Health Technology Assessment

> ### Criteria for inclusion in the *Health Technology Assessment* journal
> Reports are published in *Health Technology Assessment* (HTA) if (1) they have resulted from work for the HTA programme, and (2) they are of a sufficiently high scientific quality as assessed by the reviewers and editors.
>
> Reviews in *Health Technology Assessment* are termed 'systematic' when the account of the search appraisal and synthesis methods (to minimise biases and random errors) would, in theory, permit the replication of the review by others.

HTA programme
Health Technology Assessment (HTA) research is undertaken where some evidence already exists to show that a technology can be effective and this needs to be compared to the current standard intervention to see which works best. Research can evaluate any intervention used in the treatment, prevention or diagnosis of disease, provided the study outcomes lead to findings that have the potential to be of direct benefit to NHS patients. Technologies in this context mean any method used to promote health; prevent and treat disease; and improve rehabilitation or long-term care. They are not confined to new drugs and include any intervention used in the treatment, prevention or diagnosis of disease.

The journal is indexed in NHS Evidence via its abstracts included in MEDLINE and its Technology Assessment Reports inform National Institute for Health and Care Excellence (NICE) guidance. HTA research is also an important source of evidence for National Screening Committee (NSC) policy decisions.

Background: Osteomyelitis is an infection of the bone. Medical imaging tests, such as radiography, ultrasound, magnetic resonance imaging (MRI), single-photon emission computed tomography (SPECT) and positron emission tomography (PET), are often used to diagnose osteomyelitis.

Objectives: To systematically review the evidence on the diagnostic accuracy, inter-rater reliability and implementation of imaging tests to diagnose osteomyelitis.

Data sources: We conducted a systematic review of imaging tests to diagnose osteomyelitis. We searched MEDLINE and other databases from inception to July 2018.

Review methods: Risk of bias was assessed with QUADAS-2 [quality assessment of diagnostic accuracy studies (version 2)]. Diagnostic accuracy was assessed using bivariate regression models. Imaging tests were compared. Subgroup analyses were performed based on the location and nature of the suspected osteomyelitis. Studies of children, inter-rater reliability and implementation outcomes were synthesised narratively.

Results: Eighty-one studies were included (diagnostic accuracy: 77 studies; inter-rater reliability: 11 studies; implementation: one study; some studies were included in two reviews). One-quarter of diagnostic accuracy studies were rated as being at a high risk of bias. In adults, MRI had high diagnostic accuracy [95.6% sensitivity, 95% confidence interval (CI) 92.4% to 97.5%; 80.7% specificity, 95% CI 70.8% to 87.8%]. PET also had high accuracy (85.1% sensitivity, 95% CI 71.5% to 92.9%; 92.8% specificity, 95% CI 83.0% to 97.1%), as did SPECT (95.1% sensitivity, 95% CI 87.8% to 98.1%; 82.0% specificity, 95% CI 61.5% to 92.8%). There was similar diagnostic performance with MRI, PET and SPECT. Scintigraphy (83.6% sensitivity, 95% CI 71.8% to 91.1%; 70.6% specificity, 57.7% to 80.8%), computed tomography (69.7% sensitivity, 95% CI 40.1% to 88.7%; 90.2% specificity, 95% CI 57.6% to 98.4%) and radiography (70.4% sensitivity, 95% CI 61.6% to 77.8%; 81.5% specificity, 95% CI 69.6% to 89.5%) all had generally inferior diagnostic accuracy. Technetium-99m hexamethylpropyleneamine oxime white blood cell scintigraphy (87.3% sensitivity, 95% CI 75.1% to 94.0%; 94.7% specificity, 95% CI 84.9% to 98.3%) had higher diagnostic accuracy, similar to that of PET or MRI. There was no evidence that diagnostic accuracy varied by scan location or cause of osteomyelitis, although data on many scan locations were limited. Diagnostic accuracy in diabetic foot patients was similar to the overall results. Only three studies in children were identified; results were too limited to draw any conclusions. Eleven studies evaluated inter-rater reliability. MRI had acceptable inter-rater reliability. We found only one study on test implementation and no evidence on patient preferences or cost-effectiveness of imaging tests for osteomyelitis.

Limitations: Most studies included < 50 participants and were poorly reported. There was limited evidence for children, ultrasonography and on clinical factors other than diagnostic accuracy.

Conclusions: Osteomyelitis is reliably diagnosed by MRI, PET and SPECT. No clear reason to prefer one test over the other in terms of diagnostic accuracy was identified. The wider availability of MRI machines, and the fact that MRI does not expose patients to harmful ionising radiation, may mean that MRI is preferable in most cases. Diagnostic accuracy does not appear to vary with the potential cause of osteomyelitis or with the body part scanned. Considerable uncertainty remains over the diagnostic accuracy of imaging tests in children. Studies of diagnostic accuracy in children, particularly using MRI and ultrasound, are needed.

Study registration: This study is registered as PROSPERO CRD42017068511.

Glossary

Diagnostic odds ratio Ratio of odds of sensitivity to odds of specificity (summarises diagnostic accuracy).

Diphosphono-1,2-propanodicarboxylic acid A substance used in scintigraphy.

False negative Incorrect negative test result – an affected individual with a negative test result.

False positive Incorrect positive test result – an unaffected individual with a positive test result.

Fludeoxyglucose A radiopharmaceutical used in positron emission tomography.

Hexamethylpropyleneamine oxime A substance used in scintigraphy.

Histopathology The microscopic study of tissue samples to enable the diagnosis of osteomyelitis.

(Hydroxy)methylene diphosphonate A substance used in scintigraphy.

Index test The test for which diagnostic accuracy is being evaluated.

Indium-111 A radioisotope used in scintigraphy.

Meta-analysis Statistical (or quantitative) techniques used to combine the results of two or more studies and obtain a combined estimate of effect.

Microbiology A laboratory method used to diagnose osteomyelitis; a microbiological culture involves multiplying microbial organisms by letting them reproduce under controlled laboratory conditions.

Negative predictive value Proportion of people who test negative (for osteomyelitis) who do not have the condition.

Positive predictive value Proportion of people who test positive who have the condition.

Positive rate Proportion of people with a positive index test result (i.e. who might be diagnosed with osteomyelitis).

Sensitivity Proportion of people with the condition (osteomyelitis) who are correctly diagnosed.

Specificity Proportion of people without the condition who are correctly diagnosed.

Technetium-99m A radioisotope used in scintigraphy and single-photon emission computed tomography.

True negative A correct negative test result – an unaffected individual with a negative test result.

True positive A correct positive test result – an affected individual with a positive test result.

Plain English summary

Osteomyelitis is an infection of the bone and is treated with antibiotics. Left untreated, it can cause permanent damage and can lead to amputation.

The best method to diagnose osteomyelitis is to take a bone sample (bone biopsy) but this is invasive and painful. Imaging may help target the best locations for biopsies or remove the need for a biopsy entirely. Several methods are available, including radiography, ultrasound, magnetic resonance imaging (MRI), single-photon emission computed tomography (SPECT) and positron emission tomography (PET).

This project systematically reviewed the relevant literature to determine which tests are the most accurate and relevant for clinical practice. All types of patients and all types of osteomyelitis were reviewed. Studies were pooled using statistical methods (meta-analyses) to estimate the overall accuracy of the imaging tests.

The review identified 81 studies and concluded that MRI, PET and SPECT all had similar accuracy, correctly identifying over 85% of people who did have osteomyelitis and over 80% of people who did not have osteomyelitis. Radiography and computed tomography were less accurate. Modern forms of scintigraphy have accuracy similar to PET or MRI.

There was no evidence that the accuracy of the imaging tests was different depending on the cause of osteomyelitis or which body part was affected. In particular, diagnostic accuracy in people with diabetic foot ulcers was similar to other types of osteomyelitis in adults. There was not enough evidence about which tests are most accurate in children, so further studies in children are needed.

Scientific summary

Background

Osteomyelitis is an infection of the bone and bone marrow that may result in bone infarction and loss of limb or joint function and, in extreme cases, may necessitate amputation of the affected limb. In children, osteomyelitis may also inhibit limb growth. Osteomyelitis is common in people with vascular deficiency, such as adults with diabetes mellitus.

Patients usually present with a range of symptoms including swelling, joint pain and fever. These symptoms are often not specific to osteomyelitis, leading to delays in correct diagnosis. Blood tests are used initially to assess inflammatory markers; when these tests show evidence of possible infection, patients are referred for further diagnostic testing. The most accurate diagnostic tool is a bone biopsy or aspiration of a pus collection from the bone or tissue surrounding the bone, with a histological and/or microbiological assessment of the sample to identify the organism causing the infection. The primary treatment for osteomyelitis is a course of antibiotics, but surgery may also be used.

Diagnostic imaging for osteomyelitis

A range of diagnostic imaging methods are available, including radiography, magnetic resonance imaging (MRI) scans, computed tomography (CT) scans, scintigraphy, positron emission tomography (PET) scans, single-photon emission computed tomography (SPECT) and ultrasound.

Little formal guidance [such as guidelines produced by the National Institute for Health and Care Excellence (NICE)] exists for which imaging techniques to use to diagnose osteomyelitis. The only current NICE guidance is for the treatment of diabetic foot ulcers. In those patients, radiography is recommended, followed by MRI if osteomyelitis is suspected, but not confirmed, by radiography.

Objectives

The key objectives were to:

- perform a systematic review of all studies reporting the diagnostic accuracy of any relevant imaging test, or combination of tests used to detect osteomyelitis
- perform diagnostic meta-analyses of identified studies to formally assess their diagnostic accuracy
- investigate diagnostic accuracy across the range of different types of osteomyelitis and types of patient
- compare the diagnostic accuracy of diagnostic tests both statistically and pragmatically by systematically reviewing inter-rater reliability and also the broader issues around implementation of imaging tests, such as availability of machinery, radiation exposure and acceptability to patients
- provide useful guidance as to which imaging tests should be preferred, according to type of disease and patient, in the UK.

Methods

A systematic review of the clinical effectiveness was performed following the general principles recommended in the University of York Centre for Reviews and Dissemination's (CRD's) guidance and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement. The protocol details have been registered on PROSPERO (number CRD42017068511).

Literature searches

Comprehensive searches for published and unpublished literature were carried out during August 2017 and updated in July 2018. Databases searched included MEDLINE and EMBASE.

Study selection

Titles and abstracts and the full texts of studies were independently assessed for inclusion by two reviewers using the inclusion criteria outlined in the following sections.

Participants

Participants included any patients with suspected osteomyelitis (based on symptoms, surgical samples or blood tests). No restrictions were made for age or disease aetiology.

Index tests

Index texts included any diagnostic imaging technique that could potentially identify osteomyelitis, including radiography, MRI, CT, PET, scintigraphy, SPECT and ultrasound.

Reference standards

Histopathology or microbiology based on bone biopsy or pus aspiration, and surgery, were the reference standards. As biopsies are invasive, clinical follow-up of at least 6 months with no signs or symptoms of osteomyelitis was also accepted as confirmation of the absence of osteomyelitis.

Outcomes

Studies reporting diagnostic accuracy of imaging tests compared with a reference standard expressed in terms of sensitivity (percentage with osteomyelitis with a positive diagnostic test result) and specificity (percentage without osteomyelitis with a negative test result) were included.

Studies reporting inter-rater reliability data or other data on test interpretation were included. General implementation outcomes considered were cost-effectiveness (of relevance to the UK), availability of tests, radiation exposure and experience of patients and clinicians.

Study designs

Any study that considered an imaging test or tests for osteomyelitis and which reported data on any of the specified outcomes was included. Only studies explicitly considering testing for osteomyelitis were included.

Data extraction

Study and patient characteristics were extracted by at least one reviewer and checked by a second reviewer. The numbers of true-positive, true-negative, false-positive and false-negative test results were extracted where possible.

Inter-rater reliability estimates were extracted from the papers and tabulated. For implementation studies, relevant results (e.g. from surveys of clinicians) were extracted and summarised narratively.

Quality assessment

The quality of the included diagnostic accuracy studies was assessed using the QUADAS-2 [quality assessment of diagnostic accuracy studies (version 2)] tool. Critical appraisal was performed by one reviewer and independently checked by another.

Synthesis

Data were synthesised in meta-analyses across studies using logistic regression modelling. Random-effects models were used to account for potential heterogeneity in diagnostic accuracy across studies. Results were presented as summary sensitivity and specificity estimates, with 95% confidence intervals (CIs), and as summary HSROC (hierarchical summary receiver operating characteristic) curves. Analyses were performed separately for adults and children.

When the studies were deemed too diverse for meta-analysis to be suitable, or where only one or two studies were available, the reported diagnostic accuracy from each available study was presented in tables and on ROC (receiver operating characteristic) plots.

Separate meta-analyses were conducted for each diagnostic imaging test and, when sufficient data were available, in subcategories of patients including:

- patients with diabetic foot ulcers
- cause of osteomyelitis
- anatomical site.

When studies report diagnostic accuracy data for two or more imaging tests, these tests were compared by extending the bivariate logistic regression models to include all imaging tests in one model.

Inter-rater reliability results and qualitative data on implementation were reported narratively and tabulated. Areas where few or no data have been published were also identified.

Results

Diagnostic accuracy

The review of diagnostic accuracy included 77 studies. The sample size of the studies ranged from 7 to 339, but most (80%) included fewer than 50 participants. Nearly one-quarter of the studies were considered as being at a high risk of bias, although poor reporting meant that there was significant uncertainty about the quality of most studies. Most of the evidence focused on the diagnostic accuracy of MRI, scintigraphy and radiography for the diagnosis of diabetic foot osteomyelitis. Few studies specifically focused on the axial skeleton, the pelvis/hip/knee and long bones.

The overall meta-analysis of diagnostic accuracy in adults found that MRI can detect osteomyelitis with high accuracy (95.6% sensitivity, 95% CI 92.4% to 97.5%; 80.7% specificity, 95% CI 70.8% to 87.8%). PET also had high diagnostic accuracy (85.1% sensitivity, 95% CI 71.5% to 92.9%; 92.8% specificity, 95% CI 83.0% to 97.1%), as did SPECT (95.1% sensitivity, 95% CI 87.8% to 98.1%; 82.0% specificity, 95% CI 61.5% to 92.8%). There were similar diagnostic odds ratios and summary HSROC curves for MRI, PET and SPECT, suggesting that the three imaging tests have similar diagnostic performance.

Scintigraphy (83.6% sensitivity, 95% CI 71.8% to 91.1%; 70.6% specificity, 95% CI 57.7% to 80.8%), CT (69.7% sensitivity, 95% CI 40.1% to 88.7%; 90.2% specificity, 95% CI 57.6 to 98.4) and radiography (70.4% sensitivity, 95% CI 61.6% to 77.8%; 81.5% specificity, 95% CI 69.6% to 89.5%) all had generally inferior diagnostic accuracy when compared with MRI, PET or SPECT. The most up-to-date forms of scintigraphy, such as ^{99m}Tc HMPAO WBC (technetium-99m hexamethylpropyleneamine oxime white blood cell) scintigraphy (87.3% sensitivity, 95% CI 75.1% to 94.0%; 94.7% specificity 95% CI 84.9% to 98.3%), had high diagnostic accuracy, similar to that of PET or MRI. There were insufficient studies of ultrasound to assess its diagnostic accuracy.

Key participant subgroups

The main patient subgroup was patients with diabetic foot ulcers, representing nearly half of all studies. The results of the meta-analyses for these patients were similar to those from the main meta-analysis, although there were too few studies of SPECT or CT to reliably assess diagnostic accuracy.

Studies of patients without diabetes were divided according to scan location and by potential cause of osteomyelitis. Data within each category were generally limited, but there was no evidence that diagnostic accuracy varied by scan location or cause, or that results differed substantially from the main analysis.

Diagnostic tests in children

The evidence for the accuracy of ultrasound and MRI in children was mixed and limited overall. Ultrasonography had moderate sensitivity and specificity in children with suspected acute haematogenous osteomyelitis but had perfect sensitivity and specificity in a small study of children with negative or equivocal initial radiographic findings. MRI had good sensitivity and specificity in children with suspected acute haematogenous osteomyelitis in one study, but preoperative MRI had poor sensitivity and near perfect specificity in another study of patients with septic hip.

Inter-rater reliability and implementation

Eleven studies evaluated the inter-rater reliability of at least one imaging test, and one study provided data on clinician opinions on imaging tests for osteomyelitis.

Magnetic resonance imaging appeared to have acceptable inter-rater reliability. There was some evidence suggesting that PET and scintigraphy showed near perfect inter-rater reliability, although this is limited to two small studies. We found no evidence on patient preferences and cost-effectiveness of imaging tests for osteomyelitis.

Only one study on the implementation of diagnostic test imaging for osteomyelitis was included. A Dutch survey of clinicians found that preferred imaging strategies for diagnosing post-traumatic osteomyelitis depended on specialty and availability of machinery. Most responders were not aware of local hospital protocols for diagnosing osteomyelitis.

Discussion

Strengths and limitations of the analyses

This systematic review was the largest and most comprehensive review of the diagnosis of osteomyelitis to date, and the first to comprehensively compare all relevant imaging tests across all types of patient.

There were few studies identified that included children. This may be because studies of children do not discuss osteomyelitis directly, but instead mostly in the context of other conditions, such as septic arthritis. Hence, it is possible that some possibly relevant studies were missed.

Some imaging tests were reported, particularly ultrasound and CT scans. Some aspects of studies were inconsistently reported, such as varying descriptions of the cause of osteomyelitis, non-reporting of whether osteomyelitis was acute or chronic and lack of clarity on whether or not radiography (or other tests) had been used prior to the main test. This made assessment in these subgroups difficult.

We identified very few data beyond those on diagnostic accuracy, with few studies discussing broader implementation issues such as access to machinery, costs or radiation exposure.

Uncertainties

The main uncertainties remaining following this review arise largely because of limitations in the identified studies.

The diagnostic accuracy of imaging tests in children remains highly uncertain because of the very limited nature of the evidence. We could reach no firm conclusions on the diagnostic accuracy of any imaging test in children.

The diagnostic accuracy of ultrasound is currently unknown as the only two studies in adults had conflicting results.

Although we found no evidence that diagnostic accuracy varied across subgroups of patients, limited or inconsistent reporting of some characteristics, such as acute versus chronic osteomyelitis, or the cause of osteomyelitis, means than differences between tests or between subgroups cannot be ruled out.

Generalisability of the findings

The apparent consistency of diagnostic accuracy across the various types of patient and causes of osteomyelitis suggests that the diagnostic accuracy findings are likely to be generalisable to any population being tested for osteomyelitis. The similarity in diagnostic accuracy across MRI, PET and SPECT scans suggests that these tests should have similar accuracy in most clinical circumstances.

The review found considerable variation in the specificity of MRI across studies. This may mean that the observed specificity of MRI in any given setting may differ from the summary estimates calculated in this review, depending on how MRI is implemented.

The limited evidence on diagnosis of osteomyelitis in children means that results may not be generalisable beyond the populations in the included studies.

Conclusions

Implications for service provision

Magnetic resonance imaging, PET and SPECT all have broadly similar and high accuracy when diagnosing osteomyelitis. All are likely to be suitable imaging tests for diagnosing osteomyelitis. No clear reason to prefer one test over the others in terms of diagnostic accuracy was identified. The wider availability of MRI machines, and the fact that MRI does not expose patients to harmful ionising radiation, may mean that MRI is preferable in most cases, unless it is unsuitable for a particular patient. A PET or SPECT scan may be required if a MRI scan is inconclusive.

Positron emission tomography had poorer sensitivity but higher specificity than MRI, with more consistent results across studies. This may make PET better suited to situations where avoiding false-positive diagnoses is important, for example when the test would be followed by surgery or other invasive procedures.

There is no evidence to suggest that the diagnostic accuracy varies with the potential cause of osteomyelitis or with the body part scanned, although data on patients other than those with diabetic foot ulcers were limited. The review identified very limited data on diagnosing osteomyelitis in children, so considerable uncertainty remains over the diagnostic accuracy of imaging tests in children. Clinicians should be aware of this limitation in the evidence base.

Suggested research priorities

The most urgent research priority is to perform diagnostic accuracy studies of imaging tests in children. Large diagnostic accuracy studies are needed, which must be of high quality, with proper blinding of test assessors and consecutive recruitment of patients. The priority tests should be MRI and ultrasound, ideally comparing the two tests in the same children.

