<b>Question</b>	<b>Response</b>
Please submit a plain text version of your cover letter here.	<p>Dear Editor:</p> <p>Please find our enclosed manuscript titled "Ultrafast orbital-oriented control of magnetization in half-metallic La<sub>0.7</sub>Sr<sub>0.3</sub>MnO<sub>3</sub> ultrathin films" for submission as a Communication Article of the Advanced Materials.</p> <p>Manipulating spin in ultrafast timescale is of great interest to condensed matter physics and also important to spintronics applications. While it is well known that the spin-orbit coupling plays a key role in the spin dynamics relaxation, the possible effect of the anisotropic spin-orbit coupling on the transient magnetization is still not answered experimentally. At the same time, the colossal magnetoresistance manganite (CMR) materials provide perfect platforms to exploit this general and fundamental issue as they have the anisotropic spin-orbit coupling due to the strong coupling between spin, charge, orbital and lattice degrees of freedom.</p> <p>In our work, we demonstrate for the first time the effect of the anisotropic spin-orbit coupling on the temporal magnetization with a prototype CMR material, namely, La<sub>0.7</sub>Sr<sub>0.3</sub>MnO<sub>3</sub> ultrathin film. The results have provided new perspectives for ultrafast control of magnetic order. We believe the following specific aspects of our findings will be of interests to the general readers of Advanced Materials:</p> <ol style="list-style-type: none"><li>1. The transient magnetic order within sub-picosecond can be enhanced or attenuated by tuning the probe light polarizations. This observation is explained by a model based on the Elliott-Yafet spin-flip scattering arising from the anisotropic spin-orbit coupling.</li><li>2. The subsequent slow demagnetization component (lasting for hundreds of picoseconds) follows the four-fold symmetry of the dx<sup>2</sup>-y<sup>2</sup> orbitals, which is also attributed to the effect of the anisotropic spin-orbit coupling.</li></ol> <p>A list of potential reviewers is also attached. Thank you for your time and consideration. We are looking forward to hearing from you.</p> <p>Sincerely, Professor Yongbing Xu Director, York-Nanjing International Center of Spintronics (YNICS) The University of York, UK Nanjing University, Nanjing 210093, China Email : ybxu@nju.edu.cn</p>

<b>Abstract:</b>	<p>Manipulating spins by ultrafast pulse laser provides a new avenue to switch the magnetization for spintronic applications. While the spin-orbit coupling is known to play a pivotal role in the ultrafast laser-induced demagnetization, the effect of the anisotropic spin-orbit coupling on the transient magnetization remains an open issue. Here, we uncover the role of anisotropic spin-orbit coupling in the spin dynamics in a half-metallic La<sub>0.7</sub>Sr<sub>0.3</sub>MnO<sub>3</sub> film by ultrafast pump-probe technique. The magnetic order is found to be transiently enhanced or attenuated within the initial sub-picosecond when the probe light is tuned to be s- or p-polarized, respectively. The subsequent slow demagnetization amplitude follows the four-fold symmetry of the dx<sup>2</sup>-y<sup>2</sup> orbitals as a function of the polarization angles of the probe light. A model based on the Elliott-Yafet spin-flip scatterings is proposed to reveal that the transient magnetization enhancement is related to the spin-mixed states arising from the anisotropic spin-orbit coupling. Our findings provide new insights into the spin dynamics in magnetic systems with anisotropic spin-orbit coupling as well as perspectives for the ultrafast control of information process in spintronic devices.</p>

1 Manipulating spins by ultrafast pulse laser provides a new avenue to switch the magnetization  
2  
3 for spintronic applications. While the spin-orbit coupling is known to play a pivotal role in the  
4  
5 ultrafast laser-induced demagnetization, the effect of the anisotropic spin-orbit coupling on the  
6  
7 transient magnetization remains an open issue. Here, we uncover the role of anisotropic spin-  
8  
9 orbit coupling in the spin dynamics in a half-metallic  $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$  film by ultrafast pump-  
10  
11 probe technique. The magnetic order is found to be transiently enhanced or attenuated within  
12  
13 the initial sub-picosecond when the probe light is tuned to be s- or p-polarized, respectively.  
14  
15 The subsequent slow demagnetization amplitude follows the four-fold symmetry of the  $d_{x^2-y^2}$   
16  
17 orbitals as a function of the polarization angles of the probe light. A model based on the Elliott-  
18  
19 Yafet spin-flip scatterings is proposed to reveal that the transient magnetization enhancement  
20  
21 is related to the spin-mixed states arising from the anisotropic spin-orbit coupling. Our findings  
22  
23 provide new insights into the spin dynamics in magnetic systems with anisotropic spin-orbit  
24  
25 coupling as well as perspectives for the ultrafast control of information process in spintronic  
26  
27 devices.

