1 | INTRODUCTION

BRCA1 (MIM# 113705) and BRCA2 (MIM# 600185) are tumor suppressor genes and their inactivation promotes cancer development. Carriers of germline pathogenic variants in these genes are at high risk of developing breast and ovarian cancers, and BRCA1/2 gene testing has become a widely used procedure in the clinical management of families suspected of hereditary susceptibility to these malignancies. The individuals within these families, identified as at-risk based on their genetic profile, may benefit from risk-reduction options. However, the usefulness of genetic testing relies on the ability to ascertain the pathogenic nature of the identified genetic variants, which is not necessarily straightforward for small in-frame deletions and insertions, variants in regulatory sequences, missense, synonymous and intronic changes, and variants introducing premature protein-truncating codons at the 3’ end of the coding sequence.

The Evidence-based Network for the Interpretation of Germline Mutant Alleles (ENIGMA) has developed and documented criteria aimed at determining the clinical significance of sequence variants in BRCA genes (https://www.enigmaconsortium.org). The classification, based on a five-class system (Plon et al., 2008), is intended to differentiate high risk variants (risk equivalent to that of protein-truncating pathogenic variants), including pathogenic and likely pathogenic variants (class 5 and 4, respectively), from variants with low or no risk, including not pathogenic and likely not pathogenic variants (class 1 and 2, respectively). Variants for which clinical significance is unclear are placed in class 3 and are referred to as variants of uncertain significance (VUSs).

Although the spliceogenic nature of the BRCA2 c.68-7T > A variant has been demonstrated, its association with cancer risk remains controversial. In this study, we accurately quantified by real-time PCR and digital PCR (dPCR), the BRCA2 isoforms retaining or missing exon 3. In addition, the combined odds ratio for causality of the variant was estimated using genetic and clinical data, and its associated cancer risk was estimated by case-control analysis in 83,636 individuals. Co-occurrence in trans with pathogenic BRCA2 variants was assessed in 5,382 families. Exon 3 exclusion rate was 4.5-fold higher in variant carriers (13%) than controls (3%), indicating an exclusion rate for the c.68-7T > A allele of approximately 20%. The posterior probability of pathogenicity was 7.44 × 10−115. There was neither evidence for increased risk of breast cancer (OR 1.03; 95% CI 0.86–1.24) nor for a deleterious effect of the variant when co-occurring with pathogenic variants. Our data provide for the first time robust evidence of the nonpathogenicity of the BRCA2 c.68-7T > A. Genetic and quantitative transcript analyses together inform the threshold for the ratio between functional and altered BRCA2 isoforms compatible with normal cell function. These findings might be exploited to assess the relevance for cancer risk of other BRCA2 spliceogenic variants.
et al., 2010; Thery et al., 2011; Vreeswijk et al., 2009). A competitive quantitative PCR (qPCR) analysis estimated that the proportion of the Δ3 transcript compared to full length was approximately 25% in variant samples versus 4% in normal samples (Muller et al., 2011). More recently, segregation analyses in two families indicated that the variant did not segregate in the affected branches (Santos et al., 2014). Although a few of the above studies tentatively classified the variant as benign or likely benign, they do not provide robust genetic evidence to justify this conclusion. Conversely, a recent article asserted that the variant was associated with breast cancer, based on a relatively limited case control association study in the Norwegian population (Møller & Hovig, 2017).

As a consequence, to date the classification of c.68-7T > A in databases aggregating information on genomic variations has remained inconclusive. In particular, ClinVar (https://www.ncbi.nlm.nih.gov/clinvar/, last updated: Feb 1, 2018) reports conflicting interpretations classifying the variant as benign (seven entries), likely benign (nine entries) and of uncertain significance (four entries). Moreover, the BIC (Breast Cancer Information Core, https://research.nhgri.nih.gov/bic/) database presently annotates the variant as of unknown clinical importance, pending classification, while the BRCA Share™ (UMD-BRCA2 mutations database) (https://www.umd.be/BRCA2/) classifies it as likely benign.

In the present study, we combined genetic approaches, including a large multicentre case-control study and segregation analysis in a sizable number of families, with qualitative and quantitative analyses of the transcripts, and Mitomycin C growth inhibition test. Our findings provide a robust classification of the BRCA2 c.68-7T > A variant with respect to its effect on cancer risk, and add evidence that splicing pattern alterations do not necessarily lead to pathogenicity.

