophile and stabilizing the transition state (TS). Moreover, probes 5, 6 and 8 mimic preferentially adopt a Hα configuration, which is characteristic for β-glucosidase and β-galactosidase transition states, whereas β-mannosidases often favour a βTS. Next, the glycosidase profiling by probes 6 and 8 in lysates from mouse (C57Bl/6), Jackson’s laboratories) kidney and liver tissue, and human wild-type fibroblast cells (Lonza) was investigated, and compared to that of β-glucosidase selective probe 5. The samples were incubated with the ABPs under identical
In mouse liver lysates, 5 labels a distinct band at ~65 kDa (Fig. 3a), corresponding to the molecular weight of GBA1 (58 - 66 kDa\(^1\)), and this band is fully abolished when the sample was pre-incubated with GBA1 specific inhibitor 1.\(^9\) Similarly, incubation with 6 resulted in a band at the same height. This band could only be partially competed with 1, and pre-incubation by specific β-galactosidase inactivator 2 resulted in partial competition as well. Ultimately, full competition was achieved by pre-incubation with both cyclophellitolos 1 and 2. Thus, in contrast to labelling with 5, it was concluded that incubation with 6 resulted in the concomitant labelling of GBA1 and a β-galactosidase, presumably acid β-galactosidase (GLB1, ~63 kDa).\(^{10}\) To identify the bands labelled on gel, the proteins were enriched by incubation of the lysate with biotin probe 7 and subsequent pull-down with streptavidin beads. After tryptic digestion, the peptide fragments were identified by LC-MS/MS and the abundance of the protein hits was quantified as previously described,\(^{11}\) in unsupervised mode using the default settings of the PLGS (Waters) and IsoQuant software. Indeed, incubation with 7 resulted in enrichment of GBA1 and GLB1, corresponding to the mixed band at ~65 kDa on gel. In contrast, labelling with ABP 8 did not result in labelling of GBA1 or GLB1. Multiple bands were visible on gel, but no competition was observed except for one band at ~115 kDa of an unknown protein. We therefore conclude that the other bands were a result of non-specific binding. Regardless, the lysate was incubated with 9 and the labelled proteins were identified by proteomic analysis. Whereas no enrichment of GBA1 could be detected, the probe did show increased levels of GLB1 labelling. Additionally, LC-MS/MS analysis detected enrichment of β-galactosylceramidase (GALC), an 80 kDa protein which is processed in the lysosomes into two catalytically active subunits of ~30 and ~50 kDa,\(^{12}\) and is responsible for the hydrolysis of galactosylceramide. Interestingly, fluorescent labelling with 8 did not identify GALC on gel. However, it is known that expression levels of GALC in the liver are low.\(^{13}\)

In mouse kidney lysates (Fig. 3b), 5 only labels GBA1 minimally. In contrast, bands at ~65 kDa and ~45 kDa were observed with probe 6 which could be fully competed out by pre-incubation with 2, but not 1. This indicated the labelling of mainly β-galactosidases in this sample, presumably GLB1 and GALC, which was subsequently confirmed by proteomics experiments as described above. Enrichment of GBA1 was also detected but less pronounced, in line with the fluorescent assay. Labelling with probe 6 was also observed for GLB1-like protein 1 (GLB1L, ~68 kDa) and 2 (GLB1L2, processed mass unknown), which both possess the GLB1 active site motif.\(^{14}\) While 2,4-deoxy ABP 8 did not significantly label GBA1 or GLB1, proteomics identified GLB1L and GLB1L2 by pull-down with 9. Interestingly, a strong band at ~45 kDa was labelled, which could be competed with 2. Indeed, proteomics revealed increased labelling of GALC by this probe and it was therefore concluded that 8 is a GALC specific ABP.

Lastly, the labelling of human fibroblast lysates was investigated (Fig. 3c). A pattern of bands between 55-70 kDa is labelled by 5 which can subsequently be fully competed for with 1, indicating the labelling of different isoforms of GBA1 in this lysate. Similarly, 6 labels bands between 55-70 kDa, however with increased signal intensity. Approximately 50% competition was achieved by pre-incubation with either 1 or 2, whereas pre-incubation with both inhibitors completely abrogated labelling. Indeed, pull-down analysis identified both GBA1 and GLB1 enrichment by probe 7. Finally, 8 did not show...
significant labelling of proteins in the sample, whereas GLB1 was enriched by ABP 9 according to LC-MS/MS analysis. In summary, we have developed syntheses towards a set of deoxygenated probes which were modelled on cyclophellitol aziridine 5. None of the probes display activity towards β-mannosidases. Deoxygenation at C2 and C4 (ABPs 8-9) enables labelling of purified β-glucosidases and β-galactosidases, albeit with low potency. Nevertheless, it was found that 8 displayed unexpected specificity towards β-galactosylceramidase in mouse kidney lysate where the enzyme is abundant. Deoxygenation at C4 (ABPs 6-7) affects the binding kinetics for GBA1, however in vitro labelling proceeded with high efficiency and moreover these probes now identify retaining β-galactosidases as well. Based on the results presented herein we conclude that, indeed, probes designed for simultaneously profiling retaining glycosidases processing differently configured glycosides are within reach. We had earlier observed that probes designed for a specific class of retaining glycosidases may possess cross-reactivity towards other glycosidases, however these results could not be predicted. Here, we show that by substitution of the hydroxyl group that distinguishes glucose from galactose for hydrogen on an otherwise unaltered cyclophellitol aziridine yields probes labelling both glucosidases and galactosidases. The strategy is however not general, since stripping off OH-2 yields a largely inactive probe. Future research on differently configured, OH-deleted cyclophellitol aziridines is required to establish if and to what extent this strategy is viable to deliver a set of broad-spectrum glycosidase ABPs, for use in combination with the specific exo-glycosidase probes already in hand for dissecting large numbers of retaining glycosidases from various species. We thank The Netherlands Organization for Scientific Research (NWO-CW, ChemThem grant to JMFGA and HSO), the European Research Council (ERC-2011-AdG-290836 “Chembiosphing” to HSO, and ERC-2012-AdG-322942 “Glycopoise”, to GJD and WAO), Sanofi Genzyme (research grant to JMFGA and HSO and postdoctoral contract to MA), ChemAxon for the Instant JChem software and Diamond Light Source for access to beamline I02 (proposal number mx-9948) that contributed to the results presented here.
