ABSTRACT

We have observed the eclipsing, post-common envelope white dwarf–brown dwarf binary, SDSS141126.20+200911.1, in the near-IR with the HAWK-I imager, and present here the first direct detection of the dark side of an irradiated brown dwarf in the H band, and a tentative detection in the K_s band. Our analysis of the light curves indicates that the brown dwarf is likely to have an effective temperature of 1300 K, which is not consistent with the effective temperature of 800 K suggested by its mass and radius. As the brown dwarf is already absorbing almost all the white dwarf emission in the K_s band, we suggest that this inconsistency may be due to the UV-irradiation from the white dwarf inducing an artificial brightening in the K_s band, similar to that seen for the similar system WD0137-349B, suggesting this brightening may be characteristic of these UV-irradiated binaries.

Key words: binaries: eclipsing – brown dwarf – white dwarfs.

1 INTRODUCTION

Despite recent results reporting the discovery of brown dwarf companions to main sequence stars (e.g. Anderson et al. 2011; Siviero et al. 2012; Bayliss et al. 2017; Hodžić et al. 2018), there are still only 13 known to date, and they are very rare compared to planetary or stellar companions to main sequence stars (Metchev & Hillenbrand 2004; Grether & Lineweaver 2006). As a result, there are very few systems known to have evolved from these binaries with Steele et al. (2011) predicting only 0.5 per cent of white dwarfs having brown dwarf companions.

To date only nine post-common envelope systems have been confirmed: GD1400 (WD+L6, P = 9.98 h; Farihi & Christopher 2004; Dobbie et al. 2005; Burleigh et al. 2011), WD0137-349 (WD+L6-L8, P = 116 min; Burleigh et al. 2006; Maxted et al. 2006), WD0837+185 (WD+T8, P = 4.2 h; Casewell et al. 2012), NLTT5306 (WD+L4-L7, P = 101.88 min; Steele et al. 2013), SDSS J155720.77+091624.6 (WD+L3-L5, P = 2.27 h; Farihi, Parsons & Gänsicke 2017), SDSS J1205-0242 (WD+L0, P = 71.2 min; Parsons et al. 2017; Rappaport et al. 2017), SDSS J1231+0041 (WD+M/L, P = 72.5 min; Parsons et al. 2017), EPIC212235321 (WD+L5, P = 68 min; Casewell et al. 2018) and SDSS J141126.20+200911.1, hereafter SDSS1411+2009 (WD+T5, P = 121.73 min; Beuermann et al. 2013; Littlefair et al. 2014). All of these systems have survived a phase of common-envelope evolution, resulting in the close binary system. They are all detached, and likely tidally locked, resulting in a brown dwarf that is irradiated on one hemisphere, similar to the situation in most hot Jupiter exoplanets. Eventually, these white dwarf–brown dwarf binaries will become cataclysmic variables, such as SDSS1433+1011 in which the substellar donor was recently detected (Hernández Santisteban et al. 2016).

Irradiated brown dwarfs are expected to have very similar atmospheres to irradiated exoplanets, and have been described as the ‘fourth corner’ of the parameter space containing irradiated exoplanets, solar system planets, and isolated brown dwarfs (Showman 2016). For instance, Kelt-9b (Gaudi et al. 2017) is a 2.88 M_Jup planet orbiting a ∼10 000 K star. This planet is expected to receive ~700 times more UV irradiation than a planet orbiting the next hottest exoplanet host star (WASP-33). However, the primary star in the Kelt-9 system is still ∼3000 K cooler than SDSS1411+1011A and ∼6500 K cooler than WD0137-349A. The brown dwarf companion in this latter system has been shown to have an atmosphere that is significantly affected by UV irradiation (Casewell et al. 2015; Longstaff et al. 2017). In fact, Kelt-9b has been shown to have a day-nightside temperature difference of ~500 K, the same as the irradiated brown dwarf WD0137-349B, indicating poor heat redistribution is present in both systems, despite their differences in