2 MATERIALS AND METHODS

2.1 Nomenclature

The nucleotide numbering was based on the reference BRCA2 complementary deoxyribonucleic acid (cDNA) sequence NM_000059.3. For the purposes of the study, we defined as ▼ 3 all BRCA2 isoforms retaining exon 3 and as △ 3 all BRCA2 isoforms missing exon 3, irrespective of additional alternative splicing events.

2.2 Cell lines

Epstein-Barr virus (EBV)-immortalized human lymphoblastoid cell lines (LCLs) were obtained as previously described (Colombo et al., 2013). In this analysis 18 LCLs were considered, including six LCLs obtained from women carrying the BRCA2 c.68-7T > A variant and 12 LCLs obtained from healthy female blood donors, recruited at the Istituto Nazionale dei Tumori (INT) of Milan. The c.68-7T > A carriers had been screened in all coding exons and corresponding intron-exon junctions of both BRCA1 and BRCA2. Excluding common polymorphisms, none of them carried additional BRCA gene variants, with a single exception where a protein-truncating variant was detected in BRCA1 (c.1380dupA). Only BRCA2 exon 3 was sequenced in the LCLs from normal controls and no pathogenic variants or VUS were observed. The two BRCA2-deficient cell lines, EUFA423 immortalized fibroblasts (BRCA27691insAT/9900insA) (Howlett et al., 2002) and pancreatic cancer cell line Capan1 (BRCA2c.6174delT) (Goggins et al., 1996) were cultured as described elsewhere (Feng et al., 2011).

2.3 Cytoplasmic RNA isolation and first strand cDNA synthesis

Cytoplasmic RNA was isolated from fresh LCLs using the Cytoplasmic & Nuclear RNA Purification Kit (Norgen BIOTEK CORPORATION, Canada), including the DNase I treatment according to manufacturer’s instructions. The RNA purity and integrity was verified by measuring the A260/A280 ratio and by electrophoresis on agarose gel.

For capillary electrophoresis (CE), allele-specific expression analysis and reverse transcriptase quantitative PCR (RT-qPCR), first strand cDNA was generated using 1 μg RNA, random hexamer primers and Maxima™ H Minus RT (Thermo Scientific), following the manufacturer’s protocol in a final volume of 20 μl. For digital PCR (dPCR), 1 μg RNA was reverse transcribed with Prime-Script RT kit (TaKaRa Biotechnology, Japan) according to the manufacturer’s protocol using a mixture of random and Oligo (dT) primers. No-RT controls, containing all reagents for the reverse transcription but the enzyme, were carried out.

2.4 Capillary electrophoresis analysis

Multiplex fluorescently-labeled PCRs were performed with primers located upstream and downstream of exon 3, to simultaneously amplify both ▼ 3 and △ 3 transcripts, followed by CE analysis. A beta-2-microglobulin (B2M; MIM# 109700) cDNA fragment of 377 bp was co-amplified to normalize CE peaks and allow comparison between cases and controls. The sequences of the primers are listed in Supp. Table S1. PCR amplifications were performed in 20 μl reaction volume containing 2 μl of cDNA solution under end-point conditions. Cycling conditions were as follows: 95°C for 7 min, followed by 35 cycles at 95°C for 30′, 58°C for 30′ and 72°C for 30′. A final 7 min elongation step was performed at 72°C. The fluorescent amplification products were run on an ABI 3130 Genetic Analyzer (Applied Biosystems). GeneScan™ 500 ROX™ dye size standard was used as internal size-standard and size calling was performed with GeneMapper software v4.0 (Applied Biosystems).

2.5 Assessment of allelic expression of ▼ 3 and △ 3 transcripts

The allelic origin of the ▼ 3 and △ 3 transcripts were ascertained by amplification and sequencing of the region containing the common c.-26G > A variant (rs1799943) in the 5′-UTR of BRCA2. PCR reactions were performed as described above. The forward primer was designed to anneal to a region upstream of c.-26G > A and the reverse primers to sequences in exon 3 and across the exon2-exon4 junction, specific of the ▼ 3 and △ 3 transcripts, respectively (Supp. Table S1).
Sequencing conditions were as previously described (Colombo et al., 2013).