Ultrasound has not been widely assessed in adults. Current results suggest that ultrasound on its own may not be sufficiently accurate to diagnose osteomyelitis, but further accuracy studies are needed to resolve the uncertainty. It may be more appropriate to investigate the diagnostic accuracy of ultrasound as a precursor to MRI or other tests (e.g. as a replacement for radiography).

Given the similarities in diagnostic accuracy of MRI, PET and SPECT, suitable investigation of patient and clinician experience and opinion of these tests, through surveys or focus groups, would be useful to identify practical reasons for the choice of test. Similarly, a formal economic evaluation of these tests, accounting for test cost, availability and risk of radiation exposure, would help to clarify the choice between these tests.

Study registration

Chapter 1 Background

Osteomyelitis

Osteomyelitis is an infection of the bone and bone marrow.[1,2] Left untreated, it may result in bone infarction and loss of limb or joint function and, in extreme cases may require amputation of the affected limb. If the infection spreads, it may lead to potentially fatal septicaemia.[3] In children, osteomyelitis may also inhibit limb growth, requiring extensive orthopaedic intervention in later childhood. *Staphylococcus aureus* is the most common organism causing osteomyelitis, but other common organisms such as *Streptococcus* spp. or *Escherichia coli* may also be responsible in some cases. Bone infections occur most commonly in people aged < 20 years or > 50 years. It accounts for around 1% of all childhood hospital admissions. The incidence of osteomyelitis has increased over recent decades, notably in children and in patients > 60 years of age. This growing incidence has been associated with increased prevalence of meticillin-resistant *S. aureus* (MRSA) in children and an increase in diabetes mellitus-related infections in adults.[4]

Osteomyelitis may be acute, subacute or chronic and is divided between haematogenous osteomyelitis, in which infection transfers from a remote location in the body via the bloodstream, and contiguous osteomyelitis, in which infected material comes into direct contact with the bone.[5] The haematogenous type is more common in children whereas the contiguous type is more common in adults, usually as a result of trauma or surgery.[6] Osteomyelitis is also common in people with vascular deficiency, such as adults with diabetes, as a complication of diabetic foot ulcers.[7] Osteomyelitis may lead to infection of the adjacent joint (septic arthritis) or occur secondary to septic arthritis by contiguous spread.

Patients usually present with a range of symptoms including swelling, joint pain and fever. These symptoms are often not specific to osteomyelitis, leading to delays in correct diagnosis. Blood tests are used initially to assess inflammatory markers indicative of infection in the body, including white blood cell (WBC) count, C-reactive protein (CRP) levels and erythrocyte sedimentation rate (ESR).[8] When these tests show evidence of possible infection, patients are referred for further diagnostic testing. The most accurate diagnostic tool is a bone biopsy or aspiration of a pus collection from the bone or tissue surrounding the bone, with a microbiological assessment of the sample to identify the organism causing the infection. Biopsies are invasive and generally require a local or a general anaesthetic. The analysis of the results may take several days. Alternative diagnostic tools include blood or tissue cultures, which may be less accurate but are useful in identifying the organism causing an infection in the body, which enables the selection of the appropriate antibiotic for treatment. The primary treatment for osteomyelitis is a course of antibiotics, but surgery may also be used.[9]

Diagnostic imaging for osteomyelitis

Diagnostic imaging of the affected area before performing a biopsy may help improve diagnosis and avoid unnecessary biopsies in people who may have an infection but are unlikely to have osteomyelitis. It can also be useful to identify pus collections, assess the need for drainage procedures and establish the best way for surgical access.

A range of diagnostic imaging methods are available, including radiography, magnetic resonance imaging (MRI), computed tomography (CT), scintigraphy, positron emission tomography (PET), single-photon emission computed tomography (SPECT) and ultrasound.[9–12] These imaging methods each have their advantages and disadvantages.

Radiography are easily available and cheap to perform, but are poor at detecting osteomyelitis in its early stages. Radiography may be most useful in identifying and ruling out other causes of the patient's symptoms, such as bone fractures.[11] MRI is probably the most widely recommended and used technique. It is more accurate than radiography and able to detect osteomyelitis in its early stages, but is more expensive to perform[12] and when used in children necessitates the use of sedation or general anaesthesia. PET and bone scintigraphy are more expensive and less widely available than MRI or radiography.[11,13] These methods expose patients to ionising radiation. Ultrasound avoids the radiation exposure and is readily available, but its diagnostic accuracy is currently uncertain.[12] There is also a distinction between methods that provide two-dimensional images (radiography, scintigraphy) and those producing three-dimensional images (PET, MRI, CT, SPECT). Some tests (e.g. MRI) may be less suited to patients with hip replacements or other indwelling metalwork because the metalwork can alter the reliability of the imaging.

Current diagnostic and treatment practice

Once osteomyelitis is suspected on the basis of physical examination and blood tests, MRI is currently generally recommended as the imaging test of choice because it can detect osteomyelitis early and it can identify pus collections within bone that might require surgical drainage. Radiography is not usually recommended in isolation, because of their failure to detect early osteomyelitis, but are generally used as a first-line investigation to rule out or confirm bone fractures or other causes of symptoms.[12] CT, scintigraphy and PET are less widely recommended, but are an alternative for patients in whom MRI is not possible.

Ultrasonography is suggested as an alternative to radiological tests[7,9,11,12,14] and is widely used in paediatric practice to exclude joint effusions and pus collection next to bone.[14] This is especially helpful in young children (aged < 6 years), who would require a general anaesthetic for MRI. Ultrasound is also used to guide aspiration and biopsy.

Little formal guidance [such as guidelines produced by the National Institute for Health and Care Excellence (NICE)] exists about which imaging techniques to use to diagnose osteomyelitis. The only current NICE guidance is for the treatment of diabetic foot ulcers.[1] In those patients, radiography is recommended to either confirm advanced osteomyelitis or confirm that the symptoms are due to other causes (e.g. broken bones). Radiography is followed by MRI if osteomyelitis is suspected but not confirmed by radiography. In children, ultrasonography is sometimes used in place of MRI. Antigranulocyte Fab fragment antibody scintigraphy should not be used in patients with diabetic foot ulcers.[15] Recommendations about its use have also been published in the USA.[16,17]

Osteomyelitis is treated with a 4- to 6-week course of antibiotics.[18,19] Treatment is initially intravenous, switching to oral antibiotics after around 2 weeks. The choice of antibiotics will depend on the infecting organism, as determined by tests such as microbiological culture and the patient's medical history. Surgery may also be used for debridement of necrotic tissue and affected bone, to drain pus and to reduce bacterial load.

Pathway to diagnosis in the NHS

There are a number of ways in which a patient might be referred for imaging to diagnose osteomyelitis. Patients may present with fever and be admitted as inpatients, or may be referred directly by their general practitioner (GP) to an orthopaedic clinic. This pathway to clinic is slower than presenting directly to accident and emergency and such patients often have less virulent infection or subacute osteomyelitis. Patients may be referred from other hospitals, particularly those that lack the facilities to treat children (e.g. if the hospital does not offer MRI under general anaesthesia). Patients presenting with acute symptoms may have a musculoskeletal issue (often limping or joint pains) or non-specific systemic

symptoms and sepsis (e.g. immunodeficient patients as a result of underlying chronic condition). Generally unwell patients with sepsis are more difficult to diagnose because they might be in intensive care and joint symptoms could initially be missed while the focus is on treating severe symptoms.

The range of symptoms and possible causes of these symptoms mean that osteomyelitis may not be suspected at first. Patients may undergo one or more radiographic assessments (and ultrasound scans in children) and repeated blood tests prior to final diagnosis. Patients may also have received a course of antibiotics before diagnosis, with osteomyelitis suspected only because that treatment course was not successful. This complicates the diagnostic process, and the practical pathway to most diagnoses of osteomyelitis in many patients will differ from that used in formal diagnostic accuracy studies.

Existing review evidence

Several systematic reviews or meta-analyses have been performed to assess diagnostic imaging techniques for osteomyelitis.[20–30]

Four of these reviews considered primarily, or only, people with diabetic foot ulcers.[20,22,23,26] Their conclusions varied, depending on the tests included, but MRI, PET and WBC scintigraphy were all suggested as suitable imaging tests. Three reviews of osteomyelitis in the general population mostly recommended PET and SPECT as having the best diagnostic accuracy.[25,27,28] One review focused on patients with peripheral post-traumatic osteomyelitis and concluded that WBC scintigraphy with SPECT/CT or ^{18}F-FDG (fludeoxyglucose)-PET/CT had the best diagnostic accuracy in this population.[21] Another review of MRI in patients with pressure ulcers was inconclusive as a result of insufficient evidence.[29] Two reviews were conducted in children. One focused on calcaneal osteomyelitis and was inconclusive because of the limited evidence.[24] The other children's review focused on haematogenous acute and subacute paediatric osteomyelitis, and found that MRI had the highest sensitivity and specificity compared with radiography, scintigraphy, CT and ultrasound.[30]

Chapter 2 Aims and objectives

The overall aim of this project was to systematically review the literature on diagnostic imaging for osteomyelitis in order to identify the techniques with the best diagnostic accuracy and the greatest clinical utility, across the range of types of disease and patients. The key objectives were to:

- perform a systematic review of all studies reporting the diagnostic accuracy of any relevant imaging test, or combination of tests, used to detect osteomyelitis
- perform diagnostic meta-analyses of identified studies to formally assess their diagnostic accuracy
- investigate diagnostic accuracy across the range of different types of osteomyelitis and types of patient
- compare the diagnostic accuracy of diagnostic tests both statistically and pragmatically, by systematically reviewing inter-rater reliability, and the broader implementation of imaging tests, accounting for key factors such as availability of machinery, radiation exposure and acceptability to patients
- provide useful guidance as to which imaging tests should be preferred, according to type of disease and patient, in the UK.

Chapter 3 Methods

A systematic review of the clinical effectiveness was performed following the general principles recommended in the Centre for Reviews and Dissemination's (CRD's) guidance and the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement. The protocol details have been registered on PROSPERO (number CRD42017068511).

Literature searches

The search strategy was developed by an information specialist with input from the review team and clinical advisors. The strategy was developed in MEDLINE (via Ovid) and included search terms for osteomyelitis and relevant diagnostic imaging techniques. No language, date, geographical or study design limits were applied. The MEDLINE strategy was adapted for use in the other resources searched.

The searches were carried out during August 2017 and updated in July 2018 to capture more recent studies. The following databases were searched: MEDLINE (including Epub Ahead of Print, In-Process & Other Non-Indexed Citations, Ovid MEDLINE Daily and Ovid MEDLINE), Cochrane Central Register of Controlled Trials (CENTRAL), Cochrane Database of Systematic Reviews (CDSR), Cumulative Index to Nursing and Allied Health (CINAHL) Plus, Database of Abstracts of Reviews of Effects (DARE), EMBASE, Health Technology Assessment (HTA) database and PubMed.

In addition, ClinicalTrials.gov and PROSPERO were searched for ongoing and unpublished studies. Relevant guidelines were identified through searches of the National Guidelines Clearing House, NHS Evidence, the NICE website and the Trip database. The reference lists of relevant systematic reviews were manually checked to ensure that all relevant studies from previous reviews were identified.

The search results were imported into EndNote X8 [Clarivate Analytics (formerly Thomson Reuters), Philadelphia, PA, USA] and de-duplicated. The complete search strategies can be found in *Appendix 1*.

Study selection

Titles and abstracts and the full texts of studies were independently assessed for inclusion by two reviewers using the inclusion criteria outlined in this section. Disagreements were resolved through discussion and, where necessary, consultation with a third reviewer. Study selection was performed using EPPI-Reviewer 4 software (Evidence for Policy and Practice Information and Co-ordinating Centre, University of London, London, UK).

Participants
Participants were any patients with suspected osteomyelitis (based on symptoms, surgical samples or blood tests). No restrictions were made for age or disease aetiology.

Index tests
Index tests considered included any diagnostic imaging technique that could potentially identify osteomyelitis, either alone or in combination with other relevant tests, such as radiography, MRI, CT, PET, SPECT and ultrasound. Variations on these tests were included, such as variations in the radioisotopes used and differences in protocols or contrast agent use.

Scintigraphy was not a protocol-specified imaging test for this review as it was not expected to be widely used in the UK, particularly because three-dimensional (3D) SPECT imaging may be preferred to planar scintigraphy. However, as the protocol specified that any relevant imaging test would be considered,

and many studies of scintigraphy were identified, scintigraphy was included in this review. To focus on the more UK-relevant tests in the main analysis, data on scintigraphy were included only where they were included in a study of another relevant imaging test. Studies evaluating the diagnostic accuracy of scintigraphy alone were considered in a separate analysis.

Reference standards

The preferred reference standard was histopathology or microbiology based on bone biopsy. Surgery was also accepted as a reference standard; other accepted methods of sample collection included pus aspiration.

As biopsies are invasive, clinical follow-up of at least 6 months with no signs or symptoms of osteomyelitis was also accepted as confirmation of the absence of osteomyelitis. Similarly, clinical evidence that the symptoms had another cause was accepted as confirmation of the absence of osteomyelitis.

To avoid potential bias through overestimation of diagnostic accuracy, studies were excluded if a positive osteomyelitis diagnosis was made by using a second imaging test, or by clinical follow-up alone, without biopsy or other microbiological testing.

Outcomes

Diagnostic accuracy review

The primary outcome was the diagnostic accuracy of the imaging test compared with the reference standard expressed in terms of sensitivity (percentage of people/scans with osteomyelitis with a positive diagnostic test result) and specificity (percentage of people/scans without osteomyelitis with a negative test result). Studies reporting sensitivity and specificity, or sufficient data to calculate both measures, were included. Studies evaluating other related conditions, such as spondylodiscitis or septic arthritis, were included if they provided separate diagnostic accuracy data for osteomyelitis.

Inter-rater reliability and implementation of imaging tests

Studies reporting inter-rater reliability for any test, or any other measure of accuracy of test interpretation, were included. Studies reporting information on the broader implementation and acceptability of imaging tests for osteomyelitis were included. The following implementation outcomes were eligible for inclusion: cost-effectiveness of imaging tests (of relevance to the UK), availability of tests (e.g. access to machinery), radiation exposure and substantive data on the experience of patients or clinicians.

Study designs

Any study that considered an imaging test or tests for osteomyelitis that reported data on any of the specified outcomes was included. Therefore, studies reporting any diagnostic accuracy data, other quantitative data (e.g. inter-rater reliability) or substantive qualitative or semiqualitative data (e.g. surveys of patients and clinicians) were included. Only studies explicitly considering testing for osteomyelitis were included. Studies reporting on characteristics of the imaging tests more broadly were excluded.

The following types of reports were excluded: editorials and opinions, case reports, reports focusing only on technical aspects of imaging tests (e.g. technical descriptions or specifications of machinery). We selected the most complete or most recent report in cases of multiple reports for a given study or when we could not exclude the possibility of overlapping populations.

Data extraction

A mapping exercise informed the development of the data extraction form, which was then piloted on a small selection of studies by two reviewers. Data extracted included details of patient characteristics, diagnostic tests and reference standard tests. Data were extracted by one reviewer and independently checked for accuracy by at least one other reviewer. Discrepancies were resolved by discussion, with

involvement of a third reviewer when necessary. Given the high number of studies, authors were not contacted if relevant data appeared to be unreported. In cases of multiple reports for a given study, the most recent or most complete report was used as the main source of data.

Study characteristics were extracted, including design, year, country and patient eligibility criteria. Patient characteristics that were extracted included age, comorbidities, diabetic status, location of osteomyelitis and reason for referral. Data on study intervention (e.g. characteristics of imaging test used, radioisotope, contrast agent, diagnostic cut-off point and thresholds), unit of analysis (e.g. patient, body part) and data on exclusions from study/analysis with reasons were recorded. Types of reference standards used for confirming positive and negative cases were recorded. The numbers of patients confirmed to be positive or negative in accordance with the reference standard, and the numbers of true-positive, true-negative, false-positive and false-negative test results, were extracted, if reported. If not reported, sensitivity and specificity estimates [with their 95% confidence intervals (CIs)] or other reported diagnostic accuracy data were extracted. Where possible, sensitivity, specificity, positive predictive values (PPVs) and negative predictive values (NPVs) were calculated and checked against reported values in the publications to check for any discrepancies. When more than one test was performed for the same participant in the same body part (i.e. repeat test, or follow-up test), only the result of the first test was used.

Inter-rater reliability estimates were extracted from the papers and tabulated. For the implementation review, relevant results on cost-effectiveness or use of machinery or data from surveys of clinicians were extracted and summarised narratively.

Quality assessment

The quality of the included diagnostic accuracy studies was assessed using the QUADAS-2 [quality assessment of diagnostic accuracy studies (version 2)] tool designed for diagnostic accuracy studies.[31] Critical appraisal was performed by one reviewer alongside data extraction and independently checked by at least one other reviewer. The QUADAS-2 tool was adapted to ensure that it is applicable to assessing the quality of studies of imaging tests for detecting osteomyelitis. The tool consists of four key domains: (1) patient selection, (2) index test, (3) reference standard and (4) flow of patients through the study and timing of the index test(s) and reference standard. Each domain was assessed in terms of the risk of bias. The first three domains were also assessed for concerns regarding their applicability, that is, whether or not the participants and setting, the index test, its conduct or interpretation and the target condition (as defined by the reference standard) were applicable to the review question. Further details on the critical appraisal tool, including signalling questions to inform the assessment of the key domains, are reported in *Appendix 2*.

No validated instrument is available for appraising the quality of studies on inter-rater reliability. We used a modified version of the tool reported by van de Pol *et al.*[32]

Synthesis

Diagnostic meta-analysis

For each diagnostic imaging test, data were synthesised in meta-analyses across studies using logistic regression modelling. This approach fits a statistical model that regresses index test outcome (positive or negative for osteomyelitis) against whether each person does or does not have confirmed osteomyelitis, based on the reference standard. This has been shown[33] to be equivalent to both bivariate meta-analysis and hierarchical summary receiver operating characteristic (HSROC) analysis, which are the methods most commonly used in diagnostic meta-analyses.[34,35] It also accounts for correlation between sensitivity and specificity, and for the fact that these may vary if different test thresholds are used across studies. This proposed model is known as a 'one-stage' approach because it analyses summary diagnostic accuracy across all studies simultaneously. It provides a more flexible approach than conventional bivariate or

HSROC analysis; in particular, it permits the inclusion of extra terms in the model to identify subgroups of studies or participants, and to compare different imaging tests.

Studies were pooled if three or more studies were eligible for the analysis. Random-effects models were used to account for potential heterogeneity in diagnostic accuracy across studies. Results were presented as summary sensitivity and specificity estimates, with 95% CIs, plotted in receiver operating characteristic (ROC) space, and as summary HSROC curves.

When studies reported diagnostic accuracy for multiple tests, data for each test were included in the analysis. When studies reported multiple results for the same imaging test (e.g. at different test thresholds, or diagnosis by different clinicians) then only the data corresponding to the greatest diagnostic accuracy [i.e. having the highest diagnostic odds ratio (DOR)] were included.

The PPVs and NPVs were also analysed using the same bivariate logistic regression approach. It should be noted that PPV and NPV depend on the incidence of osteomyelitis in each study, and so may be more heterogeneous than sensitivity and specificity.

In addition to the bivariate analyses, meta-analyses of estimated DOR and positive rates (PRs) (the proportion of people whose imaging test result suggests osteomyelitis, and so who would be diagnosed with osteomyelitis on the basis of the imaging test) were also performed. Univariate meta-analyses (ignoring correlation between outcomes) of sensitivity, specificity, PPV and NPV were also performed, for comparison with the bivariate analyses. In all these meta-analyses, heterogeneity was assessed using I^2.[36]

When the studies were deemed too diverse for meta-analysis to be suitable, or when only one or two studies were available, the reported diagnostic accuracy from each available study was presented in tables and on ROC plots, and compared across studies, tests and subgroups. Studies that did not report full diagnostic accuracy data, but only summary sensitivity and specificity, were summarised in narrative form by tabulating the results.

Subgroup analyses

Separate meta-analyses were conducted for each diagnostic imaging test and, where sufficient data were available, according to the following subcategories of patients:

- children and adults (as defined by the studies)
- cause of osteomyelitis (haematogenous, contiguous, trauma, surgical, diabetes related, other)
- acute, subacute or chronic osteomyelitis (COM)
- anatomical site (long bone, spinal, foot and ankle, pelvis, other)
- patients with hip replacements or other indwelling metalwork.

