Abstract

Interest in the degradation mechanisms at the modular-taper interfaces has been renewed due to increased reported cases of adverse reactions to metal debris and the appearance of wear and corrosion at the modular taper interfaces at revision. Over the past two decades a lot of research has been expended to understand the degradation mechanisms, with two primary implant loading procedures and orientations used consistently across the literature. ASTM F1875-98 is often used as a guide to understand and benchmark the tribocorrosion processes occurring within the modular-taper interface. This paper presents a comparison of the two methods outlined in ASTM F1875-98 as well as a critique of the standard considering the current paradigm in pre-clinical assessment of modular-tapers.

Keywords: Fretting-Corrosion, Modular-Taper, ASTM F1875-98, High Nitrogen Stainless Steel, CoCrMo

1. Introduction

Interest in the performance of modular metal THR has recently been renewed due to the recent publicity associated with metal-on-metal bearings and the links to adverse reactions to metal debris (ARMD) [1]. Fretting-corrosion at the modular taper interface was first observed clinically at least 25 years ago [2]. Since then extensive effort has been made to understand the mechanisms at play at the modular taper interface and the interaction between implant and patient factors on clinical outcomes. The degradation of modular tapers is widely accepted as ‘mechanically assisted’ crevice corrosion as defined by Goldberg et al [3]. Whilst efforts have been made to optimise the taper interface in the 1990’s, clinical incidence and awareness in the systemic effects of wear and corrosion at these interfaces has increased over the past 5 years [1].

One aspect that has been relatively unchanged is the testing and simulation techniques prescribed for the analysis of modular components. Uni-axial cyclic loading is often described and used extensively in the literature. ASTM F1875-98 [4] is a standard for quantifying the occurrence of fretting corrosion that occurs in the head-stem interface of a modular hip joint. ISO 7206-6 [5] also provides a method of assessment based on an upright stem orientation. Whilst the loading profiles are similar, mounting instructions differ when compared to the ASTM standard. Whilst these are not used to predict in-vivo performance, many researchers are using these methods to understand and interrogate mechanisms occurring in-vivo. Within ASTM F1875-98 two primary test methods, one
‘upright’ and one ‘inverted’, are provided. The inverted method additionally has the choice of two sub-methods, one of which includes electrochemical analysis. A compromise between both scenarios has been adopted in literature, with the integration of electrochemical techniques within the upright ‘physiologically relevant’ sample orientation.

The mechanical loading profile is fundamentally the same for both orientations. However, the use of the inverted test method is not well documented in the literature. Differences such as fluid pressure, fluid ingress and retention of wear debris at the interface may affect the subsequent tribocorrosion processes. Some of these complicating differences likely occur in-vivo with actual components. This paper therefore aims to assess and compare the role of sample orientation on the degradation processes at the modular taper interface. The methods described in the ASTM F1875-98 standard were analysed with the inclusion of in-situ corrosion measurement and further surface analysis. The results and findings of this study will be further discussed and set in context with the current ASTM recommendations.

2. Methodology and Materials

2.1. Components and Apparatus

High nitrogen stainless steel C-Stem AMT femoral stems (12/14 taper, DePuy Synthes, UK) and Ø36 mm M-Spec (DePuy Synthes, UK) high carbon CoCr femoral heads were tested in this study. The solution used for all electrochemical measurements was aerated 0.9% NaCl solution (pH ≈ 7.4) at 37 °C, prepared using analytical grade reagents and deionised water. In each case 100 mL of fluid was used. Prior mounting of the head-stem structure within the test fixtures the femoral head was mounted onto the stem taper according to ASTM F1440 using specially design fixtures to ensure the taper and trunnion were kept concentric. The femoral head was assembled dry using a static load of 2 kN.

The stem orientations investigated in this study are shown in Figure 1. Fixtures were designed to meet the standard but also allow for the same fixture to be used for both orientations. Stemmed components were orientated according to the ASTM F 1440 and fixed using a high edge retention metallographic resin to the cement indication markers given on the femoral stem. In each case, the head – neck interface was immersed in 100 mL of 0.9 g/L NaCl. The head force was actuated against a soft polymer ring to avoid depassivation of the femoral head surface. All components were subjected to a cyclic sinusoidal load (300 – 3300 N) at 1 Hz for 1 million cycles using an E-10k fatigue machine (Instron, UK) to enable comparison of surfaces after each test.