2.6 | Quantitative PCR analysis

Specific quantitative assays were designed to capture the expression levels of the ▼3 and Δ3 transcripts. The primer sets (Supp. Table S1) were validated with end-point PCR reactions, and the specificity of the amplification products were confirmed by sequencing.

The qPCR analysis were performed on the Eco real-time PCR system (Illumina) using SYBR® Green I dye chemistry (KAPA SYBR® FAST qPCR Kit, Kapa Biosystems). All reactions were carried out in a final volume of 10 μl containing 1 μl of cDNA and 200 nM of GUSB and ▼3 transcript specific primers, and 300 nM of Δ3 transcript specific primers. The efficiency of qPCR assays was evaluated based on a relative standard curve, using threefold serial dilutions starting from pooled control cDNAs in triplicate. The thermal profile was the same for all assays (95°C for 3 min, followed by 40 cycles of 95°C for 3 sec and 62°C for 20 sec). The melting curve analysis was performed according to default conditions (95°C for 15 sec, 55°C for 15 sec and 95°C for 15 sec). All samples from both cases and controls were individually analyzed in triplicate, and the corresponding average values were considered. No template controls and no-RT controls were included in the analysis. The data, obtained in the form of quantification cycle (Cq), were normalized using the beta-glucuronidase gene (GUSB) (de Brouwer, van Bokhoven, & Kremer, 2006). The obtained values were used to compute, in both normal and mutated samples, BRCA2 exon 3 exclusion rate, that is, the percentage of BRCA2 mRNA isoforms missing exon 3 over the total amount of BRCA2 transcripts, as follows:

\[
\frac{2^{-\Delta Cq_{\Delta3}}}{(2^{-\Delta Cq_{\Delta3}} + 2^{-\Delta Cq_{\sim3}})} \times 100
\]

The distribution of transcript levels in control and mutant LCLs was calculated by normalization to that of pooled control cDNAs (reference sample) using the △△Cq method (Livak & Schmittgen, 2001).

Statistical analysis was performed using GraphPad Prism software (version 5.02). The significance of the results was established using the F test.

2.7 | Digital PCR

The dPCR experiments were performed on a QuantStudio 3D dPCR 20K platform according to the manufacturer’s instructions (Applied Biosystem, Foster City, CA). To detect BRCA2 △3 transcripts, we used a FAM-labeled custom designed TaqMan assay (Applied Biosystems) specific for the exon 2–4 junction (5’-CAAGGAGGA-3’). To detect ▼3 transcripts, we used a 2’-choloro-7’-phenyl-1,4-dichloro-6-carboxy-fluorescein labeled (VIC-labeled) predesigned TaqMan assay (Applied Biosystems, Hs00609076) specific for the exon 3–4 junction (5’-TAGGTAGGAGGAAGTTCC-3’). All relative quantification experiments were performed combining △3 and ▼3 assays in individual chips. dPCR chips were analyzed in the QuantStudio 3D Analysis Suit Cloud software v2.0 (Applied Biosystem, Foster City, CA), defining FAM as target. Default settings were used in all cases. After reviewing automatic assessment of the chip quality by the software, only green flag chips (data meet all quality thresholds, review of the analysis result not required) and yellow flag chips (data meet all quality thresholds, but manual inspection is recommended) were considered for further analyses. We used the target/total ratio, FAM/(FAM+VIC), calculated by the software as a proxy for BRCA2 exon 3 exclusion rate. Different amounts of each sample were individually tested in 20K chips, but only data from the chip with the highest precision (according to the analysis software) was included in the expression analysis shown in Figure 3.