Subgroup analyses were also performed to assess the impact of different study characteristics:

- subtypes of imaging test (e.g. owing to the use of different radioisotopes, inclusion or exclusion of CT scanning, different thresholds, or methods of image interpretation)
- choice of reference standard (biopsy, or clinical and surgical follow-up)
- study quality (based on QUADAS-2 criteria).

As having diabetic foot ulcers is one of the most common causes of osteomyelitis, we performed meta-analyses specifically of studies of people with diabetic foot ulcers.

Analyses were performed separately for adults and children.

Analyses within subgroups were performed using the logistic regression analysis approach discussed in *Diagnostic meta-analysis*. Separate analyses were performed for each subgroup.

Comparison of imaging tests

Diagnostic tests were compared by examining summary DORs derived from the logistic regression models and by comparing summary ROC curves. In general, a larger DOR indicates a better performance, but this may not be the case if ROC curves cross, in which case the trade-off between sensitivity and specificity was considered. When there were sufficient data, these comparisons were made in each of the subgroups listed in *Subgroup analyses*.

When studies reported diagnostic accuracy data for two or more imaging tests on the same patient population, these tests were compared within the study by comparing sensitivity, specificity and DOR estimates. The main bivariate logistic regression models were extended to include all imaging tests in one model, to allow tests to be formally compared for differences in DOR and specificity.

Inter-rater reliability and implementation review

Owing to heterogeneity, studies evaluating inter-rater reliability results were reported narratively and tabulated. For studies reporting qualitative data on the implementation of diagnostic tests (e.g. clinical or patient opinions), data were synthesised using a narrative synthesis approach. Areas where few or no data have been published were also identified.

Deviations from the protocol

Some changes in the review and analysis process were made as a consequence of the nature of the identified studies.

Scintigraphy was not a protocol-specified imaging test, but many of the included studies compared scintigraphy with another test. Scintigraphy was therefore included in the main review and meta-analyses where studies compared it with another eligible test. To ensure a fair analysis of scintigraphy, a separate meta-analysis of scintigraphy alone was performed. In that analysis, we also included studies reporting the diagnostic accuracy of scintigraphy alone that included > 20 participants and that had been published since 1990. These additional studies were not assessed for quality using QUADAS-2 and only basic diagnostic accuracy data were extracted from publications.

For several proposed subgroup analyses, either we identified no relevant studies or studies did not report sufficient data for synthesis, so no analyses were performed. The subgroups were patients with:

- acute symptoms (such as would be admitted as inpatients)
- sepsis
- milder or chronic symptoms (such as would be referred by a GP)
- concomitant diseases (e.g. cancer).

The number of studies of children and of ultrasound were too few to permit a meta-analysis, so these studies were combined in a narrative synthesis only.

Role of patient and clinical advisors

Clinical advisors for this project attended meetings (in person or remotely) over the course of the project to ensure that it met clinical needs. This included approving the protocol, discussing and commenting on the provisional results and meta-analyses, and commenting on this report.

Two patient representatives, both parents of children who had been treated for osteomyelitis, were contacted through telephone meetings over the course of the project to discuss their experience of imaging tests and to discuss the findings of the project.

Chapter 4 Results

Quantity and quality of research available

Included studies

Figure 1 is a flow diagram outlining the screening process with reasons for exclusion of full-text papers. The literature searches of bibliographic databases identified 18,386 unique references. After initial screening of titles and abstracts, 597 were considered to be potentially relevant and were ordered for full-paper screening. In total, 77 studies[37–113] (from 79 reports) were included in the diagnostic review, of which 69 were also included in a meta-analysis.[38–42,44–51,53–71,73–77,79–95,97,99–113] Eleven studies were included in the review of inter-rater agreement,[37,58,59,65,68,86,92,114–117] and one was included in the review of implementation.[118] Seven studies were included in both the diagnostic and inter-rater reliability reviews.[37,58,59,65,68,86,92]
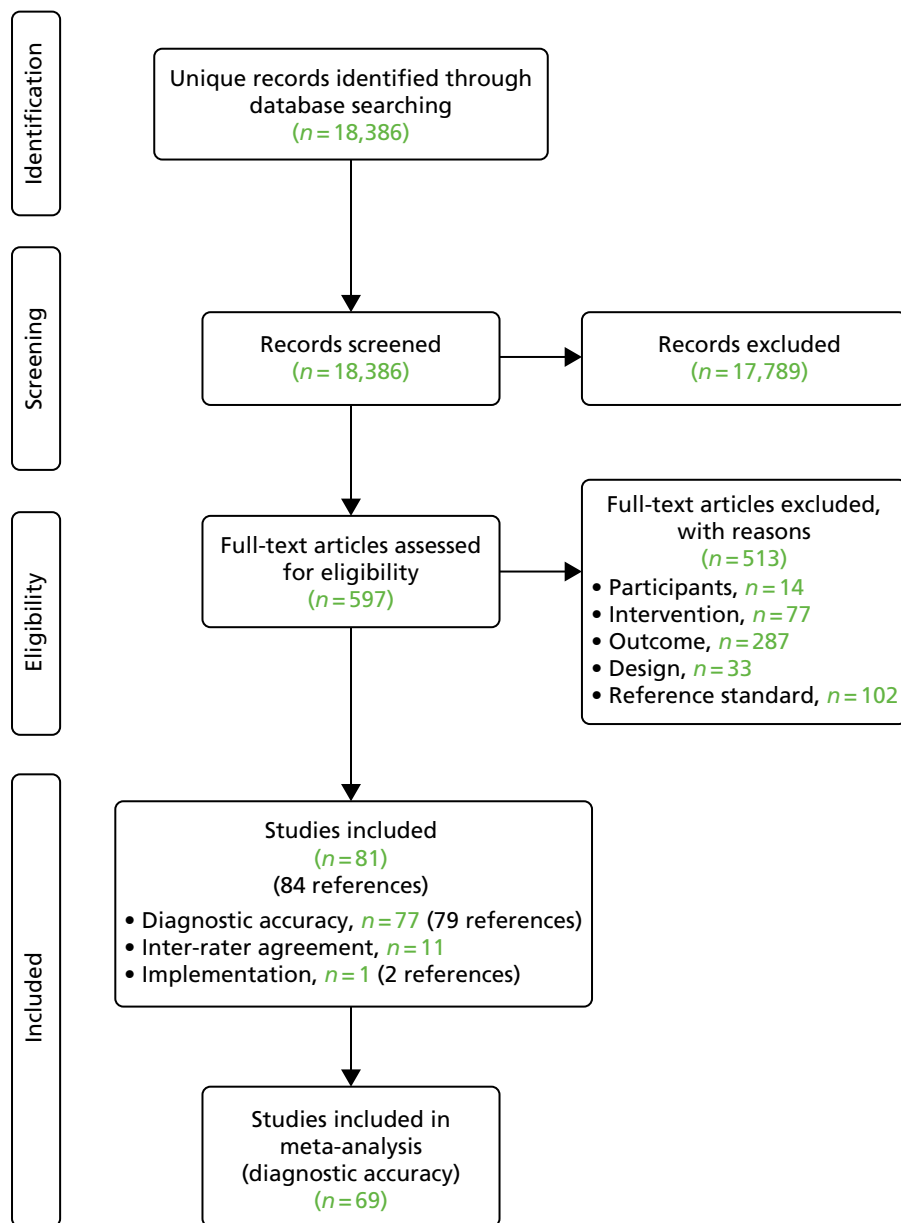

FIGURE 1 A PRISMA flow diagram showing study selection.

Excluded studies

Of the 597 potentially relevant studies, the most common reason for exclusion was lack of relevant outcome data (287 references, of which 49 did not have a full text available) and 102 references did not report an eligible reference standard. Fifty-four studies[69,119–171] evaluated the diagnostic accuracy of scintigraphy but were excluded from the main review because they did not evaluate the diagnostic accuracy of other eligible index tests. The list of references that were excluded along with the reasons for their exclusions is not reported because of the large number of exclusions, but is available from the authors on request.

Assessment of diagnostic accuracy

Characteristics of included studies

Table 1 presents a summary of design and patient characteristics of all included studies. Most studies (46 out of 77) were published in or after 2000.[37,38,40,41,43–46,48,51–57,60–65,67–70,72,73,77,78,80–82,84,88,93,95–99,103,105,108,109,111,113]

Just under half of the studies were conducted in the USA (34 studies).[39,42,46,56,63,66,67,70–72,74–76,79,80,82,83,85,86,88–92,98,100–102,104,106,107,110–112] Eight studies were conducted in Germany,[49,58–60,64,65,81,108] six in Switzerland,[41,44,61,68,73,99] five in Italy[50,53–55,95] and three in Egypt,[37,52,113] the Netherlands[48,62,105] and Turkey.[51,96,97] Two studies were conducted in France,[41,45] India,[77,93] the Republic of Korea,[69,109] Spain[40,84] and the UK.[41,94] A single study was conducted in the following countries: Austria,[108] Belgium,[57] Bulgaria,[43] Canada,[43] Israel,[103] Japan,[82] the Republic of Korea,[109] Kuwait,[38] Lithuania[78] and Oman.[87] Three studies were conducted in more than one country.[41,82,108]

None of the included studies was randomised, and 41 studies used a prospective design.[37,41–43,45,47,49,51,52,54,55,57–60,62,64–66,75–78,81,83–85,88–91,93,94,96,99,102,104,107,110–113]

The sample size of the studies ranged from 7 to 339, but most studies were small: only 15 (20%) included ≥ 50 participants.[40,41,46,50,67,70,71,75,78,84,86,88,98,108,113] Nearly all studies were conducted in adults. Three studies were conducted in children exclusively,[52,78,98] and 10 were conducted in a mixed population of adults and children.[44,50,57,85,87,96,101,104,106,109] Nine studies included at least some participants with indwelling work,[39,57,61,69,73,79,81,103,108,109] but only one focused exclusively on this population.[103]

Nearly half of the included studies included only or mostly patients with diabetes (36 studies).[37,38,40–43,47,49,51,53,55,56,62,67,70,71,74,76,77,82,84,86,88–90,92–95,97,99,102,107,111–113] A total of 10 studies focused on patients with trauma and/or previous surgery.[57,59,61,64,68,69,72,73,79,103,105,108] Osteomyelitis was caused by non-foot-related pressure ulcers and skin ulcerations in six studies[45,63,66,72,75,80] and one study attributed osteomyelitis to each of the following conditions specifically: soft tissue infection,[96] septic arthritis[98] and neuropathic osteoarthropathy.[100] Eighteen studies included patients with multiple aetiologies,[44,46,48,50,52,54,58,60,65,78,81,83,85,91,101,106,109,110] and three studies did not report any specific causes.[39,87,104] Only one study included patients with haematogenous osteomyelitis.[78] *Appendix 3* presents further details on the study participant inclusion and exclusion criteria.

Forty-seven studies stated which type of osteomyelitis they targeted. Twelve studies aimed to detect acute osteomyelitis (AOM) specifically,[37,51,52,66,74,78,87,90,91,98,99,104] 17 focused on COM[46,49,58,60,61,64,68,73,79,81,93,94,96,108,111–113] and 15 focused on a mixed population of AOM and COM.[38,42,44,48,50,54,57,63,65,69,71,80,85,92,106,107] Two studies targeted patients with either subacute osteomyelitis or COM.[39,59] The condition targeted was not specified in 30 studies.[40,41,43,45,47,53,55,56,62,67,70,72,75–77,82–84,86,88,89,95,97,100–103,105,109,110] Most studies used the dual reference standard for osteomyelitis of clinical follow-up for patients who tested negative and bone biopsy with histopathology or microbiology for test-positive patients, although 34 studies used histopathology/microbiology in all participants regardless of their imaging test results.[37,38,42,43,45,49,51,53,54,56–59,61,62,70,72,75,77,79–82,84,89,90,92,93,98,100,102,107,108,113]

Table 2 presents the distribution of included diagnostic accuracy studies according to tests and body part targeted. This shows that most of the evidence focused on the diagnostic accuracy of MRI, scintigraphy and radiography for the diagnosis of diabetic foot osteomyelitis. Few studies specifically focused on the axial skeleton, the pelvis/hip/knee and long bones.

NR, not reported.

Nearly all studies interpreted images by visual assessment without any quantitative analysis (e.g. measuring the standardised uptake value). Some studies compared the results of qualitative and quantitative analysis in parallel, including PET (two studies)[53,108] and WBC scintigraphy.[53] Other studies used a semiquantitative approach (combined qualitative and quantitative interpretation) for PET/CT (two studies),[105,108] PET[108] scintigraphy + SPECT[64] and SPECT/CT.[64]

Critical appraisal

Table 3 presents a summary of the results of the critical appraisal. Further details including justifications for decisions are presented in *Appendix 2*. Overall, 23% of studies were rated as being at a high risk of bias for at least one domain,[39,47,48,52,56,57,64,65,78,80,83,91,92,95,101,102,107,111] although poor reporting of study methods, particularly regarding the selection of patients and the conduct of the index test, means that there is significant uncertainty about the quality of most of the studies.

+, low risk of bias; −, high risk of bias; ?, unclear risk of bias.

Over half of the studies (56%) did not provide sufficient information to assess the risk of bias associated with the selection and enrolment of patients into the study.[37,38,42–47,51,53,56,58–64,67,68,70–72,74,75,78,82–87,89,94,95,97,98,100,101,103,106,108,110] In particular, most studies did not explicitly state whether or not all eligible patients were included during a defined period of time. Therefore, the risk of selection bias, for instance because of the exclusion of patients who are harder to diagnose, cannot be excluded. Nine studies did not blind the interpretation of the index test to the results of other index tests or to the reference standard, and were therefore considered as being at a high risk of bias.[39,47,48,64,65,78,83,91,95] Another 18 studies did not provide sufficient information on blinding and were therefore considered as being at an unclear risk of bias.[44,51,60,62,71–75,79,82,84,85,87,88,90,93,110] Nearly all studies were rated as being at a low risk of bias associated with the reference standard (91%) and patient flow (87%) and none of the included studies raised significant concerns about their applicability to the diagnostic accuracy review questions.

Synthesis of diagnostic accuracy in adults

In this section we consider the synthesis of diagnostic accuracy for studies of imaging tests in adults. Studies exclusively in children are considered in *Synthesis of studies in children*. Studies in mixed adult/ children groups or where the population was unclear are included in the analysis of adults.

Excluded from this analysis are studies where the combined diagnostic accuracy of two or more imaging tests was reported (e.g. the accuracy of scintigraphy in combination with SPECT); these are discussed in *Studies reporting on combinations of imaging tests*. Also excluded are studies that did not report sufficient data to calculate 2 × 2 tables of diagnostic accuracy; these are discussed in *Studies not included in the quantitative synthesis*.

This analysis included 69 diagnostic accuracy studies.[38–42,44–51,53–71,73–77,79–95,97,99–113] *Appendix 4*, *Table 19*, summarises these studies. Many of these studies compare two or more imaging tests. Comparisons between tests are discussed in *Comparisons between tests*. Many studies compare imaging tests with scintigraphy. Scintigraphy was not specified as a test of interest in the protocol, but it is included here because of the number of studies considering it. The main analysis only considers scintigraphy in studies where it was compared with other tests; for studies of scintigraphy alone, see *Studies of scintigraphy*.

Some studies reported diagnostic accuracy at multiple thresholds of a single test, or for a single test under different conditions. Where that was the case, the main analysis uses only the result with the highest DOR, as an indicator of the 'best' diagnostic accuracy for that test in that study. Where appropriate, data at multiple thresholds are considered in the sections on individual tests (see *Synthesis of specific imaging tests*).

Figure 2 summarises the sensitivity (proportion of people/scans with osteomyelitis correctly diagnosed) and specificity (proportion of people/scans without osteomyelitis correctly diagnosed) for each test in each study in a ROC plot. This figure shows considerable variation in the diagnostic accuracy both within and between tests. MRI and SPECT both generally have high sensitivity (> 80%), but with a wide range of specificities. PET is generally more consistent with high sensitivity and specificity, but with some studies having lower sensitivity. Scintigraphy results vary widely in both sensitivity and specificity. Radiographic results generally have poor sensitivity.
FIGURE 2 Summary ROC plot of diagnostic accuracy in adults.

In *Appendix 4*, *Figure 21* shows a similar plot for PPVs and NPVs. These results are also variable and difficult to interpret. MRI, SPECT and PET generally have high PPV and NPV, but with many outliers. Radiography generally has a poorer NPV.

We now consider the bivariate meta-analysis of sensitivity and specificity. *Figure 3* shows the summary bivariate meta-analysis results for each test (with 95% CIs for sensitivity and specificity). *Figure 4* shows the summary HSROC curves for each test.
FIGURE 3 Bivariate meta-analysis of sensitivity and specificity: all adult studies.
FIGURE 4 Summary HSROC curves: all adult studies.

These results show that sensitivity and specificity are highest for SPECT, but with a wide CI for specificity. MRI and PET also have high sensitivity and specificity. CT, radiography and scintigraphy all have poorer sensitivity and/or specificity. The summary HSROC curves for MRI, SPECT and PET are very similar and overlapping, suggesting that they have similar diagnostic accuracy. The curves for CT, radiography and scintigraphy are lower, showing poorer diagnostic accuracy.

Appendix 4, *Figure 22*, gives the results of the bivariate meta-analysis of PPV and NPV, which shows that MRI, PET and SPECT have higher PPV (88–93%) and NPV (> 85%) than MRI and PET, with SPECT having the highest NPV (97%). Scintigraphy and radiography have lower PPV and NPV.

Figure 5 shows forest plots of sensitivity and specificity for MRI. These highlight the generally high sensitivity and specificity of MRI, and the overall consistency of sensitivity across studies. As noted earlier, the specificity of MRI varies substantially across studies, although many studies are small with correspondingly wide CIs. This raises concerns as to the consistency of MRI performance across studies. Given the large number of tests, and hence forest plots, no further forest plots are presented in this report, but they are available on request from the authors.

Table 4 shows the results of univariate meta-analyses of sensitivity and specificity (i.e. meta-analysed separately rather than jointly) and also meta-analyses of DOR (to summarise overall diagnostic accuracy) and the PR (proportion of people testing positive for osteomyelitis based on the imaging test result alone).

The results for sensitivity and specificity match those of the bivariate analysis in *Figure 3*, as would be expected. The I^2 values for sensitivity and specificity are low or zero, which conflicts with the apparent heterogeneity observed in *Figure 2*. This may be because most studies are small, and so there is considerable within-study variability in estimates, which reduces I^2, rather than an absence of heterogeneity.

Diagnostic odds ratios are similar for MRI, SPECT and PET, suggesting similar diagnostic accuracy for these tests, as seen in *Figure 4*. The odds ratios are considerably lower for scintigraphy, radiography and CT, suggesting that these tests have poorer diagnostic accuracy. MRI and SPECT have high PRs of > 70%, so most people have an imaging test result that would lead to being diagnosed with osteomyelitis. This, in part, reflects high incidence in the studies. PET, however, has a lower PR of 52.7%. This may be because the higher specificity and lower sensitivity of PET reduce the number of positive PET scans overall, and in particular the number of false-positive diagnoses.

Comparisons between tests

Forty of the included studies of adults reported diagnostic accuracy data for two or more imaging tests. To determine whether or not these studies show evidence that one test is superior to another, we compared the DORs for each test within each study. *Appendix 4*, *Figure 23*, shows these DORs for each imaging test in each study. These results show that, when radiography was included, it was generally inferior to other tests (particularly MRI and scintigraphy); scintigraphy was generally inferior to MRI.

In *Figure 6*, each dot is the difference in log-DOR between the test in the title of each subplot and the comparator test, indicated by the colour of the dot. Points to the right of the central black line are where the 'title' test has greater DOR than the 'comparator' test. These results suggest that SPECT and PET were generally superior to whatever test they were compared with (but with few studies). MRI was superior to scintigraphy and radiography, but not to PET or SPECT. Scintigraphy was superior to radiography, but not MRI, and radiography was generally inferior to all other tests.