1 Since the observation that a femtosecond laser pulse can quench the magnetization in the  
2 ferromagnetic Ni film,<sup>[1]</sup> the field of femtosecond magnetism has attracted great attentions due  
3  
4 to the potential advantages of ultra-fast spin manipulation for the advanced data storage.<sup>[2-4]</sup>  
5  
6 One of the key issues related to the ultrafast spin dynamics of magnetic materials is the  
7 demagnetization process. In the transition 3d ferromagnetic metals,<sup>[5-8]</sup> the magnetic order was  
8  
9 found to be quenched in a sub-picosecond timescale and then re-magnetized in a longer  
10  
11 timescale of several picoseconds (ps). In half metals,<sup>[9-11]</sup> such as Sr<sub>2</sub>FeMoO<sub>6</sub>, CrO<sub>2</sub> and  
12  
13 La<sub>0.6</sub>Sr<sub>0.4</sub>MnO<sub>3</sub>, experimental observations have shown that the ultrafast demagnetization  
14  
15 involves two steps: an initial instantaneous decrease within a ps and a subsequent slow  
16  
17 decreasing response lasting for several hundreds of ps. The second step of the slow  
18  
19 demagnetization in the half metals is attributed to the spin-lattice relaxation.<sup>[9-12]</sup> However, in  
20  
21 both the 3d transition and half-metallic metals, the microscope origin of the first step of sub-ps  
22  
23 demagnetization is still in debate. One of the most prominent mechanisms is the scatterings of  
24  
25 various quasiparticles, such as electron-electron, electron-phonon and electron-magnon  
26  
27 scatterings.<sup>[7,10,13,14]</sup> Another completely different explanation for ultrafast demagnetization is  
28  
29 the superdiffusive transport of the majority and minority spin polarized electrons.<sup>[5,15]</sup>  
30  
31 Alternatively, Illg *et al.*<sup>[16]</sup> claimed that the combination of electron-phonon and electron-  
32  
33 magnon scatterings was a possible explanation for ultrafast demagnetization. The above-  
34  
35 mentioned momentum-related scattering events involve both the spin and orbit degrees of  
36  
37 freedom. For electrons, the spin-orbit interactions (SOI) connect the spin degree of freedom to  
38  
39 their orbital motion. Therefore, it is widely believed that spin-orbit interactions (SOI) play an  
40  
41 important role in ultrafast demagnetization process as also confirmed by previous X-ray  
42  
43 Magnetic Circular Dichroism (XMCD) measurements.<sup>[17,18]</sup> Hence, utilizing the SOI are  
44  
45 expected to allow the control of magnetism in the ultrafast regime.

1 The colossal magneto-resistive (CMR) materials with half-metallic properties are potential  
2 candidates for high efficient spintronic devices and their strong SOI offer the tunability of the  
3  
4 couplings between spin, charge, lattice, and orbital degrees of freedom.<sup>[19,20]</sup> The effect of the  
5  
6 anisotropic SOI on the electron transport properties in the CMR manganites is evidenced by  
7  
8 the anisotropic magnetoresistance (AMR).<sup>[21-23]</sup> Recently, the emergence of anisotropic Gilbert  
9  
10 damping has been demonstrated in ultrathin Fe layers on GaAs (001) substrate, which is  
11  
12 attributed to the anisotropic interfacial SOI.<sup>[24]</sup> Taking into account the correlation between the  
13  
14 damping and relaxation rate of the demagnetization,<sup>[13]</sup> the anisotropic SOI which determine  
15  
16 the Gilbert damping are expected to play a vital role on the ultrafast demagnetization process  
17  
18 in the CMR materials. As discussed above, the SOI have been demonstrated to play an  
19  
20 important role in the demagnetization process. However, the general issue of the effect of the  
21  
22 anisotropic SOI on the temporal magnetization has not been addressed so far. This issue is  
23  
24 fundamental to both the understanding of ultrafast demagnetization mechanisms and the optical  
25  
26 manipulation of spins in fs/ps time scale.  
27

34 In this letter, we demonstrate the ultrafast manipulation of the magnetization through the orbital  
35  
36 orientation in ferromagnetic  $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$  (LSMO) thin films by using the time-resolved  
37  
38 magneto-optical Kerr effect (TR-MOKE) technique. The ultrafast enhancement or decrease of  
39  
40 magnetization within one ps is achieved under s- or p-polarized probe light, respectively. This  
41  
42 fast magnetization process correlated with the polarization orientation of the probe light within  
43  
44 a ps is explained by a model based on the Elliott-Yafet spin-flip scattering. After this initial  
45  
46 fast stage, a slow demagnetization process is then followed, lasting for hundreds of ps. The  
47  
48 demagnetization amplitudes under different directions of probe light polarization are found to  
49  
50 follow the four-fold symmetry of the orbital order.  
51  
52  
53  
54  
55  
56