2.8 | Genotyping and sample sets

Direct genotyping of BRCA2 c.68-7T > A was conducted as part of the Collaborative Oncological Gene-environment Study (COGS) detailed elsewhere (Michailidou et al., 2013). This study included genotype results from breast cancer cases and controls participating in the Breast Cancer Association Consortium (BCAC; http://bcac.ccge.medschl.cam.ac.uk/), and from the carriers of assumed pathogenic variants in BRCA genes, participating in the Consortium of Investigators of Modifiers of BRCA1/2 (CIMBA; http://cimba.ccge.medschl.cam.ac.uk/). The BCAC and CIMBA datasets are described in de la Hoya et al., (2016). Information on breast tumor estrogen receptor and grade status were available for 189 variant carrier cases from BCAC. Via the Evidence-based Network for the Interpretation of Germline Mutant Alleles (ENIGMA; https://enigmaconsortium.org/) (Spurdle et al., 2012), we identified 16 families recruited through familial cancer clinics where at least one member tested positive for BRCA2 c.68-7T > A, and test results (negative or positive) were available from at least one relative. All study participants had been previously enrolled into national or regional studies under ethically approved protocols.

2.9 | Statistical methods

The association of the BRCA2 c.68-7T > A variant with breast cancer risk was evaluated in BCAC using logistic regression models, as previously detailed (de la Hoya et al., 2016).

In addition, multifactorial likelihood analysis was conducted as detailed in the Supp. Text. In brief, odds for causality were calculated based on carrier frequency and ages at diagnosis/interview in cases and controls, as previously described (Goldgar et al., 2004).

Bayes scores for segregation were derived as previously described (Thompson, Easton, & Goldgar, 2003). Pathology likelihood ratios (LRs) were applied as indicated in Spurdle et al., (2014). The segregation scores, pathology LRs and case-control LRs are mutually independent and were combined to derive a combined odds for causality as described previously (Goldgar et al., 2004; Goldgar et al., 2008). Prior probability of pathogenicity was assigned based on predicted effect of the variant on splicing, as derived in Valle et al., (2016). Variant classification was based on the IARC 5-tier scheme (Plon et al., 2008).
FIGURE 1 Evaluation of the effects of the BRCA2 c.68-7T > A variant at mRNA level. (A) Capillary electrophoresis analysis of BRCA2 cDNA showing the relative increase of Δ3 transcript and decrease of ▼3 transcript in c.68-7T > A carriers compared to normal controls B2M reference transcript. Since the PCR assays were performed under end-point conditions, the results of these assays were not used to quantify the fold-change of Δ3 versus ▼3 transcript ratio in cases compared to controls. (B) Assessment of allele-specific expression of the ▼3 and Δ3 transcripts in c.68-7T > A carriers and normal controls by analysis of the common c.-26G > A variant. The sequencing of the RT-PCR products obtained by selectively amplifying the ▼3 and Δ3 transcripts in separate reactions (left panels and right panels, respectively) shows that the variant allele, which is in linkage with the A allele of the common variant, retained the ability to synthesize the ▼3 transcript.

2.10 Mitomycin C (MMC) growth inhibition test and statistical analyses

A total of 3 x 10^6 cells/ml were seeded in triplicate in 25 ml flasks and grown for 72 hr in the absence or in the presence of MMC (Sigma-Aldrich) at a final concentration of 170 ng/ml. Percentage of viable cells was determined using trypan blue dye exclusion assay, following the manufacturer’s instruction (Sigma-Aldrich). Statistical differences in cell viability after exposure to MMC compared to controls were determined by two-tailed Student t-test using GraphPad Prism software.

3 RESULTS

3.1 Transcript analyses

3.1.1 Confirmation of Δ3 transcripts increase in variant carriers

The effect of the BRCA2 c.68-7T > A variant at the mRNA level was evaluated by fluorescently-labeled end-point RT-PCR on cDNAs derived from six LCLs obtained from women carrying the investigated variant and from 12 nonvariant carrier females. The visual inspection of the CE outputs confirmed the increase of the Δ3 transcripts and the corresponding decrease of the ▼3 transcripts in variant carriers compared to controls (a representative example is shown in Fig. 1A), in agreement with previous studies (Houdayer et al., 2012; Jarhelle et al., 2016; Sanz et al., 2010; Thery et al., 2011; Vreeswijk et al., 2009).

3.1.2 Quantitative mRNA analyses

To quantify the relative amount of BRCA2 ▼3 and Δ3 transcripts in LCLs from both normal individuals (n = 12) and variant carriers (n = 6), a qPCR analysis was performed. The analysis showed a 3.1-fold increase in the relative level of Δ3 transcripts (p < 10^-4) in carriers (average 2.98; range 1.28–4.31) compared to controls (average 0.97; range 0.79–1.23) and a 0.5-fold not statistically significant (p = 0.4) decrease in the relative level of ▼3 transcripts in carriers (average 0.44; range 0.27–0.66) compared to controls (average 0.86; range 0.49–1.11) (Fig. 2).