* E-mail: s1c25@le.ac.uk
internal temperature. Studying irradiated brown dwarfs can therefore provide a useful proxy for exoplanets, especially to explore the effects of UV irradiation and any resultant photochemistry, as in general hot Jupiters host stars replicating the same conditions must be very large, making them challenging systems to observe. One of the most recently discovered of the post-common envelope systems, and the first eclipsing system to be discovered, SDSS1411+2009, was discovered as part of the Catalina Sky Survey by Drake et al. (2010). The substellar nature of the companion to the white dwarf was confirmed by Beuermann et al. (2013). While its period is very similar to that of the well-studied WD0137-349, the white dwarf is cooler with $T_{\text{eff}} = 13,000 \pm 300$ K and log $g = 7.86 \pm 0.07$, giving a mass of $0.53 \pm 0.03$ M$_{\odot}$ (Littlefair et al. 2014). The brown dwarf mass is calculated to be $50 \pm 2$ M$_{\text{Jup}}$, and has an estimated spectral type of T5, derived from the secondary’s mass. The $z$ band eclipse and $K_s$ excess present in Littlefair et al. (2014) were used to estimate the dayside spectral type to be between L7 and T1, suggesting significant irradiation.

2 OBSERVATIONS AND DATA REDUCTION

We observed SDSSJ1411+2009 with the infrared imager HAWK-I (Kissler-Patig et al. 2008) on the VLT as part of programme 94.C-0032. The data were obtained on the nights of the 2015 April 04, 2015 April 05, and the 2015 MArCH 13 for J, H, and $K_s$, respectively. The seeing was $1 Writer's note: This data reduction and analysis is beyond the scope of this summary.
Figure 1. $JHK_s$ band light curves phased on the ephemeris in Beuermann et al. (2013). The light curves have been offset for display purposes by 0.05 mJy in the $H$ and $J$ bands. The data have been plotted in 400 error-weighted flux bins for display purposes and the models are plotted with the red solid line. The shaded-blue region represents the $1\sigma$ prediction of the binary model, plus the Gaussian process model of the systematics.

Figure 2. $H$-band light curve phased on the ephemeris in Beuermann et al. (2013), and zoomed in on the eclipse. The top panel shows the raw light curve and the binary plus Gaussian process model. The middle panel shows the data with the Gaussian process subtracted, and the binary model alone. The bottom panel shows the residuals to the binary model, and the Gaussian process. The models are plotted with the red solid line, and zero flux is marked by the dotted line.

The semi-amplitude of this variability is $0.0019 \pm 0.0003$ mJy in the $H$ band, and $0.0039 \pm 0.0006$ mJy in the $K_s$ band. This variability is slightly larger than that detected for the WD0137-349AB system (Casewell et al. 2015) which has a similar period, but a hotter, and less massive white dwarf ($T_{\text{eff}} = 16500$ K, $M = 0.4 M_\odot$ Maxted et al. 2006), but the errors are large on these measurements.

We also used the MOLLY software package to search for any emission lines from the brown dwarf in the 28 UVB and VIS XSHOOTER spectra used to measure the radial velocity in Littlefair et al. (2014). We did not detect He\textsc{ii} emission, as is seen for WD0137-349B (Maxted et al. 2006), or any other emission lines as were detected by Longstaff et al. (2017) for the same system. As SDSS1411+2009 is 3 mag fainter in the optical than the WD0137-349 system, we phase binned the data and combined the spectra in phase, but still did not detect any emission features from the brown dwarf. The data from the NIR arm of XSHOOTER are of not good enough quality to be used in any analysis.

4 DISCUSSION

We calculated brightness temperatures for the dayside of the brown dwarf for the $J$ band using a model white dwarf spectrum and the method detailed in Casewell et al. (2015). For the $H$ and $K_s$ bands where we have models of the system from LCURVE we generated a temperature map of the surface of the brown dwarf as was done...
in Hernández Santisteban et al. (2016). The average dayside and nightside temperatures are reported in Table 1, although from the surface map of the brown dwarf we were also able to model the maximum and minimum temperatures present across the surface. These temperatures had a maximum of 1940 ± 70 K in the $H$ and 2000 ± 150 K in the $K_s$ bands, and a minimum of 1530 ± 90 K and 950 ± 500 K in the $H$ and $K_s$ bands, respectively.