57 The sample studied here with a thickness of 16 nm (40 unit cells) was grown on (001) oriented  
58  
59 single crystalline  $\text{SrTiO}_3$  (STO) terraced substrate. The crystallographic c-axis [001] is normal  
60  
61  
62  
63  
64  
65

1 to the sample plane. The in-plane crystallographic directions of [100] and [010] are shown in  
2 Figure 1 (a). More details of the growth information are given in the Supplemental Materials  
3 (SM) and other refs.<sup>[25,26]</sup> The Curie temperature  $T_C$  of the film is  $\sim 334$  K (See Figure.S1(a) of  
4 SM). This well resembles the previous results for bulk LSMO,<sup>[10,27]</sup> indicating the high quality  
5 of the film. In bulk LSMO, the  $d_{x^2-y^2}/d_{z^2-y^2}$  orbitals that partially filled by electrons are  
6 responsible for the metallic character and the double-exchange interaction between  $Mn^{3+}$  and  
7  $Mn^{4+}$  is responsible for the ferromagnetic order. As the sample exceeds the critical thickness  
8 of 2.5 nm, ferromagnetism is well reserved.<sup>[28]</sup> The LSMO thin film used in our measurements  
9 exhibits in-plane magnetic anisotropy, which originates from the in-plane tensile strain caused  
10 by the STO substrate. In the epitaxial film, the strain that originated from the substrate may  
11 modify the orbital occupancy.<sup>[29]</sup> As demonstrated by recent X-ray linear dichroism (XLD)  
12 measurements,<sup>[29,30]</sup> the tensile strain in LSMO thin film induced by STO substrate implies a  
13 preferential occupancy of the  $d_{x^2-y^2}$  orbital. The static Kerr rotation at room temperature is  
14 shown in Figure.S1 (b), showing relatively strong magneto-optical response at high photon  
15 energy. In our pump-probe measurements, 3.1 eV photons were used to probe the sample's  
16 magnetism as indicated by the blue arrow in Figure.S1(b). All the measurements were  
17 performed at room temperature.

18 The measurement geometry is schematically shown in Figure 1 (a). We used 1.55 eV photons  
19 to excite the sample and the s-polarized 3.1 eV photons to measure the resulting changes of  
20 magnetization. Figure 1 (c) shows the photoinduced change of Kerr rotation  $\Delta\theta$  normalized by  
21 the static value  $\theta_0$  before optical excitation. After the photoexcitation at  $\Delta t = 0$  ps, an  
22 instantaneous increase of  $\Delta\theta/\theta_0$  up to 0.15 is observed within 1 ps. Following this  
23 instantaneous increase, the amplitude of  $\Delta\theta/\theta_0$  continuously decreases, passes zero at 40 ps,  
24 and finally reaches a minimum of -0.6 at 1.36 ns. Note that the positive sign here represents  
25 the increase of magnetization. Upon the observation of the transient increase of magnetization

1 with the s-polarized probe beam, the hysteresis loops at different delay-times were measured  
2 as shown in Figure 1(d). It clearly shows two reversed types of the transient hysteresis loops at  
3  
4 0.67 ps and 1.36 ns, respectively. These results confirm that, as probed with s-polarized light,  
5  
6 an ultrafast increase in magnetization occurs after photoexcitation.  
7

8  
9 The ultrafast increase in magnetization of perovskite manganites has been reported in several  
10  
11 refs.<sup>[31-35]</sup> The underlying physical mechanisms are fundamentally linked to the density of  
12  
13 photogenerated carriers. For example, Yada *et al.*<sup>[31]</sup> found that the magnetization in  
14  
15  $\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3/\text{SrTiO}_3$  heterostructures increased within 0.2 ps due to the rapid hole injection  
16  
17 from STO into the manganite. Li *et al.*<sup>[34]</sup> showed a femtosecond generation of ferromagnetic  
18  
19 order in  $\text{Pr}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$  with photoexcitation threshold behaviour. If the photogenerated  
20  
21 carriers dominate the ultrafast increase of magnetism in our sample, then tuning the carrier  
22  
23 density will lead to the variation of the ultrafast enhancement. We have conducted one  
24  
25 experiment to test this prediction. As shown in Figure2, we extract respectively the amplitudes  
26  
27 of the transient hysteresis loops at  $\Delta t = 0.67$  ps and 1.36 ns under different pump excitation  
28  
29 intensity. The raw data of the transient hysteresis loops under different pump fluence is shown  
30  
31 in Figure S2. Clearly, the values at  $\Delta t = 0.67$  ps exhibit independence on the pump fluence,  
32  
33 demonstrating that the photo-carrier generation does not contribute to this fast magnetization  
34  
35 increase.  
36  
37  
38  
39  
40  
41  
42  
43

