We explore the feasibility of exciting localized spin wave modes in ferromagnetic nanostructures using surface acoustic waves. Time-resolved Faraday effect is used to probe the magnetization dynamics of an array of nickel nanowires. The optical pump pulse excites both spin wave modes of the nanowires, and acoustic modes of the substrate, and we observe that when the frequencies of these coincide the amplitude of magnetization dynamics are substantially enhanced due magnetoelastic coupling between the two. Notably, by tuning the magnitude of an externally applied magnetic field, optically excited surface acoustic waves can selectively excite either the upper or lower branches of a splitting in the nanowire’s spin wave spectrum, which micromagnetic simulations indicate to be caused by localization of spin waves in different parts of the nanowire. Thus, our results indicate the feasibility of using acoustic waves to selectively excite spatially confined spin waves, an approach that may find utility in future magnonic devices where coherent structural deformations could be used as coherent sources of propagating spin waves.

PACS numbers:

A. Introduction

With CMOS technology reaching the end of its scaling potential1 there is great interest in developing novel technologies that will allow further growth in the power and efficiency of computational hardware. Magnonic devices2,3, in which information is transported and processed via the propagation and interaction of spin waves, are attractive candidates amongst these, since they can hypothetically perform computations without transporting electrical charge, thus increasing energy efficiency.

Unfortunately, while propagating spin waves does not require current flow, their excitation, which is typically achieved using optical pulses4–8, the Oested field of microwave strip-lines9–11, or via spin torque effects12–14, is more problematic. Here, the former approach is limited by the difficulties of miniaturizing powerful laser systems and optics, while the latter two cases inherently require current flow.

To address these limitations, methods of exciting spins waves using applied voltages, rather than electric currents must be developed. For example, Cherepov et al.15 have demonstrated spin wave generation and detection in an artificial multiferroic cell where voltage contacts are used to create localized radiofrequency stresses in a piezoelectric layer, which then excite spin waves in a coupled magnetic channel via the inverse-magnetostrictive effect. Alternatively, to avoid the complex electrical contacting required for local actuation of a multiferroic system, one may attempt to use inverse-magnetostriction to couple spin waves to surface acoustic waves (SAWs). SAWs have similar frequencies to spin waves at the micro- and nano-scale, and can be excited by applying high frequency voltages to interdigitated transducers mounted to the surface of suitable piezoelectric substrates. Furthermore, because SAWs exhibit low propagation losses, one can envisage using a single transducer pair to coherently and efficiently excite spin waves in a large number of channels simultaneously, in a manner that would be beneficial for future magnonic technologies. Previous studies have shown the feasibility of using SAWs to excite ferromagnetic resonance16–22, and to create sub-resonance dynamics23–28 in thin films and nanostructures. However, the coupling of SAWs to the complex spin wave spectra of magnetic nanostructures has not yet been comprehensively explored, with only the work of Yahagi et al.29 making passing reference to the fact that localized resonant modes can be excited in this way.

In this paper, we use time-resolved Faraday rotation and micromagnetic simulations to examine the coupling between surface acoustic waves and spin wave modes of an array of nickel nanowires. Our data reveals strong excitation of magnetization dynamics at applied fields where either of the nanowire’s two primary spin wave modes are coincident with the frequency of a SAW excited by the optical pump pulse. Micromagnetic simulations show these two modes to be spatially localized in the body and edges of the nanowire respectively, thus verifying the feasibility of using SAWs to selectively excite localized spin waves in magnetic nanostructures.

B. Methodology

Large area arrays of rectangular profile nickel nanowires are fabricated on glass (N-BK7) wafers using electron beam lithography, thermal evaporation, and lift-
off processing. The arrays characterized in this study have widths of 250 nm, thicknesses of 40 nm, and periods of 500 nm. The length of the wires are several millimeters and extend beyond the aperture of the excitation and detection beams. Equivalenty evaporated continuous thin films are characterized using a vector network analyzer ferromagnetic resonance (VNA-FMR) system. The films saturation magnetization, $M_s = 315 \text{kA/m}$ is found by fitting the variation of the films resonance frequency with applied field to the Kittel equation, while the variation of resonance line width with frequency allows the determination of its damping parameter, $\alpha = 0.04^{39}$. We note that the value of $M_s$ is lower than that for bulk nickel, perhaps indicating some oxidation of the uncapped films. Atomic Force Microscopy (AFM) data illustrating the geometry of the array are shown in Figure 1(a) including an inset linecut showing the uniformity of the final structures.