The relative quantification of Δ3 and ▼3 transcripts in each sample allowed us to compare the exon 3 exclusion rates (see methods) in carriers and controls and to obtain a quantitative score reflecting the magnitude of the splicing alteration induced by the variant. The exclusion rate in LCLs carrying the variant allele was 5.2-fold higher.
Co-occurrence of the c.68-7T>A variant (Supp. Table S2). To exclude a bias due to preferential exclusion of the c.68-7T>A carrier cases but not controls. However, the OR was similar after exclusion of four studies that performed such genetic testing, (OR 1.09; 95% CI 0.89–1.33). The odds for causality based on carrier frequency and ages at diagnosis/interview in these cases and controls was 9.44 × 10^-9. There was also strong evidence against causality from segregation analysis (6.39 × 10^-9) and breast tumor pathology (2.40 × 10^-14). Considering all data together, and assigning prior probability of 0.34 based on splicing prediction, the posterior probability of pathogenicity was calculated to be 7.44 × 10^-115 (see Supp. Text for further details).

3.4 | Evaluation of the effect of the BRCA2 c.68-7T>A on cellular sensitivity to mitomycin C

Carriers of bi-allelic BRCA2 inactivating variants are affected with Fanconi Anemia (FA), complementation group D1. FA is characterized by congenital defects, including anatomical abnormalities, congenital disabilities and increased risk of cancer, most often acute myelogenous leukemia (Auerbach, 2009). In addition, the cells of FA patients exhibit hypersensitivity to DNA interstrand cross-links (ICLs) caused by agents such as mitomycin C (MMC) (Godthelp et al., 2006). A breast cancer−affected woman, with no clinical signs of FA, was found by segregation analysis to carry the truncating BRCA2 c.5722_5723delCT variant in trans with the c.68-7T>A variant (Supp. Table S2). To exclude an FA phenotype at the cellular level, we evaluated the sensitivity to MMC of an LCL derived from this patient. An LCL carrying one copy of the c.68-7T>A variant in trans with the wild-type c.68-7T>A was identified in 242/41,890 (0.58%) invasive breast cancer cases and 216/41,746 (0.52%) controls of reported European ancestry recruited through BCAC studies. Standard case-control analysis adjusted for six principle components yielded an odds ratio (OR) of 1.03 (95% CI 0.86–1.24). However, some studies indicated that they had performed BRCA1/2 mutation screening of cases and might have excluded cases with BRCA1/2 VUS. This could have created a bias due to preferential exclusion of the c.68-7T>A carrier cases but not controls. However, the OR was similar after exclusion of four studies that performed such genetic testing, (OR 1.09; 95% CI 0.89–1.33). The odds for causality based on carrier frequency and ages at diagnosis/interview in these cases and controls was 9.44 × 10^-9. There was also strong evidence against causality from segregation analysis (6.39 × 10^-9) and breast tumor pathology (2.40 × 10^-14). Considering all data together, and assigning prior probability of 0.34 based on splicing prediction, the posterior probability of pathogenicity was calculated to be 7.44 × 10^-115 (see Supp. Text for further details).

3.3 | Co-occurrence of the c.68-7T>A with pathogenic variants

Overall 15 female individuals from 13 apparently unrelated families with clear evidence of the c.68-7T>A being in trans with a pathogenic variant in BRCA2 were assessed. Thirteen individuals from 11 families were detected through the genotyping of the CIMBA sample set, one was reported via the ENIGMA consortium, and another one was ascertained at INT (Supp. Table S2). None of these cases was included in the RNA analyses described above.
with that of the untreated cells. As shown in Supp. Figure S2, EUFA423 (FA-D1) and Capan1 cells showed a significant decrease of the cellular viability (p < 0.01) after exposure to MMC, while no differences were observed in LCLs from normal donor and carriers of BRCA2 c.68-7T > A, either in heterozygosity or in trans with the pathogenic variant.