44 We notice that the ensuing slow decreasing component in Figure1 (c) is in the ns timescale.  
45  
46 This slow magnetization relaxation is associated with the demagnetization due to the increase  
47  
48 of the spin temperature by optically heating the spin system through the transferred energy  
49  
50 from the equilibrium electron-lattice system. Such spin-lattice relaxation is consistent with  
51  
52 previous empirical demagnetization process observed in materials with half-metallic  
53  
54 property.<sup>[9,10,36,37]</sup> In Figure 2, the amplitude of the slow demagnetization component (1.36 ns)  
55  
56 increases with increasing pump excitation intensity, which also supports the expectation of the  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 thermal demagnetization. However, the transient enhancement of the magnetization observed  
2 with s-polarized probe light cannot be expected from the thermal process, which should lead  
3 to an instantaneous drop rather than increase in magnetization as previously reported.<sup>[8]</sup>  
4

5  
6  
7 Considering the strongly coupled degrees of freedom between the spin and orbital in the LSMO  
8 film, we expect that the orbital orientation plays a role in the magnetization enhancement. To  
9  
10 verify this assumption, we have investigated the effect of the probe light polarization  
11 orientation on the pump-induced spin dynamics. In Figure 3(a), the recorded temporal trace  
12 was measured by the p-polarized probe beam. The polarization orientation and the excitation  
13 intensity of the pump beam remain the same as those in Figure 1(c). Under this experimental  
14 configuration, the instantaneous change of  $\Delta\theta/\theta_0$  within the initial 1 ps points to the negative  
15 direction, representing the ultrafast demagnetization. With p-polarized probe beam, the  $\Delta\theta/\theta_0$   
16 trace shows a typical two-step demagnetization characteristics, consisting of a step-like  
17 decrease and a subsequent slow demagnetization process of hundreds of ps or ns timescale.  
18  
19 This observation is consistent with the previous results mentioned above. The transient  
20 hysteresis loops at  $\Delta t = 30$  ps and 1.36 ns shown in Figure 3(b) confirm the in-phase decrease  
21 of magnetization. To further study the demagnetization behaviors under different polarization  
22 orientations of the probe beam, we have carried out systematic measurements to address this  
23 issue. In Figure 3(c), the values of  $\Delta\theta/\theta_0$  at time delay of 0.67 ps and 1.36 ns are plotted as a  
24 function of the polarization angles of the probe beam. Here,  $\varphi = 0^\circ$  and  $90^\circ$  represent the p-  
25 and s-polarization of the probe beam, respectively. The orientation of the s-polarized probe  
26 beam aligns with the [010] crystallographic axis of the LSMO thin film. The values of  $\Delta\theta/\theta_0$   
27 at 0.67 ps crosses zero at  $130^\circ$ . The sign of the values at 1.36 ns remains the same but their  
28 amplitudes change periodically. In Figure 3(d), the demagnetization amplitudes under different  
29 probe polarization angles at  $\Delta t = 1.36$  ns show a four-fold symmetry, which is similar to the  
30 occupied  $d_{x^2-y^2}$  orbitals as included in Figure 1(b). As experimentally demonstrated by  
31

1 Buchner *et al.*,<sup>[38]</sup> the MOKE method is a powerful tool of probing the interfacial SO coupling  
2 by tuning the polarization angle of the probing laser beam. The polarization orientation of the  
3 pump beam is found to have no impact on the demagnetization in our measurements (see in  
4 Figure S3). This suggests that the pump laser disturbs the sample mainly by the heating effect  
5 rather than the electron transition.  
6

7  
8  
9  
10  
11 The initial quenching of magnetization in half metals has been explained by several models  
12 based on the Elliott-Yafet(EY) type spin dependent scattering, such as the electron-electron,  
13 electron-phonon or electron-impurity interactions.<sup>[14,37,39,40]</sup> These microscopic mechanisms  
14 are all momentum-dependent scattering events due to the spin-orbit coupling, which would  
15 lead to a mixture of the two spin states near the Fermi level. The four-fold symmetry of the  
16 demagnetization amplitude at  $\Delta t = 1.36$  ns in Figure 3(d) reveals different spin scattering rates  
17 along different spatial directions, as expected from the anisotropic spin-orbital coupling in the  
18 CMR materials. We have also obtained similar results on two other samples with different  
19 thicknesses of 30 and 35 uc, respectively (as shown in Figure S4). The consistent results on  
20 different samples support our findings very well. We notice that the anisotropic Gilbert  
21 damping in  $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$  thin film is recently reported,<sup>[41]</sup> which is ascribed to the anisotropic  
22 SO coupling. Similar spin relaxation rates were also reported in other materials arising from  
23 the anisotropic spin-orbit coupling.<sup>[24,42,43]</sup> The fast change of magnetism ( $\sim 0.67$  ps) in Figure  
24 3(c) also has a dependence on probe light polarization orientation, showing different spin  
25 scattering rates along various orbital orientations. Note that the polarization of the light can  
26 access to different spatial directions of the orbitals.<sup>[44,45]</sup>

