One Sentence Summary: East Asia is the source of amphibian panzootic chytrid fungi causing global amphibian declines that have emerged during the 20th century.
Abstract:

Globalized infectious diseases are causing species declines worldwide but their source often remains elusive. We use whole-genome sequencing to solve the spatiotemporal origins of the most devastating panzootic to date, caused by the fungus *Batrachochytrium dendrobatidis*, a proximate driver of global amphibian declines. We trace the source of *B. dendrobatidis* to the Korean peninsula where one lineage, *BdASIA-1*, exhibits the genetic hallmarks of an ancestral population that seeded the panzootic. We date the emergence of this pathogen to the early 20th century coinciding with the global expansion of commercial trade in amphibians and show that intercontinental transmission is ongoing. Our findings point to East Asia as a geographic hotspot for *B. dendrobatidis* biodiversity, and the original source of these lineages that now parasitize amphibians worldwide.
Main Text:

Discovery of the amphibian-killing fungus *Batrachochytrium dendrobatidis* (1, 2) was a turning point in understanding why amphibian species worldwide are in steep decline. Amphibian declines and extinctions had been recorded by herpetologists as early as the 1970s, but were only recognized at a landmark meeting in 1990 as a global phenomenon which could not be explained by environmental changes and anthropogenic factors alone (3).

The emergence of *B. dendrobatidis* and the disease that it causes, amphibian chytridiomycosis, as a causative agent of declines has been documented across six different regions: Australia (~1970s and 1990s) (4), Central America (~1970s) (5), South America (~1970s and 1980s) (6, 7), the Caribbean islands (~2000s) (8), the North American Sierra Nevada (~1980s and 1990s) (9), and the Iberian Peninsula (~1990s) (10). The panzootic has been attributed to the emergence of a single *B. dendrobatidis* lineage, known as *BdGPL* (Global Panzootic Lineage) (11). However, twenty years after identification of the disease, the timing of its worldwide expansion remains unknown and previous estimates for time to most recent common ancestor (TMRCA) for *BdGPL* span two orders of magnitude, from 100 ybp (11) to 26,000 ybp (12). The geographic origin of the pathogen is similarly contested, with the source of the disease variously suggested to be Africa (13), North America (14), South America (15), Japan (16) and East Asia (17).

Global diversity of *B. dendrobatidis*

To resolve these inconsistencies, we isolated *B. dendrobatidis* from all the candidate source continents and sequenced the genomes of 177 isolates to high depth then combined our data with published genomes from three prior studies (11, 12, 18) to generate a globally representative panel of 234 isolates (Fig. 1A). This dataset covers all continents from which *B. dendrobatidis* has been detected to date, and spans infections of all three extant orders of
Amphibia (Fig. S1 and Table S1). Mapped against the *B. dendrobatidis* reference genome JEL423, our sequencing recovered 586,005 segregating single nucleotide polymorphisms (SNPs). Phylogenetic analysis recovered all previously detected divergent lineages (Fig. 1B and Fig. S2). The previously accepted lineages *BdGPL* (global), *BdCAPE* (African), *BdCH* (European) and *BdBRAZIL* (Brazilian), were all detected (19), but our discovery of a new hyperdiverse lineage in amphibians native to the Korean peninsula (*BdASIA-1*) redefined these lineages and their relationships. The *BdCH* lineage, which was previously thought to be enzootic to Switzerland (11) now groups with the *BdASIA-1* lineage. A second Asian-associated lineage (*BdASIA-2*) was recovered from invasive North American bullfrogs in Korea and is closely related to the lineage that is enzootic to the Brazilian Atlantic forest (*BdBRAZIL*) (20). It was not possible to infer the direction of intercontinental spread between isolates within this lineage so it was named *BdASIA-2/BdBRAZIL*. Conditional on the midpoint rooting of the phylogeny in Fig. 1B, we now define the main diverged lineages as *BdGPL*, *BdCAPE*, *BdASIA-1* (which includes the single *BdCH* isolate) and *BdASIA-2/BdBRAZIL*. Previous phylogenetic relationships developed using the widely used ribosomal intragenic spacer ITS-1 region do not accurately distinguish *B. dendrobatidis* lineages (Fig. S3) and this likely explains much of the place-of-origin conflict in the literature (15-17).