To formally assess whether or not these apparent differences are genuine, regression modelling was used to compare studies. This regressed the diagnostic accuracy data to estimate differences in DORs and specificity between tests across studies (see *Chapter 3, Comparison of imaging tests*). Two models were fitted: one using radiography as the baseline test and one using MRI as the baseline test. The formal results of these models are given in *Appendix 4*, *Table 20*, and a summary is presented in *Table 5*.
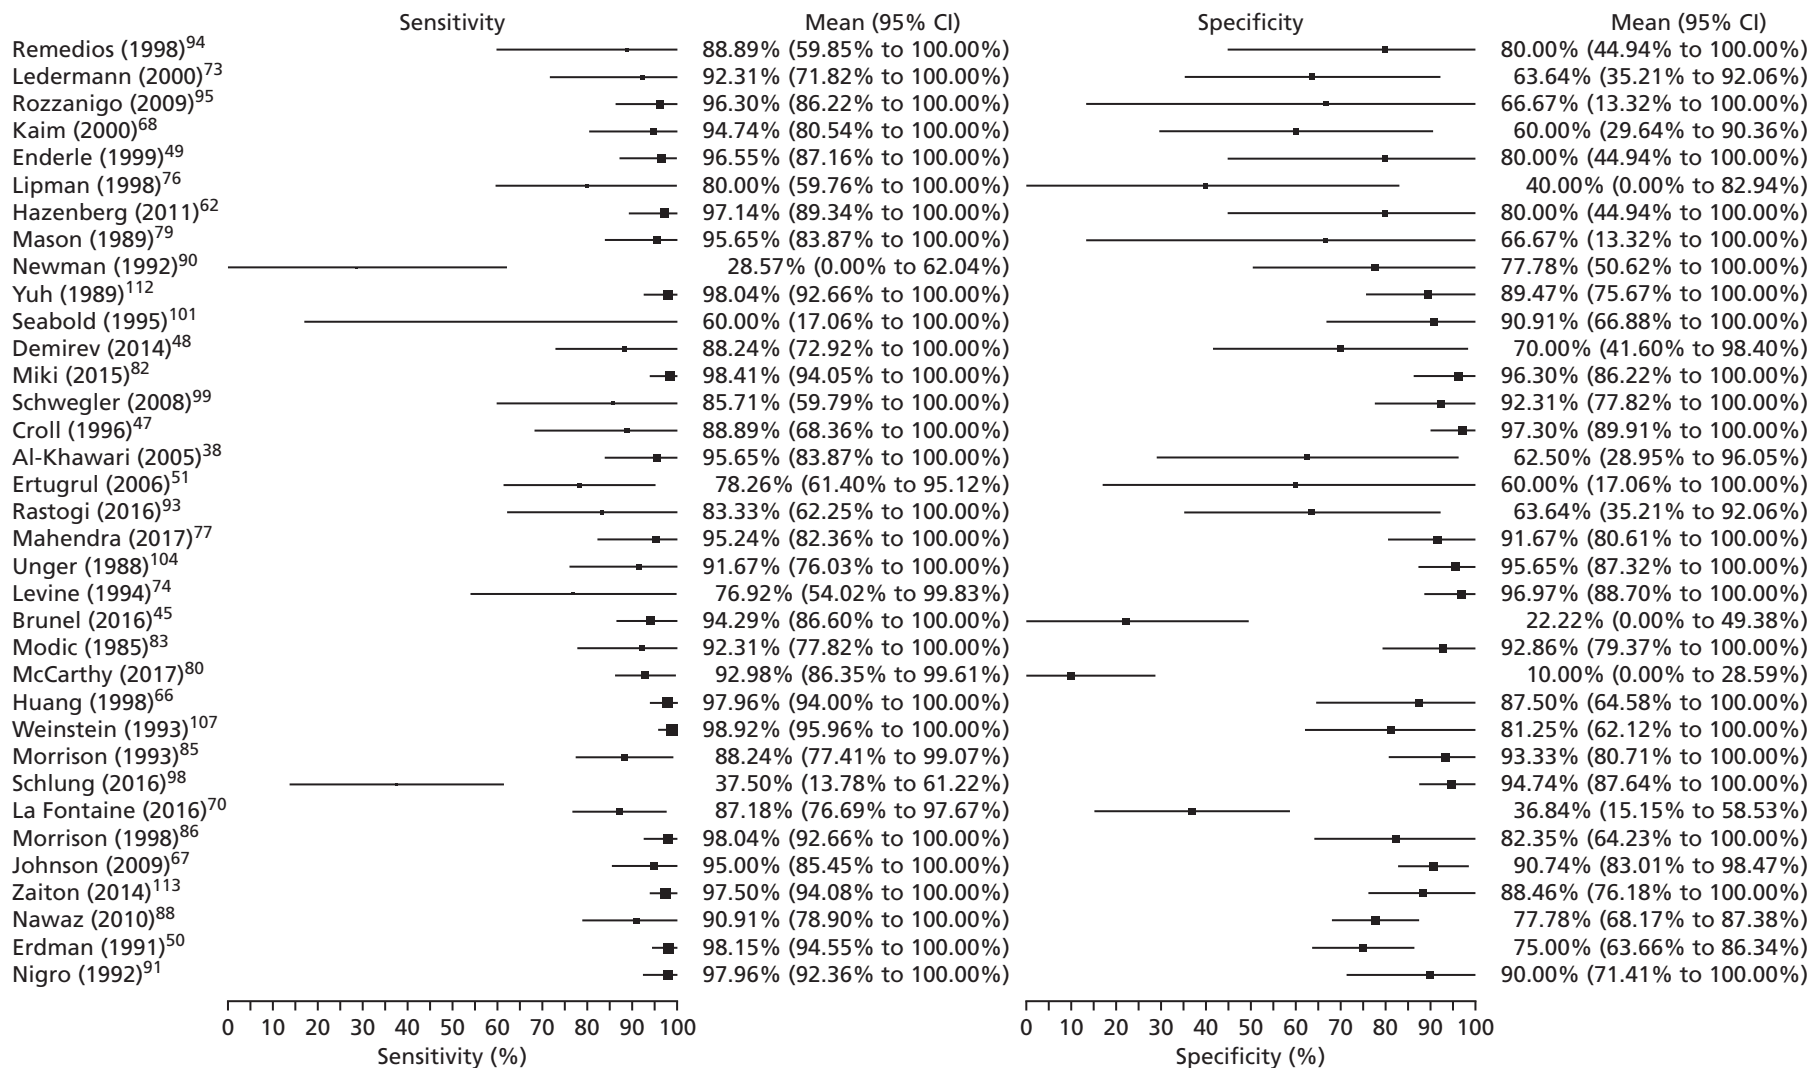

FIGURE 5 Forest plots of sensitivity and specificity for MRI.

TABLE 4 Results of univariate meta-analyses

Test	Outcome	Estimate (%)	95% CI	I^2
CT	Sensitivity	69.68	40.12 to 88.74	0
	Specificity	90.24	57.64 to 98.43	0
	DOR	10.28	3.86 to 27.39	0
	PR	55.8	39.49 to 78.83	0
MRI	Sensitivity	95.56	92.36 to 97.46	0
	Specificity	80.7	70.78 to 87.84	0
	DOR	44.05	22.76 to 85.23	54
	PR	72.79	66.89 to 79.22	25
PET	Sensitivity	85.11	71.52 to 92.86	0
	Specificity	92.77	83 to 97.12	0
	DOR	38.51	17.79 to 83.38	34
	PR	53.00	44.2 to 63.55	0
Scintigraphy	Sensitivity	83.6	71.83 to 91.07	0
	Specificity	70.58	57.72 to 80.82	0
	DOR	8.3	5.36 to 12.85	17
	PR	72.7	66.1 to 79.96	0
SPECT	Sensitivity	95.06	87.82 to 98.09	0
	Specificity	81.99	61.54 to 92.83	30
	DOR	65.3	18.38 to 232	57
	PR	74.1	65.15 to 84.29	0
Ultrasound	Sensitivity	94.07	50.17 to 99.6	0
	Specificity	50.99	3.16 to 97.08	0
	DOR	13.92	1.94 to 99.74	0
	PR	82.08	61.66 to 100	0
Radiography	Sensitivity	70.35	61.64 to 77.8	0
	Specificity	81.5	69.61 to 89.45	7
	DOR	6.39	3.7 to 11.01	52
	PR	53.13	43.64 to 64.69	52

These results largely confirm what was observed from the main diagnostic analysis in *Diagnostic meta-analysis*. Radiography has the lowest diagnostic accuracy (in terms of DOR) of all the tests. Its specificity is similar to that of CT, MRI and SPECT, but it has lower sensitivity than any of these. It has lower sensitivity and specificity than PET, but has higher specificity than scintigraphy.

Magnetic resonance imaging has similar diagnostic performance to SPECT and PET, but has lower specificity (and consequently higher sensitivity) than PET. MRI has higher DORs than CT, radiography or scintigraphy.

Synthesis of specific imaging tests
This section considers in more detail the diagnostic accuracy of each of the included imaging tests.
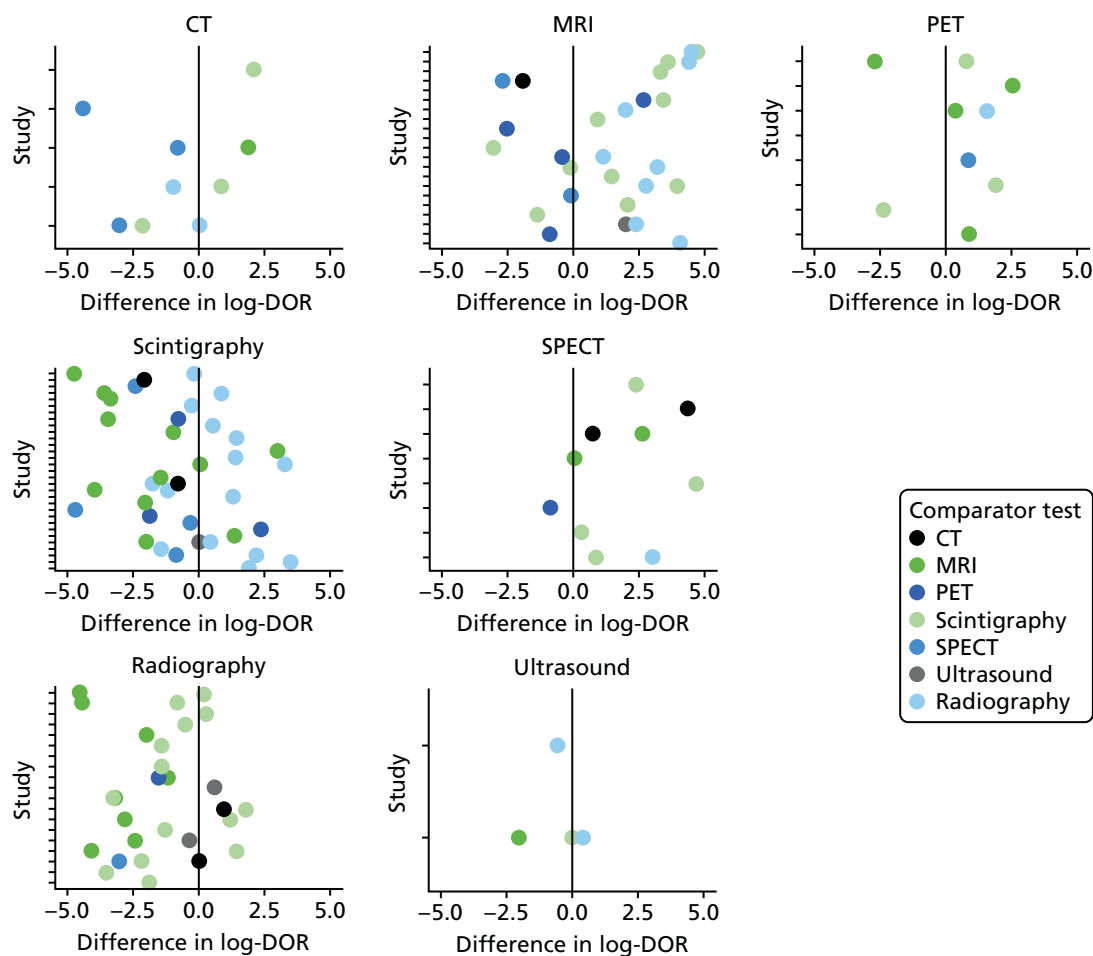

FIGURE 6 Comparing DORs within studies.

TABLE 5 Summary of regression model to compare imaging tests

Parameter	Radiography worse than	Radiography similar to	Radiography better than
DOR	CT, MRI, PET, scintigraphy and SPECT	None	None
Specificity	PET	CT, MRI and SPECT	Scintigraphy
	MRI worse than	**MRI similar to**	**MRI better than**
DOR	None	PET, SPECT	CT, scintigraphy and radiography
Specificity	PET	CT, SPECT and radiography	Scintigraphy

Studies of scintigraphy

Scintigraphy was not specified as an imaging test of interest in our protocol, but was included in many of the eligible studies as a comparator with other tests. Hence, we included it in our main analysis in *Synthesis of diagnostic accuracy in adults*. To facilitate a more complete examination of the diagnostic value of scintigraphy, we identified larger, recent studies (> 20 participants and published since 1990) of scintigraphy for analysis, where scintigraphy was the only imaging test reported in the publication. Nine studies[132,136,142,148–152,165] from our database searches met these criteria and reported sufficient data for meta-analysis. Because they were off-protocol, we note that the additional nine studies have not been formally assessed for risk of bias. These nine studies were combined with the studies of scintigraphy included in the main meta-analysis, in order to explore the impact of this additional evidence on scintigraphy, and as a sensitivity analysis compared with using only the primary included studies.

A summary of all scintigraphy studies is given in *Appendix 4*, *Table 21*. As with other imaging tests, most of the studies are in people with diabetic foot ulcers. A range of types of scintigraphy have been reported, including (hydroxy)methylene diphosphonate [(H)MDP], WBC, hexamethylpropyleneamine oxime (HMPAO) and gallium scans. Some studies reported combinations of these tests. Three radioisotopes were used: technetium-99m (^{99m}Tc), indium-111 (^{111}In) and gallium-67 (^{67}Ga).

Figure 7 presents a summary ROC plot for the sensitivity and specificity results from these studies, classified by scintigraphy type used. This suggests that there is considerable variation both within and between types of scintigraphy.

A bivariate meta-analysis of all scintigraphy studies gave an overall sensitivity of 85.6% (95% CI 80.9% to 89.2%) and an overall specificity of 71.7% (95% CI 62.1% to 79.6%). This is similar to the result seen in the main analysis (see *Figure 3*), but with a slightly higher sensitivity, suggesting that the additional studies (of scintigraphy only) have higher sensitivity than those where scintigraphy was compared with other tests. This could be as a result of either bias against scintigraphy in comparative studies, or poorer quality of the scintigraphy-only studies.

Figure 8 shows the results of bivariate meta-analyses categorised according to the type of scintigraphy performed. This suggests that ^{99m}Tc HMPAO WBC scintigraphy and mixed ^{111}In WBC with ^{99m}Tc MDP (methylene diphosphonate) scintigraphy can have very high diagnostic accuracy, with sensitivity > 85% and specificity > 90%; this is similar to the diagnostic accuracy of PET, as seen in *Figure 3*. The ^{99m}Tc (H)MDP scintigraphy, by contrast, has a much lower specificity, of < 50%.

Studies of magnetic resonance imaging scans

Most studies reported only one diagnostic accuracy result for MRI, and there was insufficient information to distinguish between different types of MRI scan. One study[86] reported results for four types of MRI, with no evidence of any difference in diagnostic accuracy among them.

The MRI results in the main analysis had a very wide range of specificities, despite fairly consistent sensitivity. We sought to identify any characteristics of the included studies that might explain this variation in specificity.
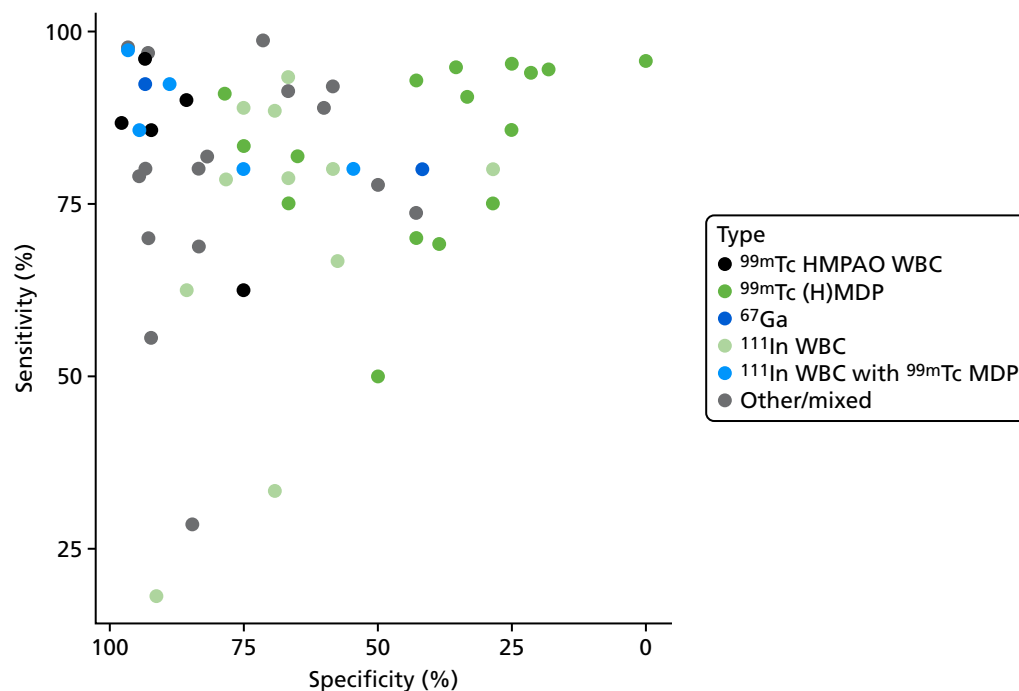

FIGURE 7 Summary ROC plot for scintigraphy studies.
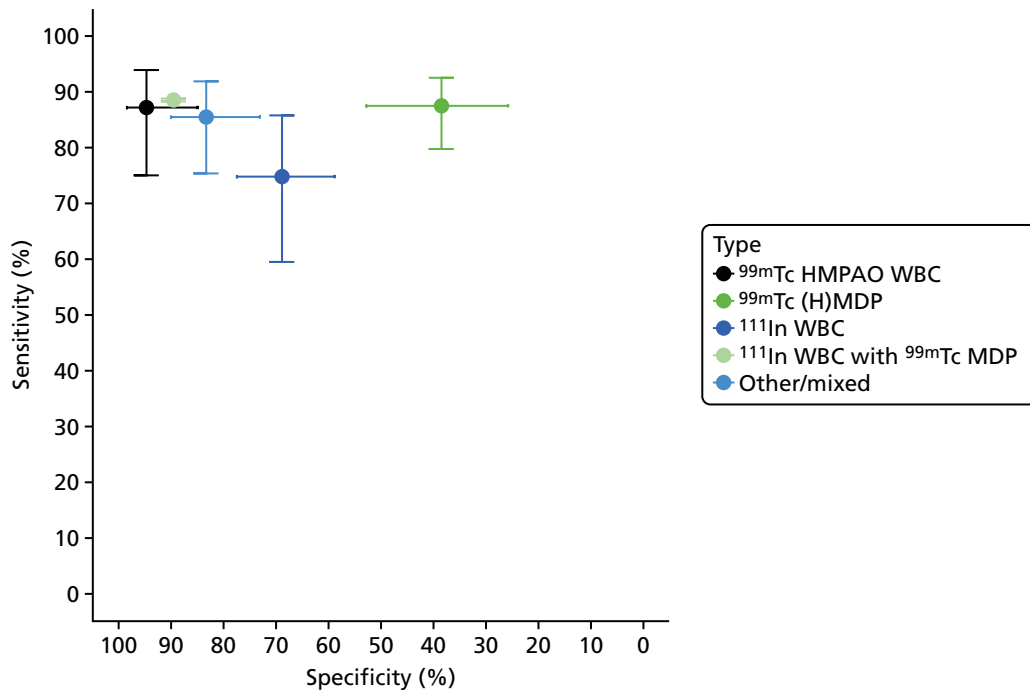

FIGURE 8 Diagnostic accuracy of scintigraphy according to type of test performed.

Appendix 4, *Figure 24*, shows the association between specificity and incidence of osteomyelitis for each study. This shows that specificity declines as incidence increases. This association was statistically significant (a decline in log-odds of specificity of 0.31 per 10% increase in incidence, $p = 0.008$). This suggests that osteomyelitis may be over-diagnosed using MRI in populations in which osteomyelitis is common. The model was not a good fit (adjusted $R^2 = 0.17$), so incidence does not explain all the variation in specificity. No other possible causes of this variation could be identified.