We have generated irradiated brown dwarf models using the atmospheric structure model of Marley et al. (1999), Marley et al. (2002), and Fortney et al. (2005) using the log $g$ from Littlefair et al. (2014) and intrinsic effective temperatures (the temperature the brown dwarf would have in the absence of the white dwarf) ranging from 500 to 1500 K (Fig. 4). The white dwarf irradiation was modelled using a 13 000 K black body at the appropriate separation. We have chosen to use surface flux densities in displaying these data, as this removes any uncertainties associated with the radius of the brown dwarf and the distance to the system. While the dayside $H$ and $K_s$ band fluxes are consistent with an irradiated brown dwarf of 1300 K, it is clear that the dayside $K_s$ flux also encompasses temperatures much hotter than 1500 K (the hottest model plotted). This is consistent with our findings in Casewell et al. (2015), where the $K_s$ band was much brighter than the models predicted.

It can be seen that SDSS1411-2009B has an average difference in day–night side temperatures of 93 ± 12 K in the $H$ band, and a 360 ± 80 K day–night difference in the $K_s$ band. As these measurements are derived from the LCUVE model, they take into account the errors on the radii and the correlated errors relating to the distance to the binary. The distance from Gaia DR2 is 177 ± 5 pc (Luri et al. 2018), compared to 190 ± 8 in Littlefair et al. (2014). These distances agree to within 1.5 σ. Surface flux densities for the brown dwarf were derived from the brightness temperatures of each element using the Planck curve. To compare the nightside fluxes with models, we used non-irradiated cloud-free brown dwarf models, again using the atmospheric structure of Marley et al. (1999), Marley et al. (2002), and Fortney et al. (2005). These models and the nightside fluxes can be seen in Fig. 5. Both the $H$ and $K_s$ bands are consistent with $T_{eff} = 1300$ K. This raises an interesting conundrum, as the estimated $T_{eff}$ of the brown dwarf using the radius from the light curves and the mass from the radial velocity solution combined with evolutionary models of Baraffe et al. (2003) is $\sim 800$ K (Littlefair et al. 2014).

In comparison with a similar system, both SDSS1411-2009B and WD0137-349B have similar brightness temperatures (within the errors) in the $H$ band on both the day and night sides, although the nightside of WD0137-349B is an upper limit, and the dayside temperature is not well constrained at 1585 ± 329 K compared to 1730 ± 70 K for SDSS1411-2009B. The nightside of SDSS1411-2009B in the $H$ band appears to be hotter than both WD0137-349B, despite SDSS1411-2009B being of a being of a later spectral type, but the errors on the upper limit mean we cannot state this conclusively.

In the $K_s$ band, the dayside of WD0137-349B (2015 K) is hotter than the nightside of 1620 K (1620 K), as would be expected for a brown dwarf orbiting a hotter white dwarf in a shorter orbit. The nightside brightness temperatures of both objects have large errors, however, as with the $H$ nightside measurements, they may be similar temperatures.

Despite the white dwarf in SDSS1411+2009 being $\sim 3500$ K cooler than the white dwarf in WD0137-349B, there is not a large difference in the SED of the irradiated brown dwarfs in these systems. WD0137-349B emits much more strongly in the ultraviolet (by a factor of $\sim 10$) than SDSS1411-2009A does, although the peak of the white dwarf SED is approximately at the same wavelength in both cases. This is likely to be the explanation for the lack of emission lines seen in the atmosphere of SDSS1411-2009B. The lack of UV irradiation means SDSS1411+2009 is unlikely to have a chromosphere, similar to that suggested for WD0137-349B by

Figure 4. Dayside average surface flux densities of the brown dwarf (boxes) are shown with irradiated brown dwarf models of effective temperatures: 1200, 1300, 1400, and 1500 K.