A schematic diagram illustrating the experimental geometry is presented in Figure 1(b). Excitation of the nanowire array is achieved by $\sim 100fs$ optical pulses with wavelength $\lambda_{\text{pump}} = 400nm$ directed at near-normal incidence onto the sample surface. The nanowire’s magnetic response is characterised via the Faraday rotation of a time delayed, linearly polarized probe beam ($\sim 100fs$ pulses, $\lambda_{\text{probe}} = 800nm$), directed at normal incidence onto the sample surface. Analysis of the probe beams polarized using standard polarization bridge techniques as a function of time delay thus allows elucidation of the nanowire’s magnetization dynamics. The diameter of the pump beam is several hundred microns (fluence $\sim 5mJ/cm^2$), with the probe beam being fully contained within the pump, meaning that a large number of nanowires are characterized simultaneously. The measurements are performed within the poles of an electromagnet that can be continuously rotated around the sample normal to vary $\phi_H$, the angle between the applied field, $H$, and the array’s wavevector.

Micromagnetic simulations of the nanowire’s magnetization dynamics are performed using the Mumax3 software package. We model a single 500 nm (width) x 1000 nm (length) section of the array and employ periodic boundary conditions in both in-plane directions to emulate both the arrays periodicity and the long lengths of the nanowires. A $5 \times 5 \times 5 \text{nm}^3$ mesh is used for all simulations. Values of $M_s$ and $\alpha$ are chosen to align the material properties of simulated nanowires with those measured via VNA-FMR from continuous films, while the exchange stiffness is set to a standard value of $D_{\text{ex}} = 9pJ/m$. We neglect the effects of magneto-crystalline anisotropy due the polycrystalline nature of the experimental samples. To simulate the nanowire’s spin wave spectrum under given applied field conditions, we first initialize the nanowire’s magnetization along a vector $(H_x, H_y, H_z) = (1,1,0)$ before relaxing it under the required values of $H$ and $\phi_H$. We then apply an abrupt 20 Oe out-of-plane field pulse in order to excite magnetization dynamics within the nanowire, and Fourier transform the resulting time domain data for $M_z/M_s$ (i.e. the out-of-plane component of magnetization) to obtain the nanowire’s frequency domain response. The localization of spin waves modes are then examined by exciting the array with frequency-matched, sinusoidally varying, out-of-plane applied fields with amplitudes of $10Oe$.

C. Results

Figure 2 presents time and frequency domain experimental data for $\phi_H = 10^\circ, 20^\circ$, and $30^\circ$, along with micromagnetically simulated frequency domain data. The top row of panels (a - c) show the background subtracted time-resolved Faraday signals at these magnetic field angles, which are accompanied by their Fourier transforms in (d - f). The time delay data exhibits complex oscillatory dynamics of the average magnetic moment of the ensemble of Ni wires. In combination with the frequency domain representation we can understand their salient features.

Two mechanisms for inducing magnetization dynamics are activated when the pump pulse excites the nanowire array. First, fast demagnetization processes suppress the magnetic moment of individual wires, modifying the spatial distribution of their demagnetizing fields, and thus reorienting the effective magnetic field relative to the
FIG. 2: (a - c) Time domain pump-probe Faraday measurements of the nickel nanowire array for $\phi_H = 10^\circ$, $20^\circ$ and $30^\circ$. (d - f) Equivalent frequency domain measurements. Red dashed lines indicate the peak positions of the spin wave spectrum as derived from the results of micromagnetic simulations. For $\phi_H = 10^\circ$ the white line indicates the average intensity measured between the two dashed white lines, which encompass the SAW excitation observed at $f = 6\text{GHz}$. (g - i) Micromagnetic simulations of the low-energy spin wave spectrum of the nanowire. At low angles, a split spectrum elucidates spin wave amplitudes located in the bulk and edge regions of the wires.