Studies of single-photon emission computed tomography and single-photon emission computed tomography/computed tomography

As with scintigraphy studies, SPECT studies used a range of radioisotopes and test types to perform SPECT imaging. *Figure 9* shows the ROC plot of sensitivity and specificity according to the type of test used. There are too few studies to distinguish between tests, or to perform a bivariate meta-analysis. The results show no clear evidence of difference between the types of test. When comparing results with those for scintigraphy (see *Figure 8*), the results suggest that SPECT produces higher sensitivity than planar scintigraphy for the same test type.

There was no evidence that studies of SPECT/CT had differing diagnostic accuracy to those of SPECT alone, although the number of studies was limited (results not shown).

Studies of positron emission tomography and positron emission tomography/computed tomography

There was no evidence that studies describing the test used as PET/CT differed in diagnostic accuracy from those describing the test only as PET (see *Appendix 4*, *Figure 25*). All but one study used ^{18}F-FDG PET.

There was no evidence that quantitative analysis (such as measuring the standardised uptake value) improved the accuracy of PET (results not shown).
FIGURE 9 Diagnostic accuracy of SPECT studies according to type of SPECT used.

Studies of ultrasound

Only two studies of ultrasound for diagnosing osteomyelitis in adults were identified, so they could not be included in any bivariate meta-analysis. The results of these studies are summarised in *Table 6*. The two studies are not consistent in their estimated sensitivity and specificity. Both have DORs that suggest poorer diagnostic performance than MRI, PET or SPECT (see *Table 4*).

Studies reporting on combinations of imaging tests

Twelve studies[40,43,54,55,64,65,69,75,84,96,109,141] reported data on the diagnostic accuracy of combining two tests. These were mostly combinations of scintigraphy with SPECT. Two studies combined radiography with probe-to-bone tests. These are summarised here, although we note that probe to bone is not an imaging test and so is not covered in this review.

Figure 10 shows the sensitivity and specificity estimates for all the combination tests. This shows considerable variation in the diagnostic accuracy of combination tests. Most tests have too few studies to draw any conclusions. A bivariate meta-analysis of the SPECT + scintigraphy studies gives a summary sensitivity of 87.3% (95% CI 87.2% to 87.5%) and specificity of 83.4% (95% CI 83.3% to 83.6%). This is a lower sensitivity and specificity than was estimated for SPECT alone (see *Table 4*).

TABLE 6 Summary of diagnostic accuracy of ultrasound studies

	Study	
	Enderle *et al.* (1999)[49] (*n* = 19)	**Nath and Sethu (1992)[87] (*n* = 25)**
	Cause: diabetic foot ulcers	**Cause: long bone pain or swelling**
Sensitivity (%) (95% CI)	78.6 (57.1 to 100)	96.8 (88 to 100)
Specificity (%) (95% CI)	80 (44.9 to 100)	30 (1.6 to 58.4)
DOR (95% CI)	14.7 (1.2 to 185.2)	12.9 (0.6 to 292.8)
PPV (%) (95% CI)	91.7 (76 to 100)	68.2 (48.7 to 87.6)
NPV (%) (95% CI)	57.1 (20.5 to 93.8)	85.7 (49.1 to 122.4)
FIGURE 10 Diagnostic accuracy results for combination tests.

Figure 11 compares the DORs for the combination tests with those for the individual tests within each study. This shows no evidence that combining tests improves diagnostic accuracy; in most studies the combined test (circle) has a DOR no higher, and often lower, than the best single test (triangle).

One study (Aragón-Sánchez et al.[40]) of radiography combined with probe to bone obtained very high diagnostic accuracy (sensitivity 97.7%, specificity 94.6%). However, this study also achieved much higher diagnostic accuracy for radiography alone than was observed in most other studies. It is unclear whether this result is meaningful or a chance result in one study.
FIGURE 11 Diagnostic odds ratios for combination tests.

Other factors and subgroups

This section considers other factors that may affect diagnostic accuracy: the choice of reference standard, risk of bias, the presence of indwelling metalwork, the use of imaging tests prior to the main test and whether osteomyelitis is acute or chronic.

Choice of reference standard

The eligible reference standards for confirming the absence of osteomyelitis were histopathology, microbiology or clinical follow-up of at least 6 months. It is possible that the choice of reference standard could affect the diagnostic accuracy.

In *Appendix 4*, *Figure 26* shows the ROC plots of diagnostic accuracy in accordance with the reference standard, for each imaging test. These results suggest that, when only clinical follow-up was used, specificity might be higher than average, particularly for MRI. A formal regression model to assess this, however, found no statistically significant evidence of a difference between reference standards in either specificity or DOR. We conclude that choice of reference standard is unlikely to lead to bias in the main meta-analyses.

Study quality and risk of bias

The impact of the QUADAS-2 assessment of each study on diagnostic accuracy was investigated. In *Appendix 4*, *Figure 27* shows the ROC plots of sensitivity and specificity for each study according to whether the study was rated as being at a high, unclear or low risk of bias for patient selection. In *Appendix 4*, *Figure 28* repeats this for quality of the index test.

Neither figure suggests that there is any evidence that diagnostic accuracy results were biased by quality factors. Reference standard and patient flow issues were rated as being at a low risk of bias for most studies, and there was no evidence that these had any impact on diagnostic accuracy (results not shown).

Indwelling metalwork

Few studies reported on the number of patients (if any) who had indwelling metalwork at the time of their scan. In *Appendix 4*, *Figure 29* shows the diagnostic accuracy data for each imaging test according to whether indwelling metalwork was present in some patients, not present in any, or unreported. This figure shows no evidence that indwelling metalwork alters diagnostic accuracy.

Prior use of other imaging tests

In some studies, patients were included only after performing a prior imaging test, usually radiography. Patients would go on to the main imaging test only if osteomyelitis had not been ruled out by the initial test. This extra testing could affect the diagnostic accuracy observed.

Figure 12 shows the sensitivity and specificity for all imaging tests, according to the prior imaging test used (if any). This suggests that prior use of radiography might improve specificity in MRI studies, and both sensitivity and specificity in scintigraphy studies.

Formal regression analysis to test this possibility found no statistically significant evidence that radiography prior to MRI improved specificity ($p = 0.472$) or DOR ($p = 0.201$). There was some evidence (but not conventionally statistically significant) that radiography prior to scintigraphy increased the DOR ($p = 0.141$). Hence it is possible, but uncertain, that using radiography as a precursor test to MRI or scintigraphy may improve diagnostic performance.

Other than radiography, few tests were used in addition to the main test. This analysis considered only instances when prior tests were explicitly reported. In practice, it is likely that radiography will be used as an initial test in most patients.
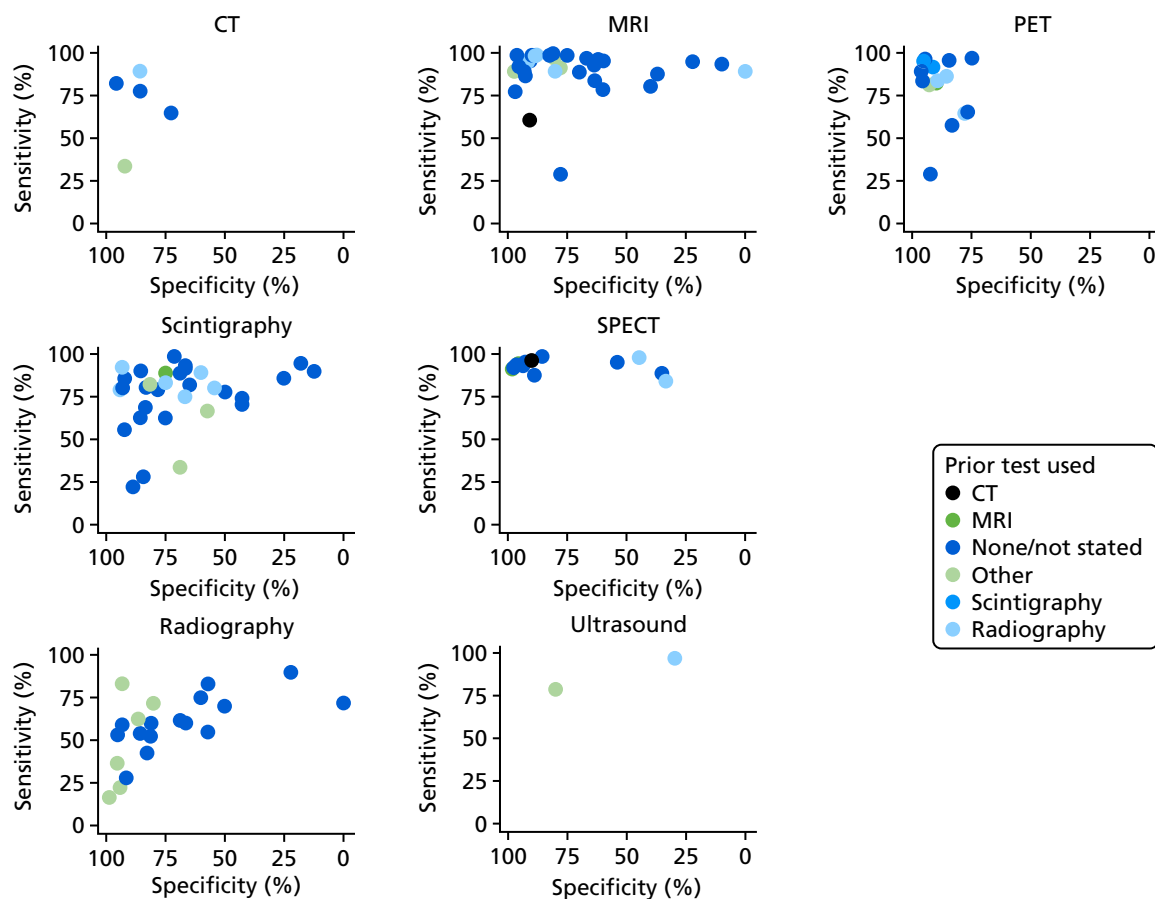

FIGURE 12 Sensitivity and specificity according to whether or not any imaging test was used before the main test.

Acute and chronic osteomyelitis

Studies were divided according to whether the suspected osteomyelitis was acute or chronic. Studies were categorised as:

- acute or subacute osteomyelitis
- COM
- COM and AOM
- not reported.

Figure 13 shows the sensitivity and specificity results according to the test used and acute or chronic status. There appears to be some pattern in the choice of test used. PET and SPECT have not been evaluated in people with AOM; almost all studies of PET are in people with COM. This may be a consequence of the types of people in these studies; nearly all studies of AOM were in people with diabetic foot ulcers. From these data, there is no clear evidence that diagnostic accuracy for any of the tests differ between COM and AOM.

Figure 14 shows the results of bivariate meta-analysis according to acute or chronic status. There is no compelling evidence that diagnostic accuracy for any test varies with acute or chronic status. It is possible that MRI is more specific (91%) but less sensitive (89%) in acute cases than in chronic cases (78% and 98%, respectively). The results are consistent with those in the overall analysis (see *Figure 3*), with MRI, PET and SPECT generally having greater diagnostic accuracy than radiography, CT or scintigraphy.
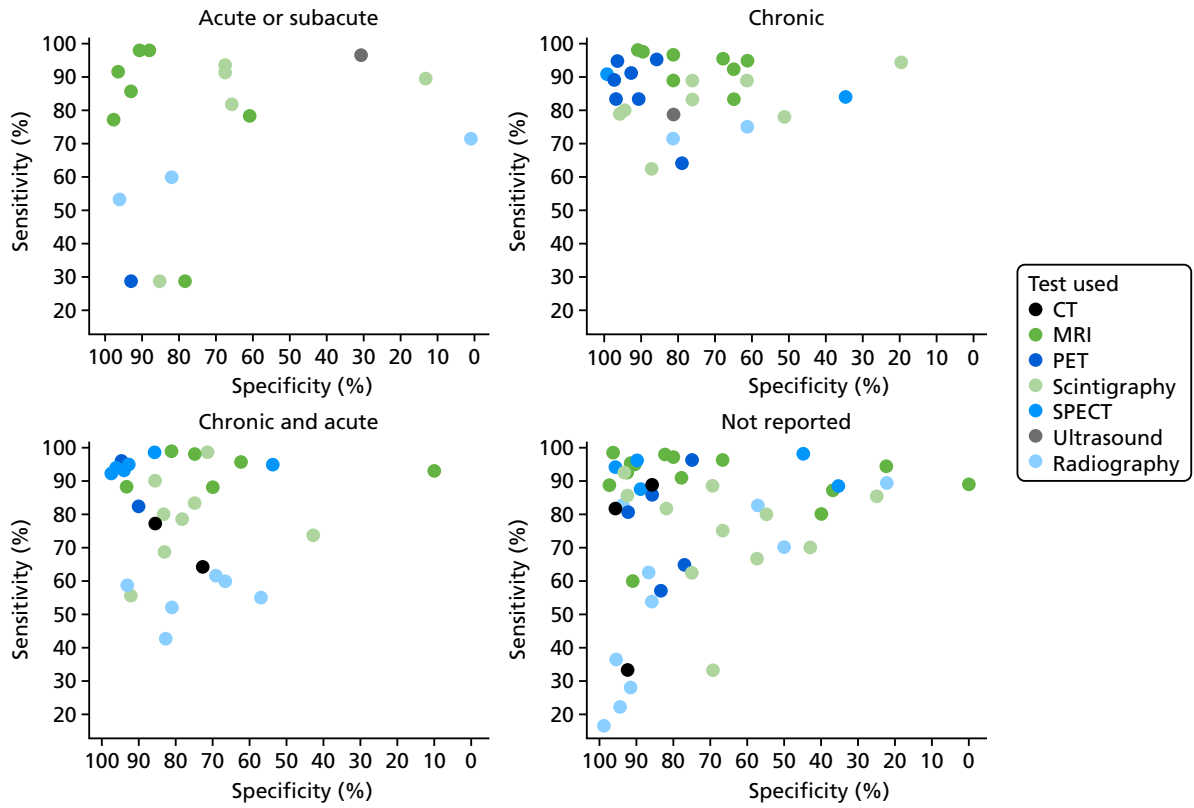

FIGURE 13 Sensitivity and specificity according to whether the study was of AOM or COM.
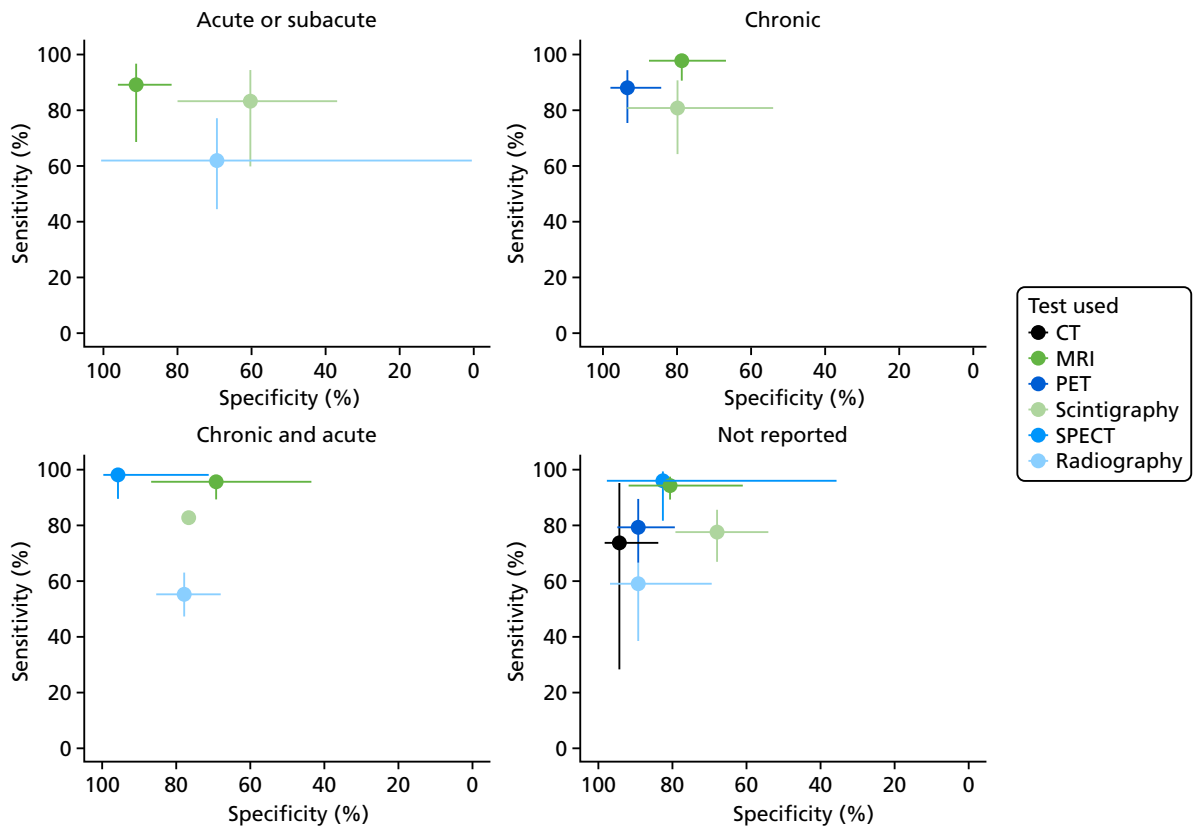

FIGURE 14 Bivariate meta-analysis according to acute or chronic status.

Synthesis of diagnostic accuracy in people with diabetic foot ulcers

This section considers the 35 studies in which diabetic foot ulcers were the primary reason for testing for osteomyelitis.[37,38,40–43,47,49,51,53,55,56,62,67,70,71,74,76,77,82,84,86,88–90,92–95,97,99,102,107,111–113] This includes studies in which at least 60% of patients had diabetic foot ulcers; studies with smaller numbers of people with foot ulcers were excluded. Studies primarily of patients with diabetic foot ulcers constitute around half of the total studies in this review. One study did not report sufficient data to be included in this analysis and is presented in *Studies not included in the quantitative synthesis*.[37]

The sensitivity and specificity estimates from these studies are presented in *Figure 15*. The results suggest high sensitivity (generally > 80%) for MRI and scintigraphy, but with a wide range of specificities. PET showed high specificity, but a range of sensitivities. Radiography generally had low sensitivity. There were too few studies of SPECT or ultrasound to draw any conclusions, and none of CT. In *Appendix 4*, *Figure 30* shows the results for PPV and NPV, with considerable diversity in PPV and NPV values across studies.

Figure 16 shows the results of a bivariate meta-analysis of sensitivity and specificity. The results here are similar to those for all studies (see *Figure 3*). Owing to non-convergence of their respective bivariate analyses, the univariate results are presented for PET and SPECT. Both MRI and PET have high accuracy, with MRI having higher sensitivity but lower specificity. Scintigraphy and radiography have lower specificity, but here scintigraphy has higher sensitivity than PET. The summary HSROC curves (see *Appendix 4*, *Figure 31*) suggest that MRI and PET (and possibly SPECT, although data are limited) have similar overall HSROC curves, and so similar diagnostic accuracy, whereas radiography and scintigraphy have lower accuracy.

In *Appendix 4*, *Figure 32* gives the results of the bivariate meta-analysis of PPV and NPV, which shows that both MRI and PET have high PPV (88%) and NPV (> 85%), with MRI having a higher NPV (95%). Scintigraphy and radiography have lower PPV and NPV rates.

In *Appendix 4*, *Table 23* gives the results of univariate meta-analyses. The results are consistent with bivariate analyses. As in the overall analyses, PET has a markedly lower PR (46%) than MRI (70%). This means that fewer people are considered to have osteomyelitis using PET; this is a consequence of its higher specificity and lower sensitivity.
FIGURE 15 Sensitivity and specificity in studies of patients with diabetic foot ulcers.
FIGURE 16 Bivariate analysis of sensitivity and specificity in people with diabetic foot ulcers.

In studies using scintigraphy in patients with diabetic foot ulcers, a range of different types of scintigraphy were used. In *Appendix 4*, *Figure 33* shows the results of bivariate meta-analysis of these scintigraphy studies according to the test used. This shows substantial variation in diagnostic accuracy, with ^{99m}Tc HMPAO WBC scintigraphy being notably most accurate (89% sensitivity for 92% specificity). This makes it more sensitive than PET, and more specific, but less sensitive than MRI.