51 Considering the significant effect of the anisotropic spin-orbit coupling on spin relaxation, we  
52 propose a model to explain the observed ultrafast orbital-orientation demagnetization, as shown  
53 by the schematic diagram in Figure 4. In the presence of the spin-orbital coupling, an electron  
54 state near the Fermi level (straight dash line) is a mixture of the spin-up and spin-down states.<sup>[46]</sup>

Therefore, a number of spin-down electrons exist in the minority-spin band gap (dash curves in Figure 4). As shown in Figure 4, after photoexcitation by the pump light, non-equilibrium electrons (solid cyan circles) and holes (open circles) with up-spins are generated above and below the  $E_F$ , respectively. Since there exist a few spin-down states near the Fermi level, only a small part of the non-equilibrium carriers can be relaxed into the minority empty states via the spin-flip scattering. The p and s polarized probe light correspond to the x and y directions, respectively, as shown in Figure 1(a). Based on the above-mentioned consideration of anisotropic spin-orbit coupling, the photoexcited spin-up electrons prefer the scattering channels along x or y directions, as probed with p- or s-polarized light, respectively. In the case of p-polarized probe light (P process in Figure 4(a)), the spin-up electrons are relaxed into the empty spin-down states via the EY-based spin flip mechanism, leading to an instantaneous decrease of magnetization. For the s-polarized probe light (S process in Figure 4(b)), the electron spin-flip scattering along x direction is prohibited. However, the minority spin-down electrons can recombine with the majority spin-up holes below the Fermi level via the spin-flip scattering along the y direction, leading to an instantaneous increase of the magnetization. In the two processes of S and P, different spin-flip behaviour are necessary to account for the ultrafast demagnetization and remagnetization, respectively. Previous theoretical and experimental studies have suggested specific scattering ways to achieve spin flipping, e.g., electron-phonon, electron-defect and electron-electron scatterings.<sup>[14,47-49]</sup> As a consequence, the spin angular momentum can be transferred quickly to other degrees of freedom or vice versa. We notice that Wüstenberg et al. have previously revealed the possibility of ultrafast remagnetization via recombination of majority holes and minority electrons in half-metallic Heusler alloy  $\text{Co}_2\text{Cr}_{0.6}\text{Fe}_{0.4}\text{Al}$  thin films.<sup>[50]</sup> Their results support ours well. After the initial EY-based instantaneous increase or decrease in magnetization, the spin order of the remaining excited electrons (labeled as slow in Figure 4) is disturbed further via the slow spin-lattice

1 relaxation channel due to the increasing of the spin temperature. To further demonstrate the  
2 effect of orbital-oriented transient magnetization, we have also measured the pump-induced  
3 Kerr rotations at time-delays of 0.67 ps and 1.36 ns respectively by rotating the sample  
4 orientation angle  $\phi$  with fixed p-polarization of the probe beam. The results obtained by  
5 rotating the sample were identical to those obtained by varying the polarization angles of the  
6 probe light. The corresponding results are shown in Figure S5 in SM. In the above discussion  
7 on the EY-based spin-flip mechanisms, we did not address the specific scattering events  
8 (electron-electron, electron-phonon, electron-magnon, or electron-impurity scattering).  
9 However, the distinct dependence of the spin order on the orbital orientation suggests that the  
10 phonon-mediated scattering events play dominant roles in the sub-ps time scale, which have  
11 been reported in previous studies.<sup>[37,39,47]</sup> We believe that the phenomena of the ultrafast orbital-  
12 orientation demagnetization should exist in other ferromagnetic perovskite manganites, where  
13 the anisotropic spin-orbital coupling is a general characteristic of this material system.

14 In summary, the ultrafast orbital-oriented demagnetization process in the thin LSMO film has  
15 been studied by the TR-MOKE measurements, which reveals the novel effect of the anisotropic  
16 spin-orbit coupling on the temporal magnetization evolution. The transient magnetization  
17 enhancement as well as the decrease within the initial 1 ps after photoexcitation has been  
18 observed via tuning the polarization orientation of the probe light. A model based on the  
19 anisotropic spin-orbit coupling has been proposed to illustrate the spin-flip scattering  
20 happening within sub-ps regime. The anisotropic spin-orbit coupling has also been found to  
21 induce a four-fold symmetry in the subsequent slowly-relaxed demagnetization process  
22 measured by tuning the direction of the probe light polarization. This work has provided new  
23 insights into the underlying physics of ultrafast magnetism in the magnetic material systems  
24 with anisotropic spin-orbit coupling and new parameters for the ultrafast optical control of the  
25 magnetic order.