applied external field. This process is equivalent to that first demonstrated by van Kampen et al.$^{33}$, and results in the frequency domain data presenting a faint trace of the nanowire’s full spin wave spectrum (Fig 2(d - f)). This can be seen most easily by comparing the experimental frequency domain data (Fig 2(d - f)) with the simulation results in (Fig 2(g - i)), which show the nanowire’s response to a sharp perturbation of the effective field. This simulated response is also overlaid onto the frequency domain data (red lines in Fig 2(d - f)) and shows good quantitative agreement with the experimental results for the displayed angles. We note that, at high applied fields the nanowire’s spin wave spectrum shows two clear branches for low angles of magnetic field, $\phi_H$. As this angle increases, and the field aligns more with the long axis of the wires, the splitting between between the two observed resonance branches lessens until at 30$^\circ$ they become nearly indistinguishable.

The second effect of the pump pulse is the excitation of acoustic waves due to the spatially varying optical absorption, and thus spatially varying thermomechanical stress, of the nanowire; a process that is known to lead to excitation of Rayleigh Surface Acoustic Waves (SAW) and the individual ‘breathing’ modes of the wires (i.e. both in-plane and out-of-plane dilation and compression of the wire width and height respectively). Thus the elastic dynamics of these wire arrays behave similarly to our previously discussed Ultrafast Transient Grating (TG) measurements on uniform magnetic films$^{34,35}$. The resultant strain profile is that of a standing acoustic wave with antinodes occurring at the center of the wires and the gaps between them. This is equivalent to the case of two counter propagating surface acoustic waves. The generated acoustic modes are presented as faint horizontal lines in the frequency domain data, and based on the periodicity of the wire array and the acoustic velocity of the substrate and wire material, we attributed these to be the Rayleigh SAW excitation at $6\text{GHz}$ and the wire (width) breathing mode at $11.25\text{GHz}$, the latter being closely associated with our previously reported Surface Skimming Longitudinal Wave (SSLW)$^{36}$.

The experimental frequency domain representation also shows clear “hotspots” whenever an acoustic mode crosses the nanowire’s spin wave spectrum, which we show explicitly for the 10$^\circ$ data as an overlayed linecut on the frequency domain data (Fig 2(d)). We understand this to be the resonant interaction between the underlying acoustic waves and the wire’s magnetization under the correct applied field conditions. However, distinct from the dynamics previously demonstrated in our TG measurements$^{34–36}$, we draw attention specifically to the fact that in the case presented here (e.g. $\phi_H = 10^\circ$) two
clear hotspots are present at the SAW frequency, namely resonances at $\sim \pm 1225\text{Oe}$ and $\sim \pm 1850\text{Oe}$ (indicated by arrows). The nature of these distinct features is the primary focus of this paper, and will be discussed in detail shortly.

The form of the nanowire’s frequency domain data can be understood further by considering figure 3, which plots the simulated frequencies (Fig. 3(a)) of the nanowire’s spin wave modes, as well as its global values (Fig. 3(b)) of $M_x/M_s$ and $M_y/M_s$ as a function of applied field for $\phi_H = 10^\circ$. At large positive fields the nanowire is almost entirely saturated along field direction, and presents two well-separated modes, the frequencies of which scale almost linearly with the applied field. The existence of these two modes can also be seen clearly in Figure 4(a), which presents a line cut through the simulated frequency domain data at $H = 1500\text{Oe}$.

Micromagnetic simulations of the spatial distributions of each branch of the spin wave spectrum are shown in Figure 4(b), for a field of 1500 Oe and driving frequencies of $5.1\text{GHz}$ and $6.9\text{GHz}$. The micromagnetic results are plotted for different time points for a full oscillation period and show the localized nature of the excitations for different precessional frequencies. For example, Figure 4(b) demonstrates that the lower frequency resonance is associated with spin wave amplitude localized at the edges of the wire’s profile, while the higher frequency resonances are localized in the centers of the individual wires. The existence of these distinct spatial distributions of the spin waves is the result of non-uniformity of the demagnetizing field across the width of the wire. This field strongly opposes the applied field at the nanowire’s edges, lowering the effective field about which the magnetization precesses. This decreases the resonant frequency of these regions compared to those in the middle of the nanowires, which form the upper branch on the plot.