Upon completion of fatigue testing the implants were carefully removed from the fixture and the components were separated. Head-taper pull off tests were conducted according to the ASTM F1440-98. The femoral stem-head combinations were mounted and secured between two parallel plates and secured to the machine test bed with the centre of the femoral head axial to the load cell. The actuator was brought down to the femoral head and a clamp fitted to facilitate a tensile pull off load. No additional load was applied to the femoral head. The actuator was then advanced in the tensile direction at a rate of 2 mm/s. Displacement was ceased when the test load reached 0 kN. The pull-off force was taken as the maximum measured force during separation.
2.2. Electrochemical Test Methods

In all cases, the fixed stem-head components acted as the working electrode (WE), facilitated via a conductive connection to the stem. The site of the connection and remaining interfaces were sealed using a silicone sealant to ensure they did not contribute to electrochemical and mass loss measurements. A combined silver-silver chloride (Ag/AgCl) reference electrode (RE) and platinum (Pt) counter electrode (CE) (Thermo-Scientific, UK) was used to complete the cell. All electrochemical measurements were conducted using an Autolab PGSTAT101 potentiostat (Metrohm, Netherlands) at an acquisition rate of 0.2 Hz.

Two electrochemical methodologies were employed in part reference to ASTM F1875-98:

- For tests where the taper interface was orientated in an upright configuration (Figure 1a), Open Circuit Potential (OCP) of the system was monitored continuously throughout cyclic loading. In this configuration, the potential difference between the test stem and the reference electrode was measured to provide a non-destructive semi-quantitative indication on the severity of corrosion at the taper interface. This is not prescribed by ASTM requirements but was included to facilitate comparison between loading configurations.

- For tests where the taper interface was orientated in an inverted configuration (Figure 1b), Zero Resistance Ammetry (ZRA) was employed as per the ASTM standard for the 'inverted' tests. In this configuration a high nitrogen stainless steel C-Stem AMT femoral stem acted as a second working electrode (WE2) in which the net anodic/cathodic current generated through corrosion and fretting-corrosion could be measured. The second femoral stem was immersed in the test to replicate the area of loaded stem concealed by the resin. The mixed potential of both femoral stems was also measured relative to a RE.

2.3. Surface and Solution Analysis

After testing, the taper interfaces were visually inspected and photographed. For surface form profiling a sub-micron accurate Coordinate Measuring Machine (CMM, Mitutoyo Legex 322, Japan) was used to map the surface using a Ø 1 mm ruby and a point spacing of 0.2 mm. These points on the surface were used to generate a Cartesian coordinate cloud which was then imported into Sphere Profiler (RedLux, UK) software. Deviations from the original surface were analysed by excluding areas of known contact (which can be seen visually) and fitting the surface using conical taper geometric identities. By analysing damage noted on the surface, an estimate of the volume loss could be made.

Inductively Coupled-Mass Spectrometry (ICP-MS) was used to analyse elemental composition of the electrolytes post-test after 1 million cycles. 1 mL of test electrolyte was diluted to 10 mL with HNO₃ prior to analysis. Samples were centrifuged at 1000 RPM for 10 minutes to extract particulate from the electrolyte prior to dilution. Co59, Cr52, Mo96 and Fe57 isotopes were used to analyse test electrolytes.

Optical microscopy (OM) was used to analyse the taper surfaces post simulation. To enable access to the engaged portions of the taper-trunnion interface femoral heads were sectioned by wire erosion
along the axis perpendicular to the toggling motion. Surfaces were imaged at 5mm intervals along the taper.

3. Results

3.1. Electrochemical measurements

Figure 2 shows the evolution of the open circuit and mixed potential over the duration of each test. Two distinct trends were observed; for the upright test (Figure 2a) an initial negative shift in the recorded potential was observed upon the initiation of fatigue, followed by ennoblement of the system to values more positive than noted before loading. For the inverted cell (Figure 2b) upon the application of cyclic loading a sustained decrease in OCP was observed. This remained lower than the original OCP recorded before the application of loading. For the inverted cell, at the point when load ceased, an ennoblement in the OCP was noted. This was not seen for the upright cell.

Figure 3 shows the ZRA net current measurements obtained from the inverted tests. Upon the application of cyclic loading an increase in the current was observed. This indicates an increase in current flow from WE1 to WE2, representing an increase in corrosion at the taper interface. In all cases a positive charge transfer was observed corresponding to a corrosive mass loss from the taper interfaces. Table 1 tabulates these and presents an estimate of the material lost due to corrosion (including static corrosion and mechanically induced corrosion) based on the assumptions that cobalt was the primary corrosion reactions (i.e. $\text{Co} \rightarrow \text{Co}^{2+} + 2e^-$; molar mass = 58.9 g/mol, valence = 2).