## Experimental Section

The experimental geometry of our TR-MOKE measurement is shown in Figure 1a. The incident pump beam is along the sample normal and the incident angle of the probe beam is around 45° away from the sample normal direction. The femtosecond pulse laser is generated by an amplified Ti: sapphire laser system with a 1 KHz repetition rate, a ~ 50 fs duration time, and a central wavelength of 800 nm (1.55 eV). The majority of the output laser intensity is used to excite the sample as a pump beam. The remainder passing through a BBO crystal is employed to measure the pump induced magnetic variation. The time delay between the two beams is achieved by a mechanical delay stage. The polarization angle of the probe light is tuned by a half-wave plate, as shown in Figure 1a. To obtain the genuine magnetic information, we define  $\Delta\theta/\theta_0 = (\Delta\theta_+/\theta_0 - \Delta\theta_-/\theta_0)/2$ . Here,  $\Delta\theta_+$  and  $\Delta\theta_-$  represent the pump-induced Kerr rotations under positive and negative magnetic fields, respectively.  $\theta_0$  represents the static Kerr rotation without pump excitation. In the measurements, the sample temperature rise induced by laser illumination was ignored as the time interval between two laser pulses (a millisecond) is long enough for the heat diffusion. One thing that needs to be addressed here is that the raw data in FIG. 3(d) was measured only from 90 – 270°. The data of 270 – 90° was obtained by the four-fold symmetry.