4 | DISCUSSION

In the present study, we analyzed the BRCA2 c.68-7T > A variant, located in the proximity of the acceptor site of exon 3, in order to establish its clinical relevance and association with breast cancer risk. In accordance with previous studies (Houdayer et al., 2012; Jarhelle et al., 2016; Sanz et al., 2010; Ther& et al., 2011; Vreeswijk et al., 2009), we observed that this variant leads to a modest increased expression of the transcript lacking exon 3 (∆3) in carriers compared to controls. Moreover, we found that in LCLs of carriers of the variant the exon 3 exclusion rate (i.e., the relative amount of BRCA2 ∆3 transcripts) was approximately 4- to 5-fold higher than in LCLs of controls and the total amount of √3 transcripts in carriers was approximately 50% compared to controls. The latter finding would seem to contradict the observation that the variant allele maintains the ability to express a transcript coding for a normal (full-length) protein. The apparent discrepancy may be explained comparing the overall expression of BRCA2 transcripts in cases and controls. In fact, summing up in each sample the amount of √3 and ∆3 transcripts assessed by qPCR, and setting as 1 the average expression of BRCA2 mRNA observed in our cohort, we observed notable inter-individual variability (ranging from 0.43 to 1.50), with many control samples clustering above the average (Supp. Figure S3). Hence, it is very much possible that the strong reduction in the amount of √3 transcripts observed in carriers simply reflects random inter-individual variability in BRCA2 gene expression levels.

Although the above findings were confirmed using two complementary assays (qPCR and dPCR), it must be noted that the outcomes of transcript quantification analyses may be influenced by the nature of examined biological material. Therefore, the magnitude of changes in transcript ratio associated with the c.68-7A > T should be verified also in samples other than LCLs.

The pathogenic implication of BRCA2 exon 3 deletion has been long debated. Exon 3 is 249-bp long and its deletion does not alter the open reading frame. In addition, the ∆3 isoform has been described as one of the major naturally occurring alternatively splicing events in BRCA2 (Fackenthal et al., 2016). However, the predicted protein product is expected to be lacking important functional activities. In fact, this exon codes for BRCA2 amino acids 23 to 106, including the C-terminal portion of a primary transactivating domain (PAR, amino-acid residues 18–60) and an auxiliary transactivating domain (AAR, residues 60–105) (Milner, Ponder, Hughes-Davies, Seltmann, & Kouzarides, 1997), whose activity may be regulated by phosphorylation (Milner, Fuks, Hughes-Davies, & Kouzarides, 2000). Interestingly, the region spanning residues 21–39 mediates the interaction with PALB2, a nuclear protein that promotes the stable intranuclear localization and accumulation of BRCA2, making possible its DNA recombinational repair and checkpoint functions, eliciting tumor suppression (Oliver, Swift, Lord, Ashworth, & Pearl, 2009; Xia et al., 2006). Moreover, the PALB2-binding site directly overlaps that of EMTY, another nuclear protein that has endogenous transcriptional repressor activity (Hughes-Davies et al., 2003).

Several BRCA2 alterations causing the complete loss of exon 3 and the exclusive synthesis of ∆3 transcripts have been ascertained, including c.316 + 5G > C (Bonnet et al., 2008), c.316 + 3delA and c.68-925,316 + 2889del (Muller et al., 2011) and c.156,157insAlu, a variant reported as a founder Portuguese mutation (Peixoto et al., 2009).

The characterization of the above variants supports the hypothesis that the exclusive synthesis of the ∆3 transcripts from one allele has a pathogenic effect. On the contrary, the association with cancer risk of variants that, like the c.68-7T > A, increase the relative amount of ∆3 isoforms but maintain the ability of transcribe a full-length mRNA, is presently unclear. Indeed, the classification of the variants with incomplete effects at the transcript level represents an important and challenging question. According to current ENIGMA criteria, splicing variants leading to in-frame deletions, but maintaining the ability to produce mRNA transcript(s) predicted to encode intact full-length protein, cannot be assumed as pathogenic or likely pathogenic, even if targeting clinical relevant domains. Such alterations require further investigation to assess pathogenicity.