Looking again at figure 3(b), as the applied field is reduced towards $\sim 1000\text{Oe}$, the nanowire’s magnetization remains closely aligned to the poling direction. However, substantial changes are observed in the frequency domain data, with the upper branch of the spin wave spectrum progressively decreasing in intensity relative to the lower branch, such that by $H = 1000\text{Oe}$ the lower branch dominates (figure 4(a)). In this applied field region the remaining lower branch continues to represent the dynamics of spins at the edges of the nanowire (figure 4(c)).

At $H = 500\text{Oe}$ the mode spectrum exhibits a local minimum in frequency as the applied field becomes comparable to the demagnetizing field, thus minimizing the effective field around which the magnetization precesses. This also results in a progressive reorientation of the nanowire’s magnetization away from the hard axes towards their easy axes, and an expansion of the remaining mode from the nanowire’s edges to the body (figure 4(d)). As the applied field is further reduced to $H = 0\text{ Oe}$ the spin wave frequency increases again due to the nanowire’s demagnetizing field becoming dominant over the applied field, resulting in a net increase of the effective field.

For applied fields in the range $H = 0\text{Oe}$ to $-500\text{Oe}$ the mode spectrum first softens and then exhibits a discontinuity at $H = -450\text{Oe}$. These phenomena are attributed to the applied field having developed a component along $-y$ while the magnetization retains a component along $+y$, due to the nanowire’s shape anisotropy preventing its reorientation (the wires are initially poled in the positive $M$ direction, and so the ‘flop’ transition occurs on the negative $M$ side). The discontinuity in the mode spectrum occurs as the magnetization overcomes this energy barrier to align along $-y$. We note that similar discontinuities can be observed in the experimental data (figure 2 (a - c)), albeit at lower fields ($H = -380\text{Oe}$), due to thermal activation assisting the magnetization reorientation in the experiments. For $H < -500\text{Oe}$ the mode spectrum is symmetric with that for equivalent positive fields, indicating equivalent magnetization dynamics are occurring.

The explanation above can also be applied to understand the variation of the frequency domain data with $\phi_H$ shown in figure 2. First, as the field angle increases, all spin wave modes and their elastic resonances shift to smaller applied fields, a general feature associated with the shape anisotropy of the wires.$^37$ Furthermore, as $\phi_H$ increases, decreased splitting is observed between the upper and lower branches of the spin wave spectrum. This can be attributed to the nanowire’s magnetization being saturated at larger angles to their hard axes, thus reducing the strength of the demagnetizing field the edge spins experience. The same reduction of the demagne-
FIG. 4: (a) Micromagnetically stimulated spin wave spectra for \( H = 500 \text{Oe} \) (blue), 1000\text{Oe} (red) and 1500\text{Oe} (black) (\( \phi_H = 10^\circ \)). (b) Micromagnetically stimulated images of the \( M_z \) component of magnetization for a complete period of oscillation at \( f = 5.1 \text{GHz} \) and \( f = 6.9 \text{GHz} \) (\( H = 1500 \text{Oe}, \phi_H = 10^\circ \)), corresponding to the lower and upper branches of the spin wave spectrum respectively. (b) Equivalent images for \( f = 4.2 \text{GHz} \), \( H = 1000 \text{Oe}, \phi_H = 10^\circ \). (c) Equivalent images for \( f = 3.4 \text{GHz} \), \( H = 500 \text{Oe}, \phi_H = 10^\circ \).

FIG. 5: (a) Time domain data for \( \phi_H = 10^\circ \) modified by a 2D Hamming window applied in the region where the spin wave spectrum of the nanowire crosses the SAW and breathing mode acoustic resonances. (b) Corresponding frequency domain data. The frequencies of the SAW and breathing mode (B.M.) acoustic resonances are indicated by dashed red lines. The white lines are guides for the eye and indicate the frequencies of the upper and lower branches of the spin wave spectrum.

Having explained the physical origin of the nanowire’s spin wave spectrum we now return our attention to its increased. The key result here is that, depending on the value of the applied magnetic field, the SAW mode resonantly excites either branch the spin wave spectrum, which as we have shown previously, were localized in different sections of the nanowire array. Thus, our measurements provide evidence of the feasibility of selectively exciting localized spin wave modes by coupling them to acoustic waves.