3.2. ICP-MS

Figure 4 shows ICP-MS data for solution samples taken after upright (Figure 4a) and inverted (Figure 4b) testing ($n = 3$). Each measurement was conducted three times during each test and the results presented as an average ± standard deviation. Differences were observed between the orientations with the inverted orientation demonstrating increased release of Co and Cr compared to the upright tests. No difference in Mo concentration was observed. An increase in Fe was noted in the upright cell compared to the inverted. In both cases a preferential release of Co was observed accounting for 50-70% of the total ions released. A correspondence between the release of ions in and alloy ratio was not observed.
3.3. Optical Photography

Figure 5 shows both surfaces of the taper interface after 1 million cycles of fatigue loading in the upright cell. Little to no evidence of wear or corrosion was seen after the tests. Light abrasion of the female taper was seen in test 2, although not observed in the other tests.

Figure 6 shows the modular taper surfaces after 1 million cycles in the inverted cell. Evidence of wear and corrosion was observed in all cases. Corrosion deposits on both surfaces was seen. Imprinting of the male trunnion topography on the female taper surface was also observed, especially in ‘test 2’.

3.4. CMM

Figure 7 shows the CMM profiles obtained for the upright tests. Some deviation away from the original surface was observed; in the region of 500 nm and within the accuracy of the machine. Such profiles were consistently observed in all upright test. This is also supported by optical images. Estimated volume loss is 0.20±0.048 mm$^3$.

Figure 8 shows the CMM measurements for the inverted tests. Clear evidence of material loss was observed, with deviations from the original surface similar to those observed in-vivo. A Coup-contra-coup appearance was observed, characteristic of a toggling action. Deviations in the region of 1.5 – 6 µm were observed, with imprinting of the male trunnion threads on the taper surface visible. This is supported with digital photography and visual inspection. Estimated volume loss was 0.84±0.35 mm$^3$.

Figure 9 shows the CMM plots for the male trunnion surface. Due to the nature of the fitting algorithms used, an accurate measurement of surface deviation is not possible due to the course nature of the threads. Qualitative assessment shows no visible loss of threads on either test.

3.1. Optical Light Microscopy

Figure 10 shows OM images taken across the length of the female taper surface. For the upright tests, the surface showed little deviation in surface appearance across the length of the taper with a typically machined surface evident. Towards the top end of the taper, evidence of corrosion was observed. For the inverted tests, evidence of damage was seen within the region of engagement. Evidence of corrosion was seen, along with imprinting of the trunnion thread surface onto the surface of female taper, as indicated by the white arrows. The extent of corrosive damage increase towards the top end of the taper.

4. Discussion

Fretting-corrosion, fretting-crevice corrosion and mechanically assisted crevice corrosion are terms interchangeably used to describe the processes occurring at the interface [1,9]. The use of passive metallic materials has been practiced extensively in the orthopaedic sector since the 1950s. However, when used in load-bearing aqueous environments, corrosion and wear are inevitable. This combination of mechanical and electrochemical factors enhances degradation of materials – better known as tribocorrosion [6]. This describes the co-existence and inseparable action of corrosion and
wear owing to abrasion of the native oxide film and exposure of the reactive bulk alloy. As a result, metallic ions and particles are generated, potentially resulting in local and systemic biological reactions. Whilst an initial body of work was conducted in this area in the 1990’s by Goldberg and co-workers [3, 7-11], simulation methods and interrogation of the test standards remain unexplored.

The results from this study further the current understanding by highlighting some key differences between methods prescribed by ASTM and ISO. Whilst some variables (e.g. durations and loading rates) differed from those described by the standard, this was done to ensure results were comparable between each test series. In summary;

- Differences in outcomes based on component orientation were observed – a higher degree of material loss was observed using ASTM F 1875 method II.
- Inclusion of electrochemical, CMM and ICP-MS methods are vital if degradation mechanisms at the interface are going to be determined.
- Fretting-corrosion at the modular surface can occur in stainless steel – CoCrMo alloys systems; a lesser investigated system despite the high levels of implantation especially in the United Kingdom.

The tribocorrosion processes occurring at the modular taper interface are well studied. However, the investigation of stainless steel-CoCrMo combinations has not received much attention despite its use in UK and EU markets. Gilbert et al [12] presented a systematic study showing high nitrogen stainless steel (Orthinox 90™)-CoCrMo systems to be more susceptible to corrosion when assembled under wet and dry conditions when compared to all CoCrMo systems. Chaplin et al [13] demonstrated evidence of fretting and corrosion on retrieved Exeter stainless steel femoral stems. However when compared to the work presented by Gilbert and Goldberg [7] the extent of corrosion was not as great. Despite this study demonstrating the existence of wear and corrosion at the head-neck interface, reports of clinical revisions are low and high nitrogen stainless steel femoral stems with CoCrMo femoral heads remain the gold standard for cemented THR [14]. Extensive work has been carried out to identify the role of taper variables such as finish, angle, length etc. and the incidence of revision. Morlock et al. along with many other researchers [15-17] have presented data concerning the roles of taper engagement mechanisms and surface finish on the degradation of modular tapers.