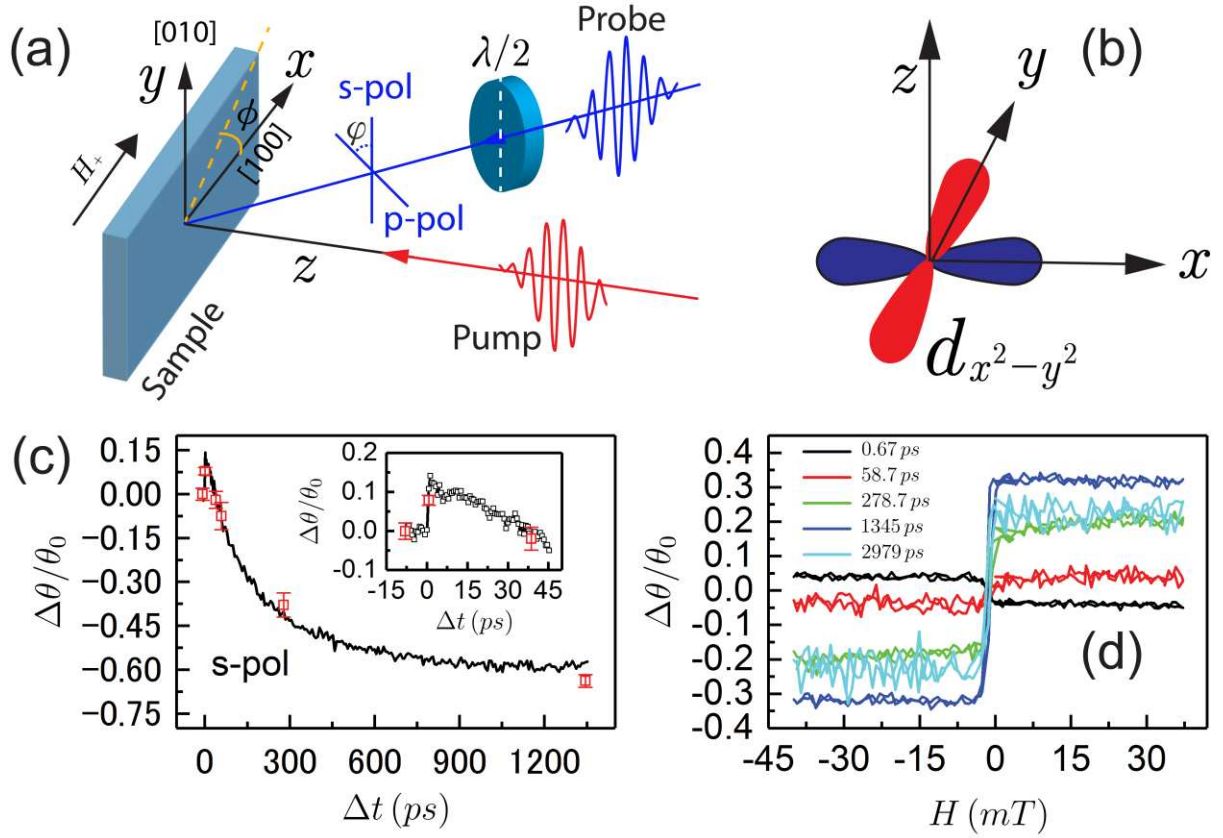

Figure 1. (a) The geometry diagram of the time-resolved magneto-optical Kerr effect. The pump beam is incident perpendicularly on the sample surface. The incident angle of the probe light is  $45^\circ$  with respect to the sample normal direction. A half-wave plate ( $\lambda/2$ ) is used to rotate the polarization plane of the probe light.  $\varphi$  here represents the rotation angle with respect to the incident plane of probe light. In the case of  $\varphi = 0^\circ$ , the electric field of light lies in the plane of the incident probe beam.  $\phi$  is defined as the angle between the spatial x-axis and the crystallographic axis [100] of the LSMO thin film. (b) Diagram of the  $d_{x^2-y^2}$  orbitals occupied by the  $e_g$  electrons. (c) Temporal characteristics of the pump-induced Kerr rotation with the s-polarized probe beam. The inset shows a magnified view of the ultrafast increase of  $\Delta\theta/\theta_0$ . (d) The transient hysteresis loops of LSMO film measured at different delay-times. The hysteresis loop probed at 0.67 ps is obviously opposite to those measured at other delay-times. The red squares in (c) represent the amplitude of the transient hysteresis loops at different time delays as shown in (d).

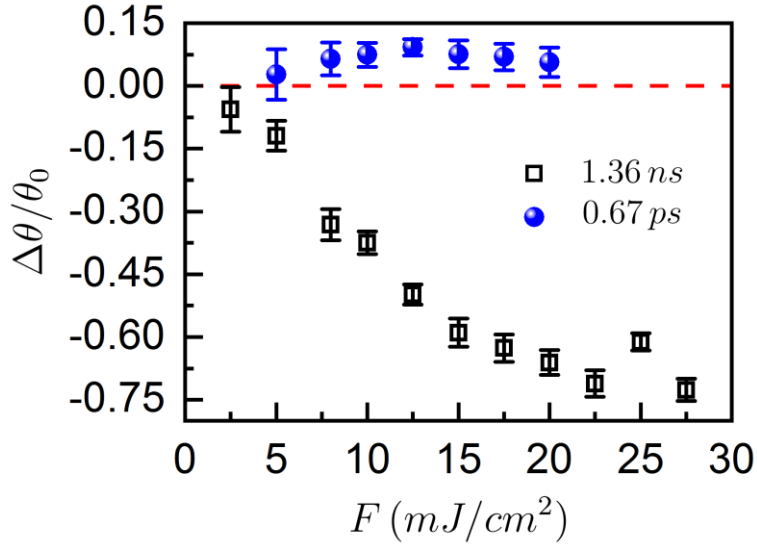

Figure 2. Fluence dependence of the normalized Kerr rotations at different time-delays. The blue and black squares represent the values of  $\Delta\theta/\theta_0$  at  $\Delta t = 0.67$  ps and 1.36 ns, respectively. The positive sign means the increase of magnetization, while the negative shows the demagnetization. The transient enhancement in magnetization is nearly independent of the pump fluence, while the slow demagnetization component is affected by laser heating.