Comparisons of tests

We also considered studies that compared different imaging tests in people with diabetic foot ulcers. In *Appendix 4*, *Figure 34* shows the difference in DORs between tests within studies. This suggests that MRI was generally superior to radiography and scintigraphy, and scintigraphy was moderately superior to radiography. It should be noted that this includes all types of scintigraphy together and, as shown in *Figure 8*, ^{99m}Tc HMPAO WBC scintigraphy may have better diagnostic accuracy. There were too few studies of other comparisons to draw any conclusions. Results from logistic regression models to compare the tests are summarised in *Table 7* (for full results, see *Appendix 4*, *Table 24*). These results are in agreement with the analysis using all studies (see *Table 5*).

TABLE 7 Comparison of tests in people with diabetic foot ulcers

Parameter	Radiography worse than	Radiography similar to	Radiography better than
DOR	MRI, PET and scintigraphy	None	None
Specificity	PET	MRI	Scintigraphy
	MRI worse than	**MRI similar to**	**MRI better than**
DOR	None	PET	Scintigraphy and radiography
Specificity	PET	Radiography	Scintigraphy

Synthesis of diagnostic accuracy for osteomyelitis not related to diabetes

The systematic review identified 31 studies in adults where osteomyelitis was not explicitly related to diabetes.[39,44–46,48,50,54,57–61,63–66,68,73,75,79–81,83,85,87,101,103,105,106,108,109] This excludes studies where some of the participants had diabetes, but includes studies where diabetes was not reported, or where the studies had a range of inclusion criteria, which may have included people with diabetes.

The studies were classified according to the location of the suspected diabetes as follows:

- axial skeleton (skull and spine)
- long bone (leg)
- pelvis, hip or knee
- multiple locations or unreported location.

Studies were also classified according to the suspected cause of osteomyelitis:

- infections and ulcers
- trauma and surgery
- contiguous disease
- multiple causes
- other or unstated cause.

Figure 17 shows the sensitivity and specificity estimates by imaging test and scan location. Similarly, *Figure 18* shows results by suspected cause. There are generally few studies of any imaging test within each category, so it is not possible to draw firm conclusions. The results are broadly similar to those obtained when
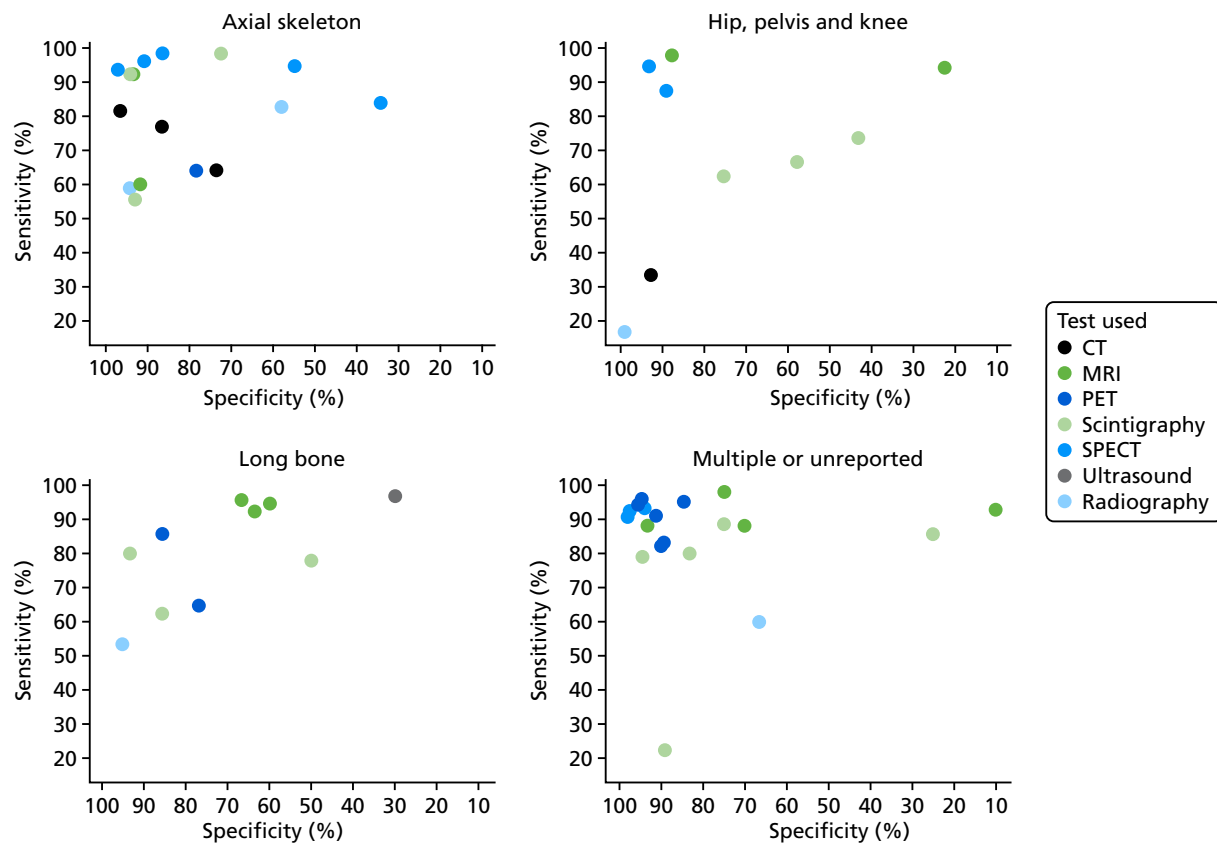

FIGURE 17 Sensitivity and specificity according to scan location.
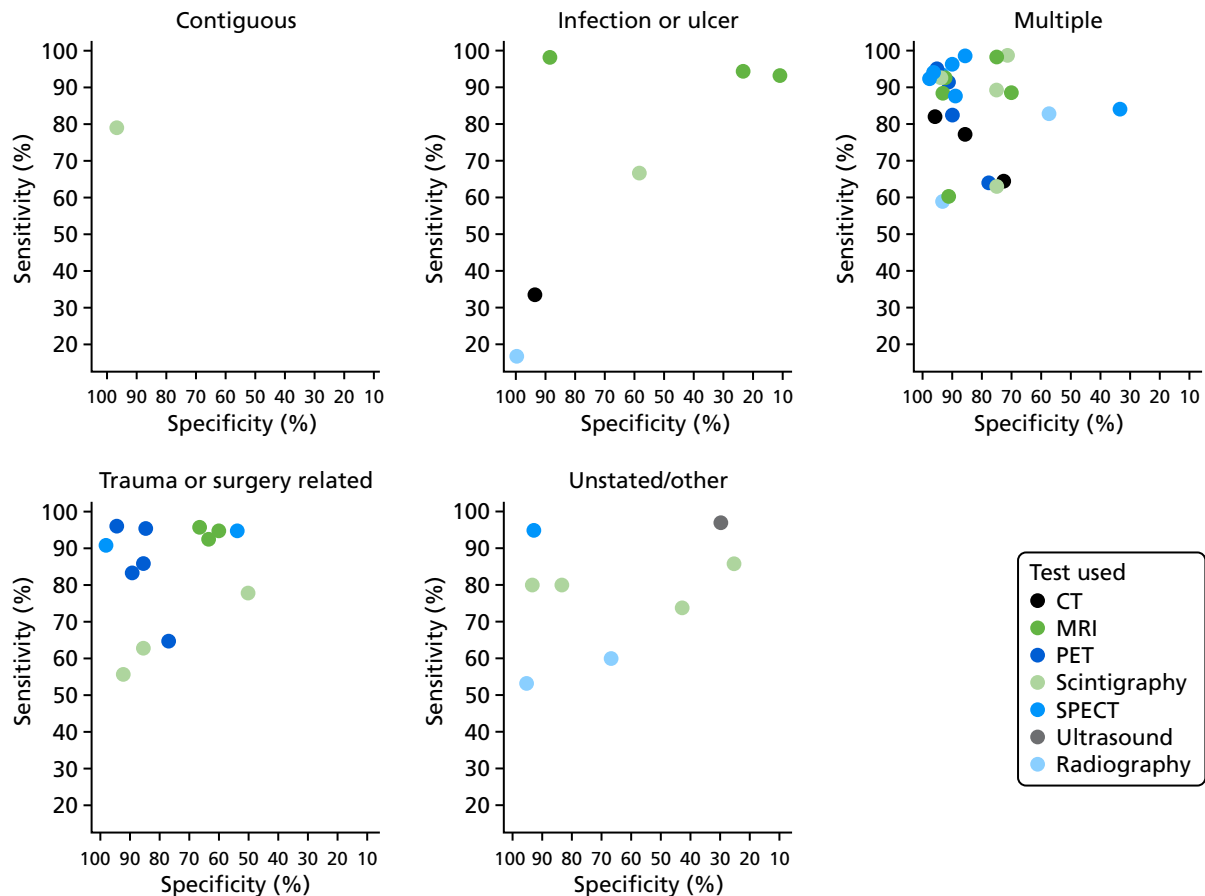

FIGURE 18 Sensitivity and specificity according to likely cause of osteomyelitis.

considering all studies and to the results in studies of diabetic foot ulcers. There is no immediate evidence that diagnostic accuracy varies according to location or cause. The choice of imaging test may vary according to location, with SPECT and CT being used more commonly to image the axial skeleton, where MRI is used less.

Plots for PPV and NPV by location are given in *Appendix 4*, *Figure 35*, and by cause in *Appendix 4*, *Figure 36*. There is no clear evidence that PPV or NPV varies by location of imaging or cause of osteomyelitis.

Given the limited numbers of studies in each location or cause category, bivariate meta-analysis of sensitivity and specificity could be performed for only a few tests. Results of the analyses are shown in *Appendix 4*, *Figure 37*, by location and in *Appendix 4*, *Figure 38*, by cause. The limited number of studies means that CIs for most meta-analysis results are wide, so it is difficult to draw any firm conclusions. There is no clear evidence that diagnostic accuracy varies by location or cause, or that results differ from those seen in the overall meta-analysis of all studies (see *Figure 3*).

Given that there was no clear evidence that diagnostic accuracy for any of the tests varied by cause or location, a combined meta-analysis of all studies in adults without diabetes was performed. The results of the bivariate analysis of sensitivity and specificity are shown in *Figure 19*. Results from univariate meta-analyses are provided in *Appendix 4*, *Table 23*.

These results are broadly comparable to the results using all studies (see *Figure 3*). There is some suggestion that scintigraphy has slightly higher specificity and MRI has slightly lower specificity than the overall results, or to those in diabetic foot ulcer studies (see *Figure 15*), but 95% CIs are too wide to draw any firm conclusions.
FIGURE 19 Bivariate meta-analysis in studies of people without diabetes.

Comparisons of tests

We also considered studies that compared different imaging tests in people without diabetes. In *Appendix 4*, *Figure 39* shows the difference in DORs between tests within studies (as in *Figure 6* for all studies). This suggests that PET and SPECT are generally superior to radiography and scintigraphy. Results from logistic regression models to compare the tests are summarised in *Table 8* (for full results, see *Appendix 4*, *Table 26*). These appear to be similar to the results for all studies overall, but there were limited data on comparisons between tests.

Studies not included in the quantitative synthesis

Of the two adult studies that were not included in any of the above quantitative syntheses, one evaluated the accuracy of MRI[37] and one compared radiography, CT and radiography + CT[72] (*Table 9*). The results of both studies differed somewhat from the meta-analysis and showed worse diagnostic accuracy overall, although these results should be interpreted with caution owing to the relatively small size of the studies.

Abdel Razek and Samir[37] conducted a prospective study that evaluated MRI in adults with suspected acute diabetic foot osteomyelitis. MRI had a sensitivity of 65% (95% CI 46% to 85%) and a specificity of 61% (95% CI 39% to 84%). These results differ from the meta-analysis, which found higher sensitivity and

First author and year of publication	n	Population	Tests	Sensitivity (%) (95% CI)	Specificity (%) (95% CI)	DOR
Abdel Razek (2017)[37]	39	Adults with diabetic foot ulcer with suspected AOM	MRI	65 (46 to 85)	61 (39 to 84)	NR
Larson (2011)[72]	44	Adults with pelvic pressure ulcer with suspected pelvis/hip osteomyelitis	Radiography, CT, CT + radiography	Radiography: 88; CT: 50; CT + radiography: 61	Radiography: 32; CT: 85; CT + radiography: 69	NR

NR, not reported.

specificity for MRI (see *Table 4*). Larson *et al.*[72] undertook a retrospective study conducted in patients with suspected osteomyelitis associated with pelvic pressure ulcers. Results for radiography (sensitivity 88%; specificity 32%), CT (sensitivity 50%; specificity 85%) differed from the meta-analysis, which found lower sensitivity and higher specificity for radiography, and higher sensitivity for CT overall (see *Table 4*). The combination of radiography and CT increased the sensitivity of CT alone, but reduced specificity (sensitivity 61%; specificity 69%). This differs from the results of the only other study of radiography + CT reported earlier, which found that radiography and CT combined had a sensitivity of 38% and a specificity of 85% (see *Studies reporting on combinations of imaging tests*).[75]

Synthesis of studies in children

The three studies of children were conducted in single centres in patients with suspected AOM.[52,78,98] Two studies evaluated ultrasonography,[52,78] and two used MRI.[78,98] Radiography, scintigraphy and CT were evaluated in only one study.[78]

The evidence for the accuracy of ultrasound and MRI in children was mixed and limited overall. Ultrasonography had moderate sensitivity (55%, 95% CI 43% to 67%) and specificity (47%, 95% CI 24% to 70%) in 82 children with suspected acute haematogenous osteomyelitis,[78] but had perfect (100%) sensitivity and specificity in a study of 27 children with negative or equivocal initial radiographic findings.[52] MRI had a sensitivity of 81% (95% CI 64% to 93%) and a specificity of 67% (95% CI 22% to 96%) in 38 children with suspected acute haematogenous osteomyelitis,[78] but preoperative MRI had 38% sensitivity and 95% specificity in a study of 54 patients with septic hip. A study-by-study summary is provided in *Table 10*.

Malcius *et al.*[78] conducted a prospective study of 183 hospitalised children with suspected acute haematogenous osteomyelitis. A total of 169 early radiography (median first day of hospital), 142 late radiographic assessments (15th day of hospital stay), 82 ultrasonographies (second day), 76 scintigraphies (third day), 38 MRI scans (seventh day) and 17 CT scans (15th day) were conducted. Scintigraphy (^{99m}Tc-MDP) was conducted in patients who had an unclear diagnosis based on early radiography and/or ultrasound, and MRI and CT were performed when results from scintigraphy were inconclusive. The reference standard included clinical follow-up, microbiology (blood or bone culture) and/or surgery. Acute haematogenous osteomyelitis was confirmed in 156 (85.2%) patients.

Early radiography had low sensitivity (16%, 95% CI 100% to 23%) but high specificity (96%, 95% CI 78% to 100%). Late radiography had high sensitivity (82%, 95% CI 75% to 88%) and specificity (92%, 95% CI 62% to 100%).

Ultrasonography had moderate sensitivity (55%, 95% CI 43% to 67%) and specificity (47%, 95% CI 24% to 70%). Bone scintigraphy had high sensitivity (81%, 95% CI 68% to 90%) and specificity (84%, 95% CI 60% to 97%).

TABLE 10 Diagnostic accuracy results of studies in children

Malcius (2009)[78]	Lithuania	Prospective	169	Children with suspected acute haematogenous osteomyelitis	Early radiography, late radiography, ultrasound, scintigraphy (^{99m}Tc-MDP), MRI, CT	Physical examination and/or microbiology (blood or bone culture) or surgery	Early radiography: 16 (1 to 23) Late radiography: 82 (75 to 88) Ultrasound: 55 (43 to 67) Scintigraphy: 81 (68 to 90) MRI: 81 (64 to 93) CT: 67 (38 to 88)	Early radiography: 96 (78 to 100) Late radiography: 92 (62 to 100) Ultrasound: 47 (24 to 7) Scintigraphy: 84 (60 to 97) MRI: 67 (22 to 96) CT: 5 (1 to 98)	Early radiography: 4.34 (0.63 to 186.3) Late radiography: 51.17 (6.61 to 2222.0) Ultrasound: 1.08 (0.30 to 3.84) Scintigraphy: 22.3 (4.9 to 132.7) MRI: 8.67 (0.91 to 108.5) CT: 2.0 (0.02 to 172.4)
Schlung (2016)[98]	USA	Retrospective	54	Children with septic hip undergoing preoperative MRI	MRI	Positive joint fluid culture or positive peripheral blood culture with joint aspirate > 50,000 WBCs	37.5 (NR)	94.7 (NR)	NR
Ezzat (2011)[52]	Egypt	Prospective	27	Children with suspected AOM and negative or equivocal plain radiography	Ultrasound (greyscale and power Doppler)	Surgery, cytology, or clinical follow-up	100 (NR)	100 (NR)	NR

NR, not reported.

Magnetic resonance imaging had a sensitivity of 81% (95% CI 64% to 93%) and a specificity of 67% (95% CI 22% to 96%), and CT had a sensitivity of 67% (95% CI 38% to 88%) and a specificity of 50% (95% CI 1% to 98%), although results should be interpreted with caution because of the small number of patients tested.

Overall, Malcius et al.[78] found that scintigraphy and MRI are most valuable for detecting acute haematogenous osteomyelitis at the onset of the disease, and late radiography is the most valuable radiological method. The comparability of index tests is limited by the fact that more advanced tests were performed only in harder-to-diagnose subgroups.

Schlung et al.[98] conducted a retrospective study of 83 children with suspected septic hip arthritis, of whom 54 underwent preoperative MRI. Osteomyelitis was confirmed by positive joint fluid culture or positive peripheral blood culture with joint aspirate. The sensitivity of MRI was 38% and the specificity was 95%. Of the 10 false-negative cases missed by MRI, six had a positive femoral aspiration that resulted in appropriate management, but three had significant morbidity owing to missed or delayed diagnosis; results for the remaining patient were not reported.

Ezzat et al.[52] conducted a small prospective study of children with suspected AOM with negative or equivocal conventional plain radiography. The accuracy of greyscale and power Doppler ultrasound was evaluated in 27 children, of whom 23 underwent surgery. Osteomyelitis was confirmed as positive in 25 out of 27 patients. Ultrasonography had a sensitivity of 100% and a specificity of 100%. The results of this study need to be interpreted with caution because of the limited number of patients.

Review of inter-rater reliability

Characteristics of included studies

Table 11 presents a summary of study and patient characteristics of the 11 studies evaluating the inter-rater reliability of imaging tests for the diagnosis of osteomyelitis.[37,58,59,65,68,86,92,114–117]

Three studies were conducted in Germany,[58,59,65] three in the USA[86,92,116] and two in Spain.[114,115] A single study was conducted in the following countries: Egypt,[37] Switzerland[68] and the UK.[117] Five studies were conducted prospectively[37,58,59,65,114] and six were retrospective.[68,86,92,115–117] One study was conducted in children.[116] The majority of participants were male. The condition targeted was COM in four studies,[58,59,68,117] AOM in one study,[37] AOM and COM in one study,[65,92] and chronic or subacute osteomyelitis in one study.[59,65] Five studies did not report what specific osteomyelitis subtypes were targeted.[86,92,114–116] All studies included experienced raters, although two studies also involved inexperienced radiologists.[114,116]

Five studies included patients with diabetic foot ulcer,[37,86,92,114,115] one study included patients with trauma or surgery as the suspected cause of osteomyelitis,[68] and one included patients with spinal cord injury and pressure ulcers.[117] Three studies did not report the cause of osteomyelitis.[58,59,65]

The inter-rater reliability of the following tests was evaluated: MRI (five studies),[37,68,86,116,117] radiography (two studies),[114,115] PET (two studies),[58,59] scintigraphy (two studies),[58,92] scintigraphy + SPECT (one study),[65] SPECT/CT (one study)[65] and SPECT with CT, MRI or radiography (one study).[65] Four studies evaluated the inter-rater reliability of more than one test.[58,65,86,92]

Critical appraisal

Table 12 presents a summary of the results of the critical appraisal. The studies were considered to be of fair quality overall, although most were small and none provided satisfactory measures of intra-rater reliability (the degree of agreement among repeated administrations of a test by a single rater).