Clear differences can be seen between the two different implant orientations suggested by ASTM F 1875-98 with electrochemical, ICP-MS, digital photography and CMM measurements supporting this. Electrochemical measurements proved a useful tool in assessing the effects of implant orientation. A negative shift in potential was observed for both arrangements at the onset of cyclic loading. However, for Method II, a sustained cathodic excursion in OCP was observed in the inverted tests suggesting a sustained increased rate of corrosion. This is complemented by ZRA measurements which indicate a net anodic current exchange from the inverted system suggesting under these conditions, abrasion of the oxide layer is sustained resulting in an increase in corrosion during inverted cyclic loading. For Method I, an ennoblement in the potential for the upright arrangements was observed suggesting a decrease in oxide abrasion and subsequently metal ion release. Although Method I does not prescribe electrochemical measurement, the differences observed in this study demonstrate the need for such measurement methods. ICP-MS supported the electrochemical results. Where a sustained decrease in potential and subsequent increase in current was observed, an increase in the metallic ions found within the test lubricant was seen. Cobalt was
found to be the dominant element (49% of upright ions and 74% of inverted ions) suggesting degradation was concentrated on the CoCrMo taper surface. The increased Co levels may arise to the formation of Cr₂O₃ oxide phases within the interface retaining Cr within the interface similar to that observed at the stem-cement interface [18].

A higher degree of material loss was observed in the inverted system supporting the electrochemical results. In both orientations regions of taper engagement could be visually observed. However transfer of the stem taper ‘threads’ was only observed on the inverted tests (Figure 6 and Figure 10). This transfer is consistent with clinical and other in-vitro observations [19-22]. The role of surface topography and the underlying mechanisms of trunnion thread imprinting onto the CoCrMo female taper surfaces are still not fully understood. Pourzal et al. [17] recently investigated the role of surface topography on the degradation of CoCr/Ti alloy modular taper interfaces. For CoCr-CoCr systems an increase in thread height was associated with lower Goldberg damage scores whilst surface roughness had a dominant influence for CoCr/Ti alloy couples. It must be noted that the correlations reported by Pourzal et al. can only be applied for the material combinations and taper designs reported in this study. Further consideration must be taken before such concepts and findings are applied to other material combinations and taper designs. The manufacturing processes and the way in which the material responds to these processes will also vary between taper designs and manufacturers. It is reasonable to assume that the local interfacial metallurgy, chemistry and mechanical properties will be affected and as a result will impact on the evolution wear and corrosion [23-25]. Whilst consideration of the male taper topography is an important variable in modular taper design, the main driver behind the surface topography in modularity must not be forgotten; to facilitate the use of different head materials. Although topography is one aspect of consideration, it is obvious that the taper machined surface is one variable in a fine balancing act contributing to the design of an optimum modular taper.

Visual evidence of oxide formation within and at the interface was observed further strengthening the ratio of metallic elements found in the solution by ICP-MS. For the inverted tests (Method II), material loss was concentrated at either ends of the bore suggesting a coup-count-coup mechanism (i.e. rocking motion), consistent with in-vitro observations [16]. CMM analysis of the upright system demonstrated minimum deviation from the original surface. This again compliments electrochemical, solution chemistry analysis and visual assessment. In all cases, material loss from the trunnion was limited. Whilst material loss was predominantly from the CoCrMo surface (i.e. taper), ICP-MS indicated higher Fe ion release under Method I – we hypothesise that this occurred as a result of inability for crevice corrosion to occur within the taper interface.

Critique of ISO/ASTM Methodologies

To fully understand the degradation a combined electrochemical, mechanical, surface and solution analytical approach must be taken if advances in modular-taper developments are to be made. Whilst many researchers utilise a combination of these methods, standards do not reflect this. The following aspects of the ISO and ASTM standards will be discussed:

- Sample Orientation
- Electrochemical Evaluation
- Sample Loading
Sample Orientation - Whilst the mechanical loading is assumed to be the same in both configurations, fluid pressures at the interface and the rate at which fluid can penetrate will vary. Although the reasons for this are not fully understood at this time, it is hypothesised that fluid ingress is an important factor at the interface facilitating an increased rate of wear and corrosion. During in-vitro testing it may be the case that during the inverted position, fluid ingress will at a higher rate, electrochemically ‘activating’ areas of the interface that otherwise would be unexposed to the electrolyte and therefore not subject to corrosion processes. Higher rates of degradation will occur due to the synergistic nature of fretting-crevice corrosion when compared to the upright system in which liquid does not penetrate. Although this highlights an important aspect concerning the pre-clinical assessment of modular neck tapers it also raises questions as to the operating environment in-vivo (i.e. could a pressurisation exist due to the surrounding tissues).