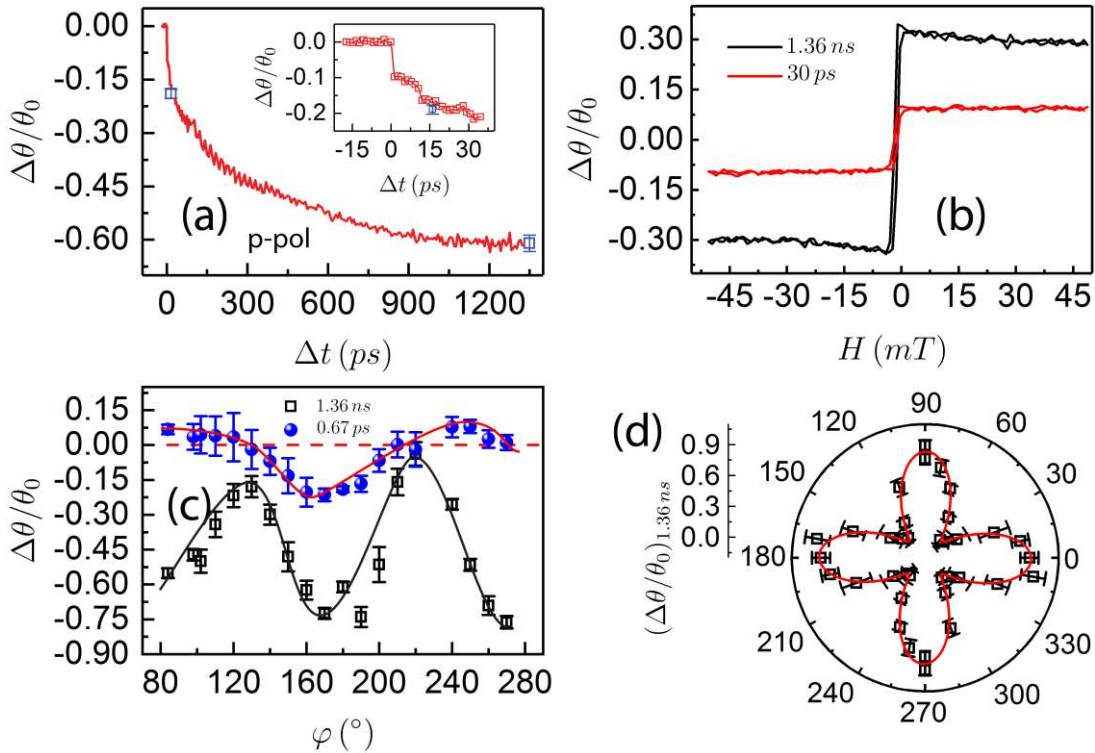

Figure 3. (a) The time evolution of the pump induced change of Kerr rotation probed with s-polarized probe. Inset: The enlargement of the pump induced Kerr signal at short time window of  $\sim 30$  ps. (b) Transient hysteresis loops measured at  $\Delta t = 30$  ps and 1.36 ns. Their amplitude with error bars are shown in (a) at the corresponding time delays. (c) The probe beam polarization orientation dependence of  $\Delta\theta/\theta_0$  values at time delays of 0.67 ps and 1.36 ns. The polarization angle of probe beam  $\varphi$  varies from  $87^\circ$  to  $180^\circ$ , corresponding to s and p polarization, respectively. (d) The probe beam polarization orientation dependence of the demagnetization amplitudes at 1.36 ns. The  $\varphi$  is ranged from  $0^\circ$  to  $360^\circ$ . The black and red solid lines in (c) and (d) are guides to the eyes.

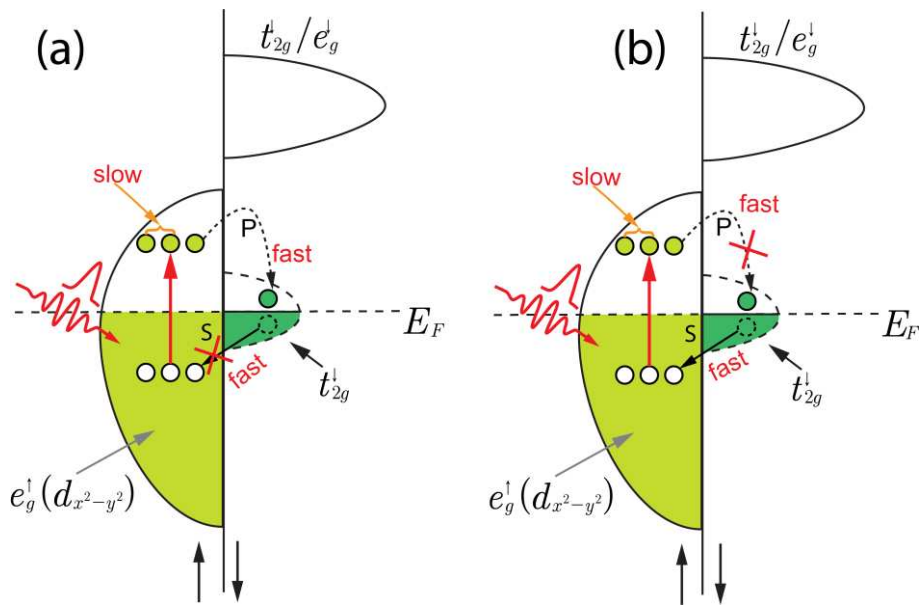

Figure 4. (a) The ultrafast magnetization decrease under p-polarized probe. The occupied and unoccupied minority spin density states (green and blank areas) are shown near the Fermi level  $E_F$ , which originates from the spin-orbit coupling. The cyan part below the Fermi level is  $e_g$  orbitals occupied by the majority spins. The red arrows mean the photoexcitation by 1.55 eV pump beam, generating non-equilibrium electrons and holes (cyan and blank circles respectively). The black dash arrow P represents that a part of the excited spin-up electrons is

1 scattered into the empty spin-down states. Note that the process S is switched off. (b) The  
2 schematic process for magnetization increase. Under s-polarized probe, the process P is  
3 blocked, while S (solid straight arrow) is switched on. The spin-down electrons in minority  
4 electron bands recombine with the excited majority spin-up holes, leading to a transient  
5 increase of the magnetism. In both (a) and (b), only a small amount of the excited carriers take  
6 part in the fast spin-flip process while the remaining part is relaxed through the slow spin-  
7 lattice channel.