TABLE 11 Characteristics of inter-rater reliability studies

First author and year of publication	Country	Design	n	Population	Mean (SD) age [range] (years)	% male	Tests

Overall, there were no significant concerns about the applicability of the study participants, raters and conduct of imaging test to the review question. Six studies blinded radiographers to relevant patient clinical information;[37,68,86,92,115,116] this may limit the applicability of these studies to clinical practice as such information would typically be available to clinicians, but may also reduce the risk of bias in the interpretation of imaging test results. Three studies did not state whether or not raters were blinded to each other's ratings, which may limit their validity.[65,68,115] There were no significant concerns about loss to follow-up. Only one study provided an estimate of intra-rater reliability, which was below our prespecified acceptability score ($\kappa = 0.8$).[114] All studies used an appropriate measure for calculating reliability (kappa), except one that used percentage agreement only.[92]

Questions: 1. Was a representative sample of participants used? 2. Was a representative sample of raters used? 3. Is replication of the measurement procedure possible? 4. Was clinical information from participants available to raters and comparable to clinical practice? 5. Were participants' characteristics stable during the study? 6. Were raters' characteristics stable during the study? 7. Were raters blinded to each other's results? 8. Can non-random loss to follow-up be ruled out? 9. Was an estimate of intra-rater reliability validly determined and was it above 0.80? 10. Were appropriate measures used for calculating reliability?

Results of inter-rater reliability studies

Table 13 presents the results of the studies of inter-rater reliability. Overall, the tests that showed the best inter-rater reliability were PET ($\kappa = 0.93$ and 0.96, two studies)[58,59] and scintigraphy ($\kappa = 0.91$ and 95% agreement, two studies).[58,92] The inter-rater reliability of MRI ranged from substantial to near perfect ($\kappa = 0.71$ to 0.93, five studies).[37,68,86,116,117] The inter-rater reliability of radiography ranged from fair to substantial ($\kappa = 0.35$ to 0.40 in one study and $\kappa = 0.77$ in one study).[114,115] One study found near-perfect agreement between raters for SPECT/CT ($\kappa = 0.86$) and SPECT with CT, MRI or radiography ($\kappa = 0.87$), and moderate agreement for scintigraphy + SPECT ($\kappa = 0.54$).[65] There was no evidence that results differed according to radiographer experience or patient population.

Review of implementation

One study of implementation was identified by the review.[118]

Govaert *et al.*[118] was a survey of orthopaedic and trauma surgeons, radiologists and nuclear medicine physicians in the Netherlands on preferred imaging strategies for diagnosing post-traumatic osteomyelitis. The 16-question survey included four patient-based clinical cases of fracture-related osteomyelitis. Each case included relevant medical history of the patient combined with a clinical picture of the affected limb and radiographic results. Participants were asked to select which imaging test(s) they considered most appropriate to diagnose or exclude the presence of post-traumatic osteomyelitis.

There were 346 responders, comprising 153 trauma surgeons, 104 orthopaedic surgeons, 56 nuclear medicine physicians and 33 musculoskeletal radiologists. There was consensus on the usefulness of radiography in patients with a late infection, but not in patients with acute infection. There was a marked difference between trauma surgeons, and orthopaedic surgeons' choice of nuclear medicine imaging for late infection: trauma surgeons preferred PET and orthopaedic surgeons favoured WBC scintigraphy. Similarly, there was a consistent difference between radiologists and nuclear medicine physicians: musculoskeletal radiologists favoured MRI whereas nuclear medicine clinicians preferred PET/CT. CT and three-phase bone imaging for late fracture-related infections were favoured by orthopaedic surgeons and some musculoskeletal radiologists, but not by trauma surgeons or nuclear medicine physicians. Ultrasound-guided biopsy was regarded by all physicians to have some role in patients with early infection but was not popular for late infections. Preference of imaging was influenced by access to equipment, with clinicians selecting imaging methods they had access to in their own hospital.

Summary of previous systematic reviews

The systematic database searches identified 11 previous systematic reviews of the diagnosis of osteomyelitis.[20–30] Most of the studies included in these reviews were also included in this review, although some did not meet our inclusion criteria. The previous reviews are summarised in *Table 14*.

Four of these reviews considered primarily, or only, people with diabetic foot ulcers.[20,22,23,26] Their conclusions varied, depending on the tests included, but MRI, PET and WBC scintigraphy were all suggested as suitable imaging tests.

The Lauri *et al.*[23] review, which is the most recent review of patients with diabetic foot osteomyelitis, concluded that MRI, PET and WBC scintigraphy have similar sensitivity, but MRI has lower specificity. This is similar to the findings of this review.

Three reviews of osteomyelitis in the general population mostly recommended PET and SPECT as having the best diagnostic accuracy,[25,27,28] but that leucocyte scintigraphy could be useful in some cases, such as for COM in the peripheral skeleton,[25] or when PET is unavailable.[28] Only one of these three reviews considered MRI.[25] One review focused on patients with peripheral post-traumatic osteomyelitis and concluded that WBC [or antigranulocyte antibody (AGA)] scintigraphy with SPECT/CT or ^{18}F-FDG-PET/CT has the best diagnostic accuracy in this population.[21] Another review of MRI in patients with pressure ulcers was inconclusive owing to insufficient evidence.[29]

Only two reviews considered osteomyelitis in children. One focused on calcaneal osteomyelitis. The review included only three diagnostic accuracy studies and was inconclusive owing to the limited evidence.[24] One review focused on haematogenous acute and subacute paediatric osteomyelitis.[30] The review included three studies of radiography that showed low sensitivity (16–20%) but high specificity (80–100%). ^{99}Tc bone imaging had variable sensitivity (53–100%) and specificity (50–100%) (three studies). MRI had the highest sensitivity (80–100%) and specificity (70–100%) (five studies), compared with CT (sensitivity 67%, specificity 50%, two studies) and ultrasound (sensitivity 55%, specificity 47%, one study). Only one of the studies included in this review met our inclusion criteria, which was the largest and most comprehensive study in children.[78] Overall, the diagnostic accuracy findings of this review broadly agree with the evidence in adults.

Clinical effectiveness summary and conclusions

Summary of included studies

The review of diagnostic accuracy included 77 studies. Nearly one-quarter of the studies were considered to be at a high risk of bias.

TABLE 14 Summary of previous systematic reviews

First author and year of publication	Studies (n)	Osteomyelitis	Index test(s)	Meta-analysis	Main findings	Conclusions
Dartnell (2012)[30]	7	Haematogenous acute and subacute paediatric osteomyelitis	Any	No	Radiography: sensitivity 16–20%, specificity 80–100%	Radiographs are essential for exclusion of other diagnoses. MRI is the gold-standard imaging technique. If unavailable or a delay is likely, bone and ultrasound scans usually give adequate diagnostic information
					^{99}Tc scintigraphy: sensitivity 53–100%, specificity 50–100%	
					MRI: sensitivity 80–100%, specificity 70–100%	
					CT: sensitivity 67%, specificity 50%	
					Ultrasound: sensitivity 55%, specificity 47%	
Dinh (2008)[20]	9	Diabetic foot osteomyelitis	Any	Yes	Radiography: sensitivity 54%, specificity 68%, DOR 2.84	MRI is the most accurate imaging test for DFO
					MRI: sensitivity 90%, specificity 79%, DOR 24.36	
					Scintigraphy: sensitivity 81%, specificity 28%, DOR 2.10	
					WBC scintigraphy: sensitivity 74%, specificity 68%, DOR 10.07	
Govaert (2017)[21]	10	Peripheral post-traumatic	Any	No	WBC scintigraphy: sensitivity 50–100%, specificity 0–97%	WBC (or AGA) scintigraphy with SPECT/CT or ^{18}F-FDG/CT have the best diagnostic accuracy for peripheral PTO
					PET: sensitivity 83–100%, specificity 51–100%	
					PET/CT: sensitivity 86–94%, specificity 76–100%	
					WBC scintigraphy + SPECT/CT: sensitivity 100%, specificity 89–97%	

TABLE 14 Summary of previous systematic reviews (*continued*)

First author and year of publication	Studies (*n*)	Osteomyelitis	Index test(s)	Meta-analysis	Main findings	Conclusions
Kapoor (2007)[22]	17	Foot osteomyelitis (mainly diabetic)	MRI, scintigraphy and radiography	Yes	MRI: DOR 42.1 (95% CI 14.8 to 119.9)	Accuracy of MRI was markedly superior to that of ^{99m}Tc bone scanning, plain radiography and WBC
					MRI vs. scintigraphy (*n* = 7): DOR 149.9 vs. 3.6	
					MRI vs. radiography (*n* = 9): DOR 81.5 vs. 3.3	
					MRI vs. WBC (*n* = 3): DOR 120.3 vs. 3.4	
Lauri (2017)[23]	29	Diabetic foot osteomyelitis	MRI, PET, WBC scintigraphy	Yes	PET: sensitivity 89%, specificity 92%, DOR 95	MRI, PET and WBC have similar sensitivities, PET and WBC have highest specificities
					WBC ^{111}In scintigraphy: sensitivity 92%, specificity 75%, DOR 34	
					WBC ^{99m}Tc-HMPAO: sensitivity 91%, specificity 92%, DOR 118	
					MRI: sensitivity 93%, specificity 75%, DOR 37	
Mooney (2017)[24]	3	Children (calcaneal osteomyelitis)	MRI and radiography	No	MRI: accuracy 100%	No clear approach to diagnosis of calcaneal osteomyelitis in children
					Radiography: accuracy 14–71.4%	

First author and year of publication	Studies (*n*)	Osteomyelitis	Index test(s)	Meta-analysis	Main findings	Conclusions
Termaat (2005)[25]	23	General (chronic)	Any	Yes	PET: sensitivity 96% (95% CI 88% to 99%), specificity 91% (95% CI 81% to 95%) Bone scintigraphy: sensitivity 82% (95% CI 70% to 89%), specificity 25% (95% CI 16% to 36%) Leucocyte scintigraphy: sensitivity 61% (95% CI 43% to 76%), specificity 77% (95% CI 63% to 87%) Bone + WBC scintigraphy: sensitivity 78% (95% CI 72% to 83%), specificity 84% (95% CI 75% to 90%) MRI: sensitivity 84% (95% CI 69% to 92%), specificity 60% (95% CI 38% to 78%)	PET has highest accuracy. Leucocyte scintigraphy has an appropriate accuracy in the peripheral skeleton, but ^{18}F-FDG-PET is superior in the axial skeleton
Treglia (2013)[26]	9	Diabetic foot osteomyelitis	PET	Yes	PET: sensitivity 74% (95% CI 60% to 85%), specificity 91% (95% CI 85% to 96%), DOR 16.96 (95% CI 2.1 to 139.7), AUC 0.874	^{18}F-FDG-PET and PET/CT showed high specificity and are potentially useful if combined with other imaging methods such as MRI, although data are limited
van der Bruggen (2010)[27]	11	General	PET	No	PET: sensitivity 94–100%, specificity 87–100%	^{18}F-FDG-PET is also useful for diagnosis of osteomyelitis with improved spatial resolution over SPECT imaging, allowing more accurate localisation. Localisation can be further improved by adding CT

TABLE 14 Summary of previous systematic reviews (*continued*)

First author and year of publication	Studies (*n*)	Osteomyelitis	Index test(s)	Meta-analysis	Main findings	Conclusions
Wang (2011)[28]	23	General	PET, scintigraphy	Yes	PET: sensitivity 92%, specificity 92%, AUC 0.97 Scintigraphy: sensitivity 83%, specificity 45%, AUC 0.65 Leucocyte scintigraphy: sensitivity 74%, specificity 88%, AUC 0.91 MOAB scintigraphy: sensitivity 88%, specificity 71%, AUC 0.89	PET is superior to scintigraphy, but leucocyte scintigraphy is reasonable if PET is unavailable
Xu (2017)[29]	3	Pressure ulcer	MRI	No	Sensitivity 98% and 94.3%, specificity 89% and 22.2%. NR for 3rd study	Insufficient evidence

AGA, antigranulocyte antibody; AUC, area under the curve; DFO, diabetic foot ulcer; MOAB, monoclonal antigranulocyte antibody; NR, not reported; PTO, post-traumatic osteomyelitis.

The review of inter-rater reliability identified 11 studies. The studies were considered of fair quality overall, although most were small and none provided satisfactory measures of intra-rater reliability.

Only one study on the implementation of diagnostic test imaging for osteomyelitis from the Netherlands was included. The applicability of its findings to other health-care systems is uncertain.

General conclusions from synthesis

In adults, MRI, PET and SPECT scans all had summary sensitivity and specificity of between 80% and 95%. Similarly, they had PPVs between 85% and 93%, and NPVs between 85% and 97%. All had similar DORs and summary HSROC curves, suggesting that overall diagnostic accuracy was similar across the three tests. Despite this good performance, MRI and SPECT showed a very high variability in specificity across studies; for MRI, specificity ranged from 0% to 98%. Results for PET were generally more consistent.

Radiography and CT generally had lower sensitivity, and scintigraphy had lower specificity than MRI, PET and SPECT. Radiography, CT and scintigraphy all had substantially lower DORs than MRI, PET or SPECT, suggesting poorer diagnostic performance in general. Formal comparisons of the tests in studies that analysed multiple imaging tests confirmed the above conclusions. These analyses also confirmed that MRI generally has higher sensitivity, but lower specificity, than PET.

There were only two studies of ultrasound, which were not consistent in their findings, so no conclusions on the diagnostic value of ultrasound can be drawn.

The diagnostic accuracy of scintigraphy depended on the type of scintigraphy performed. Although sensitivity was similar across types of scintigraphy (75% to 92%), specificity was poor for ^{99m}Tc-(H)MDP (at 36% to 46%), but high for ^{99m}Tc-HMPAO WBC (94%) and mixed for ^{111}In WBC and ^{99m}Tc-MDP scintigraphy (88%). This suggests that newer forms of scintigraphy have diagnostic accuracy similar to MRI, PET and SPECT. This is perhaps unsurprising as most SPECT studies used ^{99m}Tc-HMPAO WBC imaging.

No other differences in performance within tests were identified. In particular, there was no evidence that SPECT/CT differed from SPECT alone, or that PET/CT and PET alone differed in diagnostic accuracy. In general, there were too few data reported to distinguish between subtypes of test and few studies compared subtypes of test. In particular, we found no evidence on the impact of contrast agents for MRI.

There was some evidence that the specificity of MRI declined as the incidence of osteomyelitis in the study population increased. This might suggest that there is overdiagnosis of osteomyelitis when using MRI, particularly when most people tested will have osteomyelitis, perhaps because of a desire not to miss actual cases.

Few studies described the diagnostic accuracy when combining different tests, such as combining scintigraphy and SPECT. There was no evidence that test combinations improved diagnostic accuracy compared with using a single test (MRI, PET or SPECT). Some studies were of patients who had already received radiography prior to their main imaging test. There was some suggestion that performing radiography before MRI could improve diagnostic accuracy, but this was not conclusive.

Diagnostic accuracy by cause or nature of osteomyelitis

The largest group of people receiving imaging tests for osteomyelitis were people with diabetic foot ulcers, representing nearly half of the included studies. Results were broadly consistent with the overall analysis. MRI (96% sensitivity, 84% specificity) and PET (79% sensitivity, 92% specificity) both had high diagnostic accuracy, with MRI having higher sensitivity but lower specificity. ^{99m}Tc-HMPAO scintigraphy had high accuracy (92% sensitivity, 89% specificity), comparable to that of PET and MRI.

In studies of people without diabetes, a range of locations (including long bones, pelvis, knee, hip, spine and skull) and a range of possible causes of osteomyelitis (including infections, trauma and surgery) were tested.

The numbers of studies in any category were small so the ability to compare studies was limited. There was, however, no clear evidence that location or cause of osteomyelitis had any impact on the diagnostic accuracy of any imaging test.

When combining all studies of people without diabetes, the results were similar to the overall results and to those in people with diabetic foot ulcers. MRI (94% sensitivity, 72% specificity), PET (88% sensitivity, 90% specificity) and SPECT (96% sensitivity, 95% specificity) all had high diagnostic accuracy, although diagnostic accuracy was poorer for radiography, scintigraphy and CT.

Overall, there was no statistically significant evidence that diagnostic accuracy of any test varies according to the location or possible cause of osteomyelitis. The choice of tests did vary, with MRI most studied in people with diabetic foot ulcers. SPECT, by contrast, has been little studied in people with diabetes.

Studies of children, inter-rater reliability and implementation
Only three studies of children were identified. The evidence for the accuracy of ultrasound and MRI in children was mixed and limited overall. Only one study evaluated radiography, scintigraphy and CT in children.

There was some evidence to suggest that MRI has an acceptable degree of agreement among radiologists. The evidence for the inter-rater reliability of other imaging tests was very limited.

There is also very limited evidence on the implementation of imaging tests for the diagnosis of osteomyelitis. Notably, there is a lack of evidence on patient preferences and on the cost-effectiveness of diagnostic imaging tests and pathways for osteomyelitis.

Chapter 5 Discussion

Statement of principal findings

This systematic review identified 81 studies relating to imaging tests for the diagnosis of osteomyelitis. Seventy-seven of these were studies of diagnostic accuracy, of which 69 reported diagnostic accuracy data sufficient to be included in a quantitative synthesis. Thirty-six diagnostic accuracy studies were in patients with diabetic foot ulcers, and 40 were in patients without diabetes.

Eleven studies evaluated the inter-rater reliability of at least one imaging test and one study provided data on clinician opinions on imaging tests for osteomyelitis.

Overall, most diagnostic accuracy studies were small (80% had < 50 participants) and nearly one-quarter were considered as being at a high risk of bias, although poor reporting means that there is significant uncertainty about the quality of most of the studies. The studies of inter-rater reliability were considered of fair quality overall, although most were small and none provided satisfactory measures of intra-rater reliability.

Only one study from the Netherlands on the implementation of diagnostic test imaging for osteomyelitis was included.[118] The applicability of its findings to other health-care systems is uncertain.

Diagnostic accuracy in adults

The overall meta-analysis of diagnostic accuracy in adults found that MRI (the most widely studied test) can detect osteomyelitis with high accuracy (95.6% sensitivity, 95% CI 92.3% to 97.5%; 80.7% specificity, 95% CI 70.7% to 87.8%). There was, however, considerable variation in the specificity across tests. This may partly be as a result of the overdiagnosis of osteomyelitis, particularly in studies with a high incidence of osteomyelitis.

Positron emission tomography also had high diagnostic accuracy (85.1% sensitivity, 95% CI 71.5% to 92.9%; 92.7% specificity, 95% CI 83.0% to 97.1%), with lower sensitivity, but higher specificity, than MRI. SPECT also had high accuracy (95.0% sensitivity, 95% CI 87.8% to 98.1%; 82.0% specificity, 95% CI 61.5% to 92.8%). There was no evidence that PET alone differed in accuracy from PET/CT, nor that SPECT differed from SPECT/CT. MRI, PET and SPECT all had similar DORs and summary HSROC curves, suggesting that the three imaging tests have broadly similar diagnostic performance.

Scintigraphy (83.6% sensitivity, 95% CI 71.8% to 91.1%; 70.1% specificity, 95% CI 57.7% to 80.8%), CT (69.7% sensitivity, 95% CI 40.1% to 88.7%; 90.2% specificity, 95% CI 57.6% to 98.4%) and radiography (70.3% sensitivity, 95% CI 61.6% to 77.8%; 81.5% specificity, 95% CI 69.6% to 89.4%) all had generally inferior diagnostic accuracy to MRI, PET or SPECT. This was confirmed by their lower DORs and poorer HSROC curves. There was evidence that the diagnostic accuracy of scintigraphy depended on the type of scintigraphy used. The most up-to-date forms of scintigraphy, such as [99mTc] HMPAO WBC scintigraphy (87.3% sensitivity, 95% CI 75.1% to 94.0%; 94.7% specificity, 95% CI 84.9% to 98.3%) had higher diagnostic accuracy, similar to that of PET or MRI. However, its estimated sensitivity was lower than for 3D SPECT imaging.

There were insufficient studies of ultrasound to assess its diagnostic accuracy.

Comparisons and combinations of diagnostic tests

In studies that compared two or more imaging tests, informal and formal comparisons of these tests confirmed the findings discussed above. MRI, PET and SPECT all had similar diagnostic accuracy in terms of

DORs. MRI had higher sensitivity but poorer specificity than PET. Scintigraphy (all types combined), radiography and CT all had lower DORs than MRI, PET or SPECT.

In studies that reported the diagnostic accuracy of combinations of imaging tests (e.g. of the combination of scintigraphy and SPECT), there was no clear evidence that combining tests improved diagnostic accuracy over using a single test alone, although data were limited.