Pairwise comparisons among isolates within each lineage show that the average number of segregating sites is three-fold greater for *BdASIA-1* than for any other lineage (Fig. 1A and Table 1) and that nucleotide diversity (\(\pi\); Fig. S4) is two to four-fold greater. Seven of our eight *BdASIA-1* isolates were recently cultured from wild South Korean frogs while the other came from the pet-trade in Belgium, all of which were aclinical infections. These isolates show that the Korean peninsula is a global centre of *B. dendrobatidis* diversity and that East Asia may contain the ancestral population of *B. dendrobatidis*, as suggested by Bataille *et al*
We investigated this hypothesis further using Bayesian-based haplotype clustering (21) and found the greatest haplotype sharing among isolates within BdASIA-1 and between BdASIA-1 and all other lineages. This provides direct genetic evidence that BdASIA-1 shares more diversity with the global population of B. dendrobatidis than any other lineage (Fig. S5). In an independent test of ancestry, we used OrthoMCL (22) to root a B. dendrobatidis phylogeny to its closest known relative B. salamandrivorans which currently threatens salamanders (23). This tree indicates that the Asian and Brazilian isolates of B. dendrobatidis lie outside a clade comprising all other isolates (Fig. S6 and Table S2). To identify the signature of demographic histories across lineages we used Tajima’s D (24). Genome scans of most lineages showed highly variable positive and negative values of D with maxima exhibited by BdGPL (-2.6 to +6.2; Fig. 2F), indicating that these lineages (BdASIA-2/BdBRAZIL, BdCAPE and BdGPL) have undergone episodes of population fluctuation, strong natural selection, or both, that are consistent with a history of spatial and host radiations. In striking contrast, BdASIA-1 shows a flat profile for Tajima’s D (Fig. 2F) indicating mutation-drift equilibrium likely reflective of pathogen endemism in this region.

**Dating the emergence of BdGPL**

The broad range of previous estimates for the TMRCA of BdGPL spanning 26,000 years (11, 12) can be explained by two sources of inaccuracy: (1) unaccounted recombination and (2) the application of unrealistic evolutionary rates. To address these, we first interrogated the 178,280 kbp mitochondrial genome (mtDNA), which has high copy number and low rates of recombination compared to the nuclear genome. To resolve the structure of the mtDNA genome we resorted to long-read sequencing using a MinION device (Oxford Nanopore Technologies, Cambridge, UK), which allowed us to describe this molecules unusual configuration; *Batrachochytrium dendrobatidis* carries three linear mitochondrial segments, each having inverted repeats at the termini with conserved mitochondrial genes spread over
two of the segments (Fig. S7). Additionally, we sought regions of the autosomal genome with low rates of recombination to obtain an independent estimate of the TMRCA of BdGPL.

Detection of crossover events in the *B. dendrobatidis* autosomal genome (18) using a subset of the isolates in this study revealed a large (1.66Mbp) region of Supercontig_1.2 in BdGPL that exhibits several features that identified it as a recombination ‘coldspot’: (1) a continuous region of reduced Tajima’s *D* (Fig. 2D); (2) sustained high values of *F*$_{ST}$ when compared with all other lineages (Fig. 3A); (3) a continuous region of reduced nucleotide diversity (*π*, Fig. S4) and (4) shared loss-of-heterozygosity (Fig. S8). We expanded sampling to infer the temporal range of pathogen introductions using a broad panel of isolates with known date of isolation (*n* = 184, ranging from 1998 to 2016) and whole-genome RNA-baiting to obtain reads from preserved amphibians that had died of chytridiomycosis. We then investigated whether our dataset contained sufficient signal to perform tip-dating inferences by building phylogenetic trees using PhyML (25) (Fig. 2A and 2C) then fitting root-to-tip distances to collection dates both at the whole-tree and within-lineage scales. We observed a positive and significant correlation within BdGPL only, for both the mitochondrial and nuclear genomes, demonstrating sufficient temporal signal to perform thorough tip-dating inferences at this evolutionary scale (Fig. 2B and 2D).