To address the issue, we performed a multifactorial-likelihood analysis combining the odds for causality derived from a large case-control study, using the datasets of BCAC, pathology likelihood based on breast tumor phenotype, and co-segregation data from ENIGMA. Overall, the posterior probability of c.68-7T > A being pathogenic was 7.44 × 10⁻¹¹⁵. This value is well below the threshold established by ENIGMA for a BRCA1/2 variant to be classified as class 1, that is, not pathogenic (probability of pathogenicity < 0.001), when considered against characteristics of the average truncating pathogenic variant.

In addition, the confidence interval of the odds ratio estimate (OR 1.09: 95%CI 0.89–1.33) excludes even moderate breast cancer risk (Hollestelle, Wasielewski, Martens, & Schutte, 2010).

Additional evidence of the non-pathogenicity of c.68-7T > A was provided by the observation of its occurrence in trans with a BRCA2 pathogenic variant in 15 unrelated individuals, including 13 from 11 of 5,284 families recruited by CIMBA and genotyped for the variant. If c.68-7T > A were pathogenic, the frequency of unrelated FA affected individuals among CIMBA BRCA2 mutation carriers would be approximately 2.1 in 1,000, which is inconsistent with the frequency observed in the general population, that is, two to six in 1,000,000 (Bogliolo & Surralles, 2015). Finally, no evidence of hypersensitivity to DNA ICL agents, a characteristic of FA patients, was detected in an LCL derived from one of the individuals carrying a pathogenic variant in trans with the c.68-7T > A. Together, these findings indicate that carriers of the BRCA2 c.68-7T > A variant should not be counseled to undergo the clinical interventions recommended to carriers of high risk BRCA gene variants.

While the present article was under review, a study was published claiming that the BRCA2 c.68-7T > A variant was associated with breast cancer (Møller & Hovig, 2017). This conclusion was based on
the detection of the variant in 17 out of 714 (2.4%; 95%CI 1.4%–3.8%) Norwegian unrelated breast cancer kindreds, a frequency significantly higher (p < 0.0001) compared to the prevalence of the variant in a sample of the Norwegian population (3/1588 = 0.2%). Segregation data based on a single family was inconclusive (LR 0.36), and the estimate of prospective incidence rate in 24 variant carriers overlapped that for the general population. The authors concluded (assumedly based on their case-control findings alone) that carriers of the BRCA2 c.68-7T > A variant have increased risk for breast cancer in families selected due to aggregation of breast cancer, and state in their discussion “…carriers of the variant should be informed that they probably have a clinically actionable pathogenic variant and referred to health care accordingly”. We believe that the conclusion of Moller and Hovig (2017) is unjustified, and disagree with their recommendation on clinical action. Our much larger study (sample size 59x for cases and 26x for controls) including individuals from multiple different countries provide no evidence for increased risk of breast cases in familial cases carrying this variant: the OR was 1.03 (95% CI 0.86–1.24) including all studies, and the risk estimate was nominally greater although not significantly different (OR 1.09, 95% CI 0.89–1.33) after excluding familial breast cancer cohorts.

The difference between the findings from our much larger case-control study and that of Moller & Hovig, (2017) need for caution when utilizing case-control data for clinical interpretation of rare variants, such that significant differences in frequency can nonetheless be unreliable due to random error and bias arising from small sample size, incomplete matching of cases and controls, and when considering familial cases, co-occurrence of (other) risk-related genetic factors as acknowledged by the authors themselves.

Different hypotheses, not necessarily mutually exclusive, can be proposed to explain the lack of pathogenicity of c.68-7T > A despite it being spliceogenic. First, the reduction in full-length BRCA2 mRNAs in variant carriers compared to normal controls, which was not statistically significant, might not be enough to affect cellular tumor suppressor activity. Second, the Δ3 transcripts are predicted to lead to the synthesis of an unstable and nonfunctional protein product and, therefore, unlikely to interfere with the activity of the normal protein due to the loss of the PALB2 interaction domain, whose binding stabilizes the BRCA2 protein (Xia et al., 2006). Assuming that in the examined samples, the overall BRCA2 expression level from both alleles is similar, and that in carrier samples the accompanying normal alleles contribute on average an exclusion rate of approximately 3% as assessed by our quantitative analyses, we estimated, based on an average cumulative exclusion rate of both alleles in variant carriers of 13%, that the average exclusion rate (x) for the c.68-7T > A allele is close to 23% [x% + 3%/2 = 13%]. Therefore, the present study strongly suggests that BRCA2 spliceogenic alleles demonstrating up to approximately 20% exon 3 exclusion rates are not associated with high or even moderate risk of cancer.