Electrochemical Evaluation – Although a debate around the correct electrochemical measurement technique for the long-term evaluation of implants continues between researchers, it can be agreed that such methods provide real-time data regarding the kinetics of the corrosion processes occurring at the interface. ASTM F 1875, the only standard to prescribe electrochemical methods, describes the use of three different electrochemical methods: open circuit potential, potentiostatic polarisation and zero-resistance ammeter measurements, each of which return slightly different measurements. Based on Method I, no electrochemical methods are described. This test method is similar to the one outlined by ISO 7206-6.

Sample Loading – The effects of sample loading and rates also need to be considered when dealing with a tribocorrosion system. Whilst it is universally agreed that a simple sinusoidal loading does not replicate the physiological gait, it is used as a simplified loading profile. Mroczkowski [26] and Pantagorgio et al [19] demonstrated the important of load showing increasing load and torsional bending moments can have an antagonistic effect on the corrosion at the interface. Preuß et al [27] examined the role of bending moment and frictional torque on the rotational stability of modular tapers when mated with a Biolox Ceramic heads under static loading within a hip simulator. It was demonstrated that rotational stability was reduced after frictional rotation although no further analysis was completed. Despite the steps to better understand the role of other motions, work to quantify fretting-corrosion under complex biomechanical loading is still to be done. This includes analysis under standard gait, daily living and extreme conditions. Rates of loading also need to be considered – two different loading rates are given within the standard (Method I: 10 Hz & Method II: 1 Hz). It is unknown if wear and corrosion processes at this interface can be scaled appropriately for different rates of loading. Whilst wear may be considered proportional to the number of loading cycles (assuming a typical Archard’s type relationship) corrosion and its synergies will not as factors such as oxygen transportation and the exchange of fluid within the interface will be affected alerting subsequent rates of re-passivation [7].

5. Summary and Conclusions

The issue of modular taper corrosion is a current and future issue faced by industry and clinicians. However, until effective methods of simulation are developed, future technologies will suffer from the same underpinning flaw. Furthermore, considering the advances in modern hip simulations for the bearing surfaces, simulations for the modular taper still remain primitive, only considering 2D motions at most. It has been observed in this study and the current clinical situations that current test standards do not adequately replicate conditions observed in-vivo. Furthermore, depending on the test method employed, very different damage characteristics could be observed; replicated closer those seen in-vivo. This suggest that despite the large body of work completed in this area, a full appreciation of the environment is not evident. Based on the number of studies that have been published in this area care must be taken when interpreting results as these appear to be both
implant and test system specific (i.e. loading orientation, load actuation). Focussed efforts are needed to develop generally accepted more complex, multi-axis mechanical simulations with in-situ and real time multi-modal sensing capabilities. Furthermore, clarity regarding the test orientation and the inclusion of in-situ electrochemical measurements in all tests where corrosion is dominant is required. This study has also highlighted the importance of fluid penetration and possible retention of debris within the fretting-contact in the degradation of modular-tapers. Whilst we have observed instanced of fretting-corrosion at the interface of stainless steel – CoCrMo contacts, the clinical occurrence remains unclear.

Fig 5: Photographs of surfaces after 1 million cycles of loading in the upright cell

Fig 6: Photographs of surfaces after 1 million cycles of loading in the inverted cell

Fig 7: CMM deviation plots for the female taper of the upright cell. Note that positive deviation represents material loss. a-b represent ‘upright 1’ and ‘upright 2’ respectively (Fig 5).

Fig 8: CMM deviation plots for the female taper of the inverted cell. Note that positive deviation represents material loss. a-b represent ‘inverted 1’ and ‘inverted 2’ respectively (Fig 6).

Fig 9: CMM deviation plots for the male trunnion from the a) ‘upright 1’ and b) ‘inverted 1’ after 1 million cycles of loading. Note that positive deviation represents material gain.

Fig 10: Optical Microscope Images of modular taper surfaces after 1 million cycles. Clear differences in the damage appearance can be seen based on device orientation. White arrows indicated evidence of trunnion thread imprinting.

Table 1 – Total charge transferred over 1 million cycles of loading for inverted systems