Tip-dating in BEAST was used to co-estimate ancestral divergence times and the rate at which mutations accumulate within the *Bd*GPL lineage. The mean mitochondrial substitution rate was 1.01 x 10^{-6} substitutions/site/year (95% highest posterior density (HPD) 4.29 x 10^{-7} – 1.62 x 10^{-6}). The mean nuclear substitution rate was 7.29 x 10^{-7} substitutions/site/year (95% HPD 3.41 x 10^{-7} – 1.14 x 10^{-6}), which is comparable to a recent report of an evolutionary rate of 2.4 – 2.6 x 10^{-6} substitutions/site/year for another unicellular yeast, *Saccharomyces cerevisiae* beer strains (26). These estimates are over 300-fold faster than the rate used in a
previous study (12) to obtain a TMRCA of 26,400 years for BdGPL. Accordingly, we estimate the ancestor of the amphibian panzootic BdGPL originated between 120 and 50 years ago (Fig. 2E), with HPD estimates of 1898 [95% HPD 1809-1941] and 1962 [95% HPD 1859-1988] for the nuclear and mitochondrial dating analyses respectively (Fig. 2F).

We considered an additional calibration approach for the TMRCA of the mitochondrial genome where we included informative priors on nodes around the dates for the first historical descriptions of BdGPL detection in Australia (1978), Central America (1972), Sierra de Guadarrama (Europe) (1997), and the Pyrenees (Europe) (2000). We did not include priors for nodes where observed declines have been reported, but where the lineage responsible for those declines is unknown. This mixed dating method based on tips and nodes calibration yielded very similar estimates (TMRCA estimates of 1975 [95% HPD 1939–1989] (Fig. S9)), further strengthening our confidence in a recent date of emergence for BdGPL. An expansion of BdGPL in the 20th century coincides with the global expansion in amphibians traded for exotic pets, medical and food purposes (27, 28). Within our phylogeny, we found representatives from all lineages among traded animals (Figs. S10-14), and identified ten events where traded amphibians were infected with non-enzootic isolates (Fig. 4). This finding demonstrates the ongoing failure of international biosecurity despite the listing of B. dendrobatidis by the World Organisation for Animal Health (the OIE) in 2008.

Hybridisation between recontacting lineages of B. dendrobatidis

To determine the extent to which the four main lineages of B. dendrobatidis have undergone recent genetic exchange, we used the site-by-site based approach implemented in STRUCTURE (29). Although most isolates could be assigned unambiguously to one of the four main lineages, we identified three hybrid genotypes (Fig. 3B), including one previously reported hybrid (isolate CLFT024/2) (20), and discovered two newly identified hybrids of
BdGPL and BdCAPE in South Africa. Furthermore, BdCH (isolate 0739) appears to be a chimera of multiple lineages that may represent unsampled genomic diversity that resides in East Asia, rather than true hybridisation. These hybrid genomes demonstrate that *B. dendrobatidis* is continuing to exchange haplotypes among lineages when they interact following continental invasions, generating novel genomic diversity. We analysed isolate clustering using principle components analysis on a filtered subset of 3,900 SNPs in linkage equilibrium, revealing an overall population structure that is consistent with our phylogenetic analyses (Fig 3C). In addition, the putatively identified hybrid isolates of *B. dendrobatidis* were shown to fall between main lineage clusters (Fig. 3C) further strengthening our hypothesis of haplotype exchange occurring during secondary contact between lineages.

**Associations among lineage, virulence and declines**

Genotypic diversification of pathogens is commonly associated with diversification of traits associated with host exploitation (30), and is most commonly measured as the ability to infect a host and to cause disease post-infection. We tested for variation of these two phenotypic traits across four *B. dendrobatidis* lineages by exposing larval and post-metamorphic common toads (*Bufo bufo*). Larvae are highly susceptible to infection but do not die before metamorphosis, in contrast to post-metamorphic juveniles, which are susceptible to infection and fatal chytridiomycosis (31). In tadpoles, both BdGPL and BdASIA-1 were significantly more infectious than BdCAPE and BdCH (Fig. S15 and Tables S3 & S4). In metamorphs, BdGPL was significantly more infectious than the other treatments, compared to the control group, and significantly more lethal in experimental challenge, than the geographically more restricted BdCAPE, BdASIA-1 and BdCH (Fig. 2G). We further tested for differences in virulence among lineages by using our global dataset to examine whether chytridiomycosis was non-randomly associated with *B. dendrobatidis* lineage. We detected a significant
difference ($p < 0.001$) in the proportion of isolates associated with chytridiomycosis among the three parental lineages (BdASIA-1 and BdASIA-2/BdBRAZIL were grouped due to low sample sizes), and post hoc tests indicated significant excess in virulence in both BdGPL and BdCAPE lineages relative to the combined BdASIA-1 and BdASIA-2/BdBRAZIL (all $p < 0.05$). However, we did not detect a significant difference between BdGPL and BdCAPE (Fig. S16 and Table S5). These data suggest that although BdGPL is highly virulent, population-level outcomes are also context dependent (32); under some conditions other lineages can also be responsible for lethal amphibian disease and population declines (33).