As a final point, we now validate via further simulations the feasibility of acoustically exciting localized spin waves. We begin with the standard equation for the magnetoelastic energy density:

\[
E_{M.E.} = B_1 (\epsilon_{xx}m_x^2 + \epsilon_{yy}m_y^2 + \epsilon_{zz}m_z^2) + 2B_2 (\epsilon_{xy}m_xm_y + \epsilon_{xz}m_xm_z + \epsilon_{yz}m_ym_z)
\]

(1)

Where \( B \) are the magnetoelastic coupling constants and \( \epsilon_{ij} \) are the components of strain a magnet is subjected to. For an isotropic polycrystalline film \( B = B_1 = B_2 \) and for a Rayleigh SAW propagating along the x-axis, \( \epsilon_{yy} = \epsilon_{xx} = \epsilon_{yz} = 0 \). For the case of a film thickness much smaller than the SAW wavelength it is further the case that \( \epsilon_{xx} > \epsilon_{zz} > \epsilon_{xy} \) in the near-surface region\(^{18}\), while the in-plane applied field ensures that \( m_x \gg m_z \). Hence, for our experimental geometry we arrive at \( E_{M.E.} = B_2 \epsilon_{xx}(x,t)m_x^2 \), such that the magnetoelastic effects of the SAW were analogous to a spatially and temporally varying uniaxial anisotropy oriented along the x-axis. We note that this simple form of excitation was previously used by Weiler et al. to repro-
duce the characteristics of SAW-induced FMR, giving us confidence in the validity of our approach.

On the basis of the treatment above, we perform micromagnetic simulations where the Ni nanowires are subjected to a spatial and temporally varying uniaxial anisotropy profile of the form:

\[ K_1 = B \varepsilon_{xx} \cos(2\pi x/\lambda_a) \sin(2\pi f_{\text{saw}} t) \]  \hspace{1cm} (2)

where, \( \lambda_a \) is the array repeat period (\( \lambda_a = 500 \text{nm} \)), \( f_{\text{saw}} \) is the frequency of the optically excited SAW, as measured from the experimental data (\( f_{\text{saw}} = 6 \text{GHz} \)), \( B \sim 7.85 \text{MJ/m}^3 \) and \( \varepsilon_{xx} \sim 200 \text{ppm} \). While we believe the experimental strains to be larger than this value, micromagnetic simulations were conducted at this reduced strain to ensure linearity of the simulated results, while the experimental results do not show responses that would be associated with frequency mixing phenomena we reported previously. The anisotropy axis is applied along the x-axis of the array. The SAWs antinodes are located in the centre of the nanowires and in the centre of the gaps between them. Simulations are performed at three applied fields: \( H = 1225 \text{Oe}, 1850 \text{Oe}, \) and \( 3000 \text{Oe} \), corresponding to situations where the upper branch, lower branch, and neither branch of the spin spectrum are in resonance with the SAW (\( \phi_H = 10^\circ \)).

Figure 6(a) presents \( M_z/M_s \) (\( M_s \) is the measured quantity in the Faraday geometry) vs time for each of the applied fields listed above. As the simulations were started from a stable configuration, the data show an initial period where the dynamics increase in size, before stabilizing as they reaches equilibrium amplitude. For the two cases where the SAW is in resonance with the spin wave spectrum (\( H = 1225 \text{Oe} \) & \( 1850 \text{Oe} \)), strong excitation of magnetization dynamics is observed, whereas for \( H = 3000 \text{Oe} \) where the acoustic excitation is off resonance, only minor perturbations occurred. Corresponding spatial resolved images of the magnetization dynamics (figures 6(c)-(d)) confirm that the localization of the spin wave modes is retained under acoustic excitation, with the mode observed at \( H = 1225 \text{Oe} \) localizing in the centre of the nanowire and the mode at \( 1850 \text{Oe} \) localizing at its edges. Together with the experimental data this provides strong evidence that surface acoustic waves can be used to selectively excite localized spin wave dynamics and expect that a spatially resolved measurement, for example using time-resolved x-ray photoelectron emission microscopy (XPEEM), would validate these findings.

D. Conclusions

In this paper we have used the results of pump-probe time-resolved Faraday effect and micromagnetic simulations to demonstrate the feasibility of acoustically exciting localized spin waves in a nickel nanowires. When saturated (nearly) perpendicular to the nanowire’s length, the spin wave spectrum split into two modes, respectively localized in the body and at the edges of the nanowires.