The classification of variants based on mRNA splicing data alone is problematic for spliceogenic variants that lead to equivocal or ‘leaky’ transcript profiles. The quantitative in vitro transcript and genetic analyses conducted for BRCA2 c.68-7T > C provide important data to inform the threshold for ratio between functionally proficient and altered BRCA2 isoforms compatible with normal cell function. These findings might facilitate the future classification of rare spliceogenic variants whose relevance for cancer risk cannot easily be ascertained through multifactorial likelihood analyses.

**ENIGMA COLLABORATORS**

We thank Bent Ejlersen, Department of Oncology, and Anne-Marie Gerdes, Department of Clinical Genetics, Rigshospitalet, Copenhagen, Denmark for recruitment and genetic counselling of breast cancer patients.

**BCAC STUDIES AND COLLABORATORS**

**ABCFS:** Maggie Angelakos, Judi Maskiell, Gillian Dite. **ABCS:** Blood bank Sanquin, The Netherlands. **BBCS:** Eileen Williams, Elaine Ryder-Mills, Cara Sargus. **BIGGS:** Niall McInerney, Gabrielle Colleran, Andrew Rowan, Angela Jones. **BSUCH:** Peter Bugert, Medical Faculty Mannheim. **CGPS:** staff and participants of the Copenhagen General Population Study, and Dorthe Uldall Andersen, Maria Birna Arnadottir, Anne Bank, Dorthe Kjeldgaard Hansen for the excellent technical assistance. The Danish Cancer Biobank is acknowledged for providing infrastructure for the collection of blood samples for the cases. **CNIO-BCS:** Guillermo Pita, Charo Alonso, Nuria Alvarez, Pilar Zamora, Primitiva Menendez, the Human Genotyping-CEGEN Unit (CNIO). **CTS:** the CTS Steering Committee includes Leslie Bernstein, James Lacey, Sophia Wang, Huiyan Ma, and Jessica Clague DeHart at the Beckman Research Institute of City of Hope, Dennis Deapen, Rich Pinder, and Eunjung Lee at the University of Southern California, Pam Horn-Ross, Peggy Reynolds, Christina Clarke Dur and David Nelson at the Cancer Prevention Institute of California, Argyrios Ziozias, and Hannah Park at the University of California Irvine, and Fred Schumacher at Case Western University. **ESTHER:** Hartwig Ziegler, Sonja Wolf, Volker Herrmann, Christa Stegmaier, Katja Butterbach. **GC-HBCO:** Stefanie Engert, Heide Heilebrand, Sandra Kröber and LIFE - Leipzig Research Centre for Civilization Diseases (Markus Loeffler, Joachim Thiery, Matthias Nüchter, Ronny Baber). **GENICA Network:** Dr. Margarete Fischer-Bosch-Institute of Clinical Pharmacology, Stuttgart, and University of Tübingen, Germany [HB, Wing-Wei Lo, Christina Justenhoven], German Cancer Consortium (DKTK) and German Cancer Research Center (DKFZ) [HB], Department of Internal Medicine, Evangelische Kliniken Bonn gGmbH, Johanniter Krankenhaus, Bonn, Germany [Yon-Oschun Ko, Christian Baisch], Institute of Pathology, University of Bonn, Germany [Hans-Peter Fischer], Molecular Genetics of Breast Cancer, Deutsches Krebsforschungszentrum (DKFZ), Heidelberg, Germany [UH], Institute for Prevention and Occupational Medicine of the German Social Accident Insurance, Institute of the Ruhr University Bochum (IPa), Bochum, Germany [Thomas Brüning, Beate Pesch, Sylvia Rabstein, Anne Lotz]; and Institute of Occupational Medicine and Maritime Medicine, University Medical Center Hamburg-Eppendorf, Germany [Volker Harth]. **HEBCS:** Sofia Khan, Johanna Kiiski, Carl Blomqvist, Rainer Fagerholm, Kirsimari Aaltonen, Karl von Smitten, Irja Erkkilä. **HMBCS:** Peter Hillelmanns, Hans Christiansen and Johann H.