**Historical and contemporary implications of panzootic chytridiomycosis**

Our results point to endemism of *B. dendrobatidis* in Asia, out of which multiple panzootic lineages have emerged. These emergent diasporas include the virulent and highly transmissible BdGPL which spread during the early 20th century via a yet unknown route to infect close to 700 amphibian species out of ~1300 thus far tested (34). With over 7800 amphibian species currently described, the number of affected species is likely to rise. The international trade in amphibians has undoubtedly contributed directly to vectoring this pathogen worldwide (Fig. 4; 35,36), and within our phylogeny we identified many highly supported ($\geq 90\%$ bootstrap support) clades on short branches that linked isolates collected from wild amphibian populations across different continents (Fig. 4; Fig. S10-S14).

However, the role of globalised trade in passively contributing to the spread of this disease cannot be ruled out. It is likely no coincidence that our estimated dates for the emergence of BdGPL span the globalisation ‘big bang’, the rapid proliferation in intercontinental trade, capital, and technology that started in the 1820s (37). The recent invasion of Madagascar by Asian common toads hidden within mining equipment (38) demonstrates the capacity for amphibians to escape detection at borders and exemplifies how the unintended anthropogenic
dispersal of amphibians has also likely contributed to the worldwide spread of pathogenic chytrids.

The hyperdiverse hotspot identified in Korea likely represents a fraction of the *Batrachochytrium* genetic diversity in Asia and further sampling across this region is urgently needed because the substantial global trade in Asian amphibians (39) presents a risk of seeding future outbreak lineages. Unique ribosomal DNA haplotypes of *B. dendrobatidis* have been detected in native amphibian species in India (40, 41), Japan (16) and China (42). Although caution should be observed when drawing conclusions about lineages based on short sequence alignments (Fig. S3), other endemic lineages probably remain undetected within Asia. Significantly, the northern European countryside is witnessing the emergence of *B. salamandrivorans*, which also has its origin in Asia. The emergence of *B. salamandrivorans* is linked to the amphibian pet trade (43), and the broad expansion of virulence factors that are found in the genomes of these two pathogens are testament to the evolutionary innovation that has occurred in these Asian *Batrachochytrium* fungi (23). Our findings show that the global trade in amphibians continues to be associated with the translocation of chytrid lineages with panzootic potential. Ultimately, our work confirms that panzootics of emerging fungal diseases in amphibians are caused by ancient patterns of pathogen phylogeography being redrawn as largely unrestricted global trade moves pathogens into new regions, infecting new hosts and igniting disease outbreaks. Within this context, the continued strengthening of transcontinental biosecurity is critical to the survival of amphibian species in the wild (44).

Table 1. Comparison of common genetic diversity measures among *Batrachochytrium dendrobatidis* lineages. Total segregating sites for each lineage include all segregating sites where genotype calls were made in at least half of the isolates. Average pairwise-segregating sites is the average number of sites with different genotypes between all pairs of isolates within a lineage. Total homozygous segregating sites includes all sites within a lineage where there is at least one homozygous difference between isolates. Average pairwise homozygous segregating sites is the average number of sites with different homozygous genotypes between all pairs of isolates within a lineage. Nucleotide diversity ($\pi$) is the mean of the per-site nucleotide diversity. Tajima’s $D$ is reported as the mean over 1 kbp bins.
Figures:

Fig. 1: Genetic diversity and phylogenetic tree of a global panel of 234 *Batrachochytrium dendrobatidis* isolates. A. Map overlaid with bar charts showing the relative diversity of isolates found in each continent and by each major lineage (excluding isolates from traded animals). The bar heights are the average number of segregating sites between all pairwise
combinations of isolates of each lineage in each continent (therefore only lineages with two or more isolates from a continent are shown). Outlined points at the base of each bar are scaled by the number of isolates for each lineage in that continent. The numbers around the outside of the globe are the average number of segregating sites between all pairwise combinations of isolates grouped by continent. Colours denote lineage as given by the legend in Fig 1B. B. Midpoint rooted radial phylogeny supports four deeply diverged lineages of *B. dendrobatidis*: *BdASIA*-1; *BdASIA*-2/*BdBRAZIL*; *BdCAPE* and *BdGPL*. All major splits within the phylogeny are supported by 100% of 500 bootstrap replicates. See Fig. S2 for tree with full bootstrap support values on all internal branches.
Fig. 2: Dating the emergence of BdGPL. A. Maximum likelihood (ML) tree constructed from 1,150 high quality SNPs found within the 178 kbp mitochondrial genome. B. Linear regression of root-to-tip distance against year of isolation for BdGPL isolates in mitochondrial DNA phylogeny in panel A, showing significant temporal trend (F-statistic = 14.35, p = 0.00024). C. ML tree constructed from a 1.66 Mb region of low recombination in Supercontig_1.2. Two BdGPL isolates, BdBE3 and MG8 fall on long branches away from the rest of the BdGPL isolates (see inset zoom), due to introgression from another lineage (BdCAPE; see Fig. 3B) and were excluded from the dating analysis. D. Linear regression of root-to-tip distance against year of isolation for BdGPL isolates from phylogeny in panel C, with significant temporal trend (F-statistic = 15.92, p-value = 0.0001). E. Top figure shows BdGPL and outgroup BdCH, with the 95% HPD estimates for MRCA for BdGPL from mtDNA dating (blue) and nuclear DNA dating (red). Lower figure shows full posterior distributions from tip dating models for mtDNA (blue) and partial nuclear DNA (red) genomes. Solid vertical lines are limits of the 95% HPD. Dashed vertical lines denote the maximal density of the posterior distributions. F. Sliding 10 kb, non-overlapping window estimates of Tajima’s D for each of the main B. dendrobatidis lineages. The region highlighted in red is the low recombination segment of Supercontig_1.2. G. Survival curves for Bufo bufo metamorphs for different B. dendrobatidis treatment groups: BdASIA-1 (blue); BdCAPE (orange); BdCH (yellow); BdGPL (green) and Control (grey). Confidence intervals
are shown for *BdGPL* and *BdASIA-1*, showing no overlap by the end of the experiment.

Instances of mortalities in each treatment group are plotted along the x-axis, with points scaled by number of mortalities at each interval (day).
Fig. 3: $F_{ST}$ and site-by-site STRUCTURE analysis. A. Non-overlapping, 10 kb sliding window of $F_{ST}$ between lineages. The region highlighted in red is Supercontig_1.2:500,000-2,160,000 low recombination region. B. Site-by-site analysis of population ancestry for a random selection of 9,905 SNPs. Results show those isolates found to be either hybrid (SA-EC3, SA-EC5 and CLFT024/2), or with significant introgression from non-parental lineages (isolates BdBE3 and MG8) or a chimera of un-sampled diversity, likely originating from East Asia (0739, the $Bd/CH$ isolate). Each column represents a bi-allelic SNP position. The column is coloured according to the joint-probability of either allele copy arising from one of four distinct populations. Colours represent assumed parental lineages as given in Fig. 3C. C. Principle Components Analysis (PCA) of 3,900 SNPs in linkage equilibrium. Each point represents an isolate, coloured by phylogenetic lineage. The isolates separate into clearly defined clusters. The axes plot the first and second principle components.
Fig. 4: Genotypes of Bd isolated from infected amphibians in the international trade and phylogenetically linked genotypes from segregated geographic localities. The red diamonds on the phylogeny indicate isolates recovered from traded animals. Their geographic location is displayed by the red diamonds on the map. The red numbers link each trade isolate to the relevant picture of the donor host species atop the figure panel and their placement in the phylogeny. The arrows on the map link geographically separated isolates which form closely related phylogenetic clades with high bootstrap support (≥90%). Each clade is denoted by a different shape point on the map with the names of isolates within each clade displayed on the map. The dates displayed indicate the sampling time-frame for each clade. The phylogenetic position of each clade is displayed in Figs S10-14. The colours of points and arrows on the map indicate lineage according to the legend in Fig 1. A browsable version of this phylogeny can be accessed at https://microreact.org/project/GlobalBd.