Figure 5. Nightside average surface flux densities of the brown dwarf (boxes) are shown with non-irradiated, cloud-free brown dwarf models of the same effective temperatures as in Fig. 4.
Longstaff et al. (2017). This is also suggested by the lack of Hα emission lines in the optical spectra. However, despite this lack of emission lines, the same brightening is seen in the Ks for both WD0137-349B and SDSSJ1411-2009B.

Our nightside brightness temperatures for SDSSJ1411-2009B indicate that in the absence of any heat transport, the $T_{\text{eff}}$ of the brown dwarf is 1300 K. Our L CURVE modelling of these light curves gives an absorb parameter (the fraction of flux from the white dwarf absorbed by the brown dwarf) of 0.50 ± 0.06 in the H band and 0.80 ± 0.15 in the Ks band. These parameters mean that if only absorption and reprocessing within the brown dwarf atmosphere is important, SDSSJ1411-2009B must be absorbing 50 per cent of the H band flux and 80 per cent of the Ks band flux, in order to produce the dayside brightness temperatures.

However, the brown dwarf effective temperature as estimated from the mass and radius is 800 K (Littlefair et al. 2014). If this is the true effective temperature of the brown dwarf, were it an isolated object, then the absorb parameters must be even higher in order to produce enough heat transport to heat the nightside to 1300 K. The absorb parameter for the Ks band is already close to 100 per cent though, which would indicate there is poor energy circulation around the brown dwarf, supported by the 200 K day–nightside difference in the H band.

An additional factor that would affect estimates of temperature and energy circulation, may be fluorescence or emission within the brown dwarf atmosphere. We suggested this is present in WD0137-349B (Casewell et al. 2015), again causing brightening in the Ks and 4.5 μm bands. If this emission is present, it will increase the dayside flux, particularly in the Ks band, meaning that the absorb parameter is artificially high. In particular it would mean that the brown dwarf needs to absorb a smaller fraction of flux in order to heat the nightside. This scenario is also potentially consistent with a lower $T_{\text{eff}}$ of the brown dwarf. Emission from the dayside has artificially increased the flux, leading to an overestimate of the effective temperature.

Observations of Kelt-1b, a T2 dwarf orbiting a main sequence star (Siverd et al. 2012), seem to support the hypothesis of UV-induced brightening in the Ks band. Kelt-1b, orbiting a 6500 K F5V star lacks the intense UV irradiation of the white dwarf irradiated systems, and does not show this brightening. Indeed eclipse measurements that suggested in WD0137-349B, hinting this may be a common trait in these systems, and may be due to photochemistry.

5 CONCLUSIONS

We have observed the close, post-common envelope binary SDSSJ1411+2009 with HAWK-I in the $JHK_s$ bands, and have directly detected the brown dwarf in the $H$ and $K_s$ bands as it eclipses its white dwarf companion. We have determined the brightness temperatures for the day and night-sides of the brown dwarf and measure a temperature difference of only ~200 K, compared to ~500 K for WD0137-349B, a system with a similar period, but a hotter white dwarf primary. From comparing the surface fluxes to models of irradiated and non-irradiated brown dwarfs, we also determine that in general, the models indicate the brown dwarf is consistent with $T_{\text{eff}} \sim 1300$ K, but that the mass and radius suggest an effective temperature that is much lower. As the brown dwarf is already absorbing almost all the emission from the white dwarf in the $K_s$ band, this discrepancy suggests that an additional mechanism is making the $K_s$ band brighter. This mechanism may be similar to that suggested in WD0137-349B, hinting this may be a common trait in these systems, and may be due to photochemistry.

ACKNOWLEDGEMENTS

We thank Detlev Koester for providing the white dwarf models. This work is based on observations made with ESO Telescopes at the La Silla Paranal Observatory. This work also makes use of the white dwarf models from Pierre Bergeron: ∼bergeron/CoolingModels. SLC acknowledges support from the University of Leicester, College of Science and Engineering. SPL is supported by STFC grant ST/M001350/1, and TRM is supported by STFC grant ST/L000733. SGP acknowledges the support of the Leverhulme Trust.