Studies were generally not clear about whether or not radiography was performed prior to the main imaging test. It was possible that prior use of radiography could improve diagnostic accuracy of scintigraphy or MRI, but data were limited and results were not statistically significant.

Subgroups of patients

The main patient subgroup was patients in whom osteomyelitis was suspected as a complication of diabetic foot ulcers. This group represented nearly half of all included studies. The results of meta-analyses in these patients were similar to those from the main meta-analysis, except that there were too few studies of SPECT or CT to reliably assess diagnostic accuracy. There was no evidence to suggest that diagnostic accuracy in patients with diabetic foot ulcers differed from the overall analysis.

Studies of patients without diabetes were divided according to scan location (axial skeleton, long bone, etc.) and by potential cause of osteomyelitis (trauma or surgery, infection, etc.). Data within each category were generally limited, but there was no clear evidence that diagnostic accuracy varied by scan location or cause, or that results differed substantially from the main analysis.

When all studies of patients without diabetes were combined, results were generally similar to the overall analyses. There was some suggestion that the specificity of MRI and PET was lower than in the overall analysis, but CIs were too wide for this to be conclusive.

Few studies reported whether osteomyelitis was acute or chronic, but there was no compelling evidence that this affected diagnostic accuracy. Similarly, there was no evidence that the presence of indwelling metalwork or the choice of reference standard test (microbiology or clinical follow-up) altered diagnostic accuracy. There was no evidence of systematic bias in the results; diagnostic accuracy did not appear to vary according to risk of bias as assessed using QUADAS-2.

Diagnostic tests in children

The evidence for the accuracy of ultrasound and MRI in children was mixed and limited overall. Ultrasonography had moderate sensitivity and specificity in children with suspected acute haematogenous osteomyelitis but had perfect sensitivity and specificity in a small study of children with negative or equivocal initial radiographic findings. MRI had good sensitivity and specificity in children with suspected acute haematogenous osteomyelitis in one study,[78] but preoperative MRI had poor sensitivity and near-perfect specificity in another study of patients with septic hip.[98]

Inter-rater reliability and implementation

Magnetic resonance imaging appeared to have acceptable inter-rater reliability. There was some evidence suggesting that PET and scintigraphy had near-perfect inter-rater reliability, although this is limited to few small studies.[58,59,92] We found no evidence on patient preferences and cost-effectiveness of imaging tests for osteomyelitis.

Strengths and limitations of the assessment

Strengths

This systematic review was conducted in accordance with PRISMA guidelines; searches of numerous databases were performed, studies were assessed for quality using the QUADAS-2 framework and,

provided they reported sufficient data, studies were synthesised using bivariate meta-analysis methods to assess diagnostic accuracy.

Over 18,000 database records were assessed and 81 published studies were included in this review, making it the largest and most comprehensive review of the diagnosis of osteomyelitis to date. This was the first review in the field to consider all relevant imaging tests across all types of patient receiving imaging tests to diagnose osteomyelitis. This was, therefore, the first review to our knowledge that was able to comprehensively compare imaging tests and to investigate whether or not the choice of imaging test varies with type of patient.

This review used recommended contemporary meta-analysis methods such as bivariate analysis and HSROC analysis to synthesise studies, so the synthesis is robust and meets the highest statistical standards. This was the first meta-analysis of osteomyelitis and, to our knowledge, the first practical diagnostic meta-analysis in any field, to use regression models to formally compare different diagnostic tests. This made it the first analysis to comprehensively and reliably compare the various imaging tests for osteomyelitis.

Limitations

The limitations of this review are largely a consequence of the limitations in the identified studies.

There were numerous concerns about the potential for bias in the included studies. Most studies were small, with < 50 participants, and were conducted retrospectively. The risk-of-bias assessment suggested potential bias because of unclear methods of patient selection and lack of blinding between index tests and references standards. However, statistical analysis found no evidence that these concerns led to actual biases in the results.

There were few studies identified that included children. This may be because studies of children do not discuss osteomyelitis directly, but only in the context of other conditions such as septic arthritis. Hence, it is possible that some possibly relevant studies were missed. However, subsequent informal searches did not identify any further useful reviews or studies that could be included and so we were unable to draw any firm conclusions on the accuracy of imaging in children.

Some imaging tests were reported in a few studies, particularly ultrasound and CT, so we were not able to fully assess their diagnostic accuracy. Some aspects of studies were inconsistently reported, such as varying descriptions of the cause of osteomyelitis, non-reporting of whether osteomyelitis was acute or chronic, and lack of clarity on whether or not radiography (or other tests) had been used prior to the main test. This made assessment in these subgroups difficult.

We identified very few data beyond those on diagnostic accuracy, with few studies discussing broader implementation issues such as access to machinery, costs or radiation exposure. This meant that this review could not consider the broader issues of how imaging tests should be used, for example whether or not differences in diagnostic accuracy between PET/SPECT and MRI merit the additional radiation exposure, or suggest that PET/SPECT machines should be made more widely available.

Scintigraphy was not specified in the protocol as a test of interest as it is little used in the UK. However, many studies of scintigraphy were identified during abstract screening and many studies compare scintigraphy with other tests. Given this, we decided to include scintigraphy in the main analysis where it had been compared with other tests. Studies of scintigraphy alone were included in further analyses, but these studies were not fully assessed for quality. This uncertainty in quality, and the consequence that the scintigraphy-only studies may be of lower quality than the studies that were fully assessed, is a limitation of this analysis.

Our analysis therefore has the potential for bias, either because the diagnostic accuracy of scintigraphy may be underestimated when it is compared with other tests expected to be better, or because studies

of scintigraphy alone may be of poorer quality. However, the diagnostic accuracy of the scintigraphy-only studies was similar to that of the fully assessed studies. Any bias is likely to be modest and the overall conclusions reasonable. The benefits of assessing all the evidence on scintigraphy (e.g. being able to compare different test types) probably outweigh any risk of bias.

Uncertainties

The main uncertainties remaining from this review arise largely because of limitations in the identified studies.

The diagnostic accuracy of imaging tests in children remains highly uncertain owing to the very limited nature of the evidence. We could reach no firm conclusions on the diagnostic accuracy of any imaging test in children.

The diagnostic accuracy of ultrasound is currently unknown as the only two studies in adults had conflicting results. However, DORs in both studies were low, suggesting that ultrasound is unlikely to have similar or better diagnostic accuracy than MRI, PET or SPECT. Ultrasound, however, is a test of choice in patients with metalwork in situ as this causes artefacts in CT and MRI.

Although we found no evidence that diagnostic accuracy varied across subgroups of patients, limited or inconsistent reporting of some characteristics, such as AOM versus COM, or the cause or location of osteomyelitis, means than differences between tests or between subgroups cannot be ruled out.

Considerations from patient representatives

Both patient representatives were parents of children who were treated for osteomyelitis. Both discussed the fact that diagnosis was generally a long process, with multiple imaging tests performed, with preliminary radiography and then ultrasound tests, both of which might be repeated. MRI was used for the 'definitive' diagnosis, and MRI was also used to confirm that treatment had been effective. We note that this process of multiple tests and their interactions could not be easily captured in this systematic review, and the impact and value of multiple imaging tests remain uncertain.

Antibiotics were given early in the diagnostic process, before ultrasound or MRI was performed. This may affect evaluations of diagnostic accuracy, because osteomyelitis is treated before being formally diagnosed. In future studies, the impact on diagnostic accuracy of treatment, given the ethical need for prompt treatment, will need to be considered.

Both parents noted that there was little time to discuss the tests or decide which was best for their child and they accepted whatever their doctors recommended. Both felt that the need to correctly diagnose osteomyelitis outweighed any concerns about the tests themselves. So, for example, they were willing to accept MRI requiring general anaesthesia.

Chapter 6 Conclusions

Implications for health care

This review found that MRI, PET and SPECT all have broadly similar and high accuracy when diagnosing osteomyelitis. All three tests correctly diagnose most people with, and most people without, osteomyelitis. All three are therefore suitable imaging tests for reliably diagnosing osteomyelitis. No clear reason to prefer one test over the other in terms of diagnostic accuracy was identified. The wider availability of MRI machines, and the fact that MRI does not expose patients to harmful ionising radiation, may mean that MRI is preferable in most cases, unless it is unsuitable for a particular patient. MRI also gives additional information as to the location of fluid collections and anatomical detail for surgical planning not given by SPECT or PET in such detail. PET or SPECT may be required if MRI is inconclusive.

Magnetic resonance imaging generally had poorer specificity than PET or SPECT, with a wide range of specificities across studies. This means that there may be substantial numbers of 'false-positive' cases when using MRI and clinicians should be aware of this potential for overdiagnosis. This may mean that MRI may be best suited to cases where false-positive cases are of lesser concern, perhaps such as when patients would proceed directly to antibiotic treatment. This might, however, be an artefact of the diagnostic studies; actual diagnoses of osteomyelitis will consider the clinical background of the patient (e.g. fever and infection markers in the blood test), so diagnosis is not based on the imaging test alone.

Position emission tomography had poorer sensitivity, but higher specificity, than MRI, with more consistent results across studies. This may make PET better suited to situations where avoiding false-positive diagnoses is important, for example when the test would be followed by surgery or other invasive procedures. However, MRI may still provide greater visual detail to guide the surgical approach than PET/CT alone.

Scintigraphy, in general, is less accurate than MRI or PET, but current methods of scintigraphy, particularly ^{99m}Tc HMPAO WBC scintigraphy, may have comparable accuracy, and this should be the preferred approach. However, planar scintigraphy may have poorer diagnostic accuracy than 3D SPECT imaging, so should perhaps be used only when SPECT is unavailable or unsuitable.

Data on ultrasound and CT were limited, but suggested that these tests have poorer diagnostic accuracy and perhaps should not currently be used in adults.

Radiography on its own has poor diagnostic accuracy so should probably not be used in isolation. This review could not confirm whether or not using radiography prior to MRI or other tests improves accuracy or reduces costs. It is, therefore, unclear whether or not the common practice of using radiography as a first test and proceeding to a MRI or another test if the radiography is inconclusive maximises diagnostic accuracy. It is, however, likely that radiography can be usefully used to rule out osteomyelitis in more obvious cases (e.g. when symptoms are the result of bone fracture). Radiography is probably more useful in chronic or subacute osteomyelitis, when bone destruction is already visible, but not in acute haematogenous osteomyelitis, when early changes are looked for.

The review found that diagnostic accuracy in adults does not appear to vary with the potential cause of osteomyelitis, or with the body part scanned. In particular, there was no evidence that diagnostic accuracy was different in patients with diabetic foot ulcers. This suggests that MRI, PET and SPECT are all reasonable tests to use in adults, regardless of the underlying conditions the patient has. The choice may depend primarily on suitability for the patient, such as potential difficulties in interpreting MRI scans in patients with indwelling metalwork. However, data on specific locations or causes of osteomyelitis other than diabetic foot ulcers were limited, so the possibility that diagnostic accuracy is different for some locations or causes remains.

The review identified very limited data on diagnosing osteomyelitis in children, so considerable uncertainty remains over the diagnostic accuracy of imaging tests in children. Clinicians should be aware of this limitation in the evidence base.

There was some evidence to suggest that MRI has an acceptable degree of agreement among radiologists. The evidence for the inter-rater reliability of other imaging tests is too limited to draw conclusions. There is also very limited evidence on the implementation of imaging tests for the diagnosis of osteomyelitis. Notably, there is a lack of evidence on patient preferences and on the most cost-effective diagnostic imaging pathways for osteomyelitis.

Suggested research priorities

The most urgent research priority is to perform diagnostic accuracy studies of imaging tests in children, given the limitations of the current evidence base. Large diagnostic accuracy studies are needed to assess imaging tests in children. These should be of high quality, with proper blinding of test assessors and consecutive recruitment of patients, and reporting of the appropriate reference standard used to confirm positive and negative diagnoses. The priority tests should be MRI and ultrasound, ideally comparing the two tests in the same children.

Ultrasound has not been widely assessed in adults. Current results suggest that ultrasound on its own may not be sufficiently accurate to diagnose osteomyelitis, but further accuracy studies are needed to resolve the uncertainty. It may be more appropriate to investigate the diagnostic accuracy of ultrasound as a precursor to MRI or other tests (e.g. as a replacement for radiography).

Consistency of test interpretation is an important area in diagnostic testing that is often overlooked. Further investigation of inter- and intra-rater reliability for all tests is needed. Ideally this should be included in diagnostic accuracy tests, but it could also be investigated in case series or clinical audits.

Given the similarities in diagnostic accuracy of MRI, PET and SPECT, suitable investigation of patient and clinician experience and opinion of these tests, through surveys or focus groups, would be useful to identify practical reasons for the choice of test. Similarly, a formal economic evaluation of these tests, accounting for test cost, sequencing of tests, availability and risk of radiation exposure, would also help to clarify the choice between these tests.

Acknowledgements

We would like to acknowledge Teumzghi Mebrahtu, Alex Hodgkinson (both formerly of CRD) and Gary Raine (CRD) for their work on abstract screening and data extraction for this review; Nerys Woolacott (formerly of CRD) for her support in establishing the project and creating the protocol; Andrew Grainger, Emily Hargreaves and Sean O'Riordan (Leeds Teaching Hospitals) for their clinical advice over the course of the project; and Rachel McDonald and Ryan Harrison for their support on providing patient and carer perspectives and experience.

Contributions of authors

Alexis Llewellyn (https://orcid.org/0000-0003-4569-5136) performed the systematic review, including screening, study selection, data extraction, quality assessment and narrative synthesis. He wrote most sections of this report.

Julie Jones-Diette (https://orcid.org/0000-0003-1769-8612) performed data extraction and quality assessment and prepared data tables for the report.

Jeannette Kraft (https://orcid.org/0000-0003-2705-1302) and **Colin Holton** provided clinical expertise and commented on drafts of the protocol and this report.

Melissa Harden prepared and performed all database searches for the systematic review.

Mark Simmonds (https://orcid.org/0000-0002-1999-8515) oversaw the project as a whole, performed the statistical analyses and wrote all sections of the report pertaining to those analyses.

Data-sharing statement

This is a systematic review of published data, and no primary data were created for this report. All data used are as reported in the publications listed throughout this report. Data-extraction forms are available on request from the corresponding author.

Appendix 1 Literature searches

The aim of the literature search was to systematically identify relevant studies of diagnostic imaging for the detection of osteomyelitis. The search strategy was developed by an information specialist with input from the review team and clinical advisors. The strategy was developed in MEDLINE (via Ovid) and included search terms for osteomyelitis and relevant diagnostic imaging techniques. No language, date, geographical or study design limits were applied. The MEDLINE strategy was adapted for use in the other resources searched.

The searches were carried out during August 2017 and updated in June 2018 to capture more recent studies. The following databases were searched: MEDLINE (including Epub Ahead of Print, In-Process & Other Non-Indexed Citations, Ovid MEDLINE Daily and Ovid MEDLINE), Cochrane Central Register of Controlled Trials (CENTRAL), Cochrane Database of Systematic Reviews (CDSR), Cumulative Index to Nursing and Allied Health (CINAHL) Plus, Database of Abstracts of Reviews of Effects (DARE), EMBASE, Health Technology Assessment (HTA) database and PubMed.

In addition, ClinicalTrials.gov and PROSPERO were searched for ongoing and unpublished studies. Relevant guidelines were identified through searches of the National Guidelines Clearing House, NHS Evidence, the NICE website and the Trip database.

The reference lists of relevant systematic reviews were manually checked to ensure that all relevant studies from previous reviews were identified. Abstracts from a number of conferences were consulted, including the Annual Meeting of the European Society of Paediatric Radiology, the Annual Meeting of the Society of Skeletal Radiology, the Annual Congress of the European Association of Nuclear Medicine and Paediatric Rheumatology. The search results were imported into EndNote X8 and de-duplicated. The complete search strategies can be found below.

Database search strategies

MEDLINE [Epub Ahead of Print, In-Process & Other Non-Indexed Citations, Ovid MEDLINE(R) Daily and Ovid MEDLINE(R)] via Ovid (http://ovidsp.ovid.com/)

Date range searched: 1946 to present.

Date searched: 9 August 2017.

Records retrieved: 10,184.

The search was updated on 20 June 2018 and identified 10,274 records.

Searched for osteomyelitis – 38 results.

The search was updated on 21 June 2018 and identified 33 results.

NHS Evidence (www.evidence.nhs.uk/)

Date searched: 31 August 2017.

Searched for osteomyelitis, filtered results to limit to guidance – 161 results.

The search was updated on 21 June 2018 and identified 141 results.

National Institute for Health and Care Excellence (www.nice.org.uk/guidance)

Date searched: 31 August 2017.

Browsed the diagnostics guidance page (www.nice.org.uk/guidance/published?type=dg) – zero relevant records found.

Searched for the term osteomyelitis in the general website search box – 21 results browsed – two relevant records found.

The search was updated on 21 June 2018 but did not identify any further relevant records.

Trip (www.tripdatabase.com)

Date searched: 31 August 2017.

Searched for osteomyelitis – 95 results – browsed for relevance and checked against previous search results in EndNote for duplicates. One relevant record identified.

The search was updated on 21 June 2018 but did not identify any further relevant records.

Appendix 2 Results of critical appraisal of diagnostic accuracy studies (QUADAS-2)

TABLE 15 The QUADAS-2 signalling questions for risk-of-bias assessment

| Domain			
Domain 1: patient selection	**Domain 2: index test**	**Domain 3: reference standard**	**Domain 4: flow and timing**
SQ 1: was a consecutive or random sample of patients enrolled?	SQ 1: were the index test results interpreted without knowledge of the results of the reference standard?	SQ 1: is the reference standard likely to correctly classify the target condition?	SQ 1: was there an appropriate interval between the index test(s) and reference standard?
SQ 2: was a case–control design avoided?	SQ 2: if a threshold was used, was it prespecified?	SQ 2: were the reference standard results interpreted without knowledge of the results of the index test?	SQ 2: did all patients receive the same reference standard?
SQ 3: did the study avoid inappropriate exclusions?	SQ 3: (optional: multiple tests) were the index test results interpreted without knowledge of the results of other index tests?	SQ3: not applicable	SQ 3: were all patients included in the analysis?

SQ, signalling question.
FIGURE 20 Summary of risk of bias and applicability assessment.

TABLE 16 The QUADAS-2 risk-of-bias decisions

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Abdel Razek (2017)[37]	Unclear. Not stated if enrolment was consecutive	Low	Low	Low
Al-Khawari (2005)[38]	Unclear. Unclear if participants were included consecutively and limited reporting of selection criteria	Low	Low	Low
Al-Sheikh (1985)[39]	Low	High. Index test results interpreted with knowledge of the results of the reference standard	Low	Low
Aragón-Sánchez (2011)[40]	Low	Low. Although lack of blinding to initial probe-to-bone test for radiography cannot be excluded	Low	Low. Although 91 patients with negative radiography and probe-to-bone test did not undergo histopathology tests (25.5%)
Aslangul (2013)[41]	Low	Low. 'There were findings compatible with OM on plain radiography in 26 of 42 (60%) of the patients who underwent bone puncture. Thus the enrolled patients were all at high risk for underlying OM.' Plain radiography was not an index test in this study	Low	Low. Although ≥ 1 year follow-up and no biopsy/culture for all 13 patients with negative index test (13/53 or 25% of total patients). All positive index test patients received microbiology
Blume (1997)[42]	Unclear. Unclear if patients were recruited consecutively and limited reporting of selection criteria	Low. Although antibiotics were used in 12/27 patients	Low	Low
Bohchelian (2002)[43]	Unclear. Unclear if consecutively enrolled and exclusion criteria NR	Low	Low. Although it is unclear what methods were used to prevent soft tissue contamination when collecting bone sample for culture	Low
Bolouri (2013)[44]	Unclear. A total of 4/42 patients had a known OM with suspected exacerbation	Unclear. Owing to uncertainty regarding blinding of staff to different index tests	Low. Although 12/35 had clinical follow-up without histology, some of which were positive	Low. 30 patients had biopsy. 12 only had clinical/imaging follow-up, some of whom were confirmed positive
Brunel (2016)[45]	Unclear. Unclear if consecutively enrolled	Low	Low	Low
Chacko (2003)[46]	Unclear. Insufficient information, retrospective study	Low	Low	Low. Although the number of patients who received only 6 ≥ months of clinical follow-up in the patients confirmed negative (23/46) is unclear

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Croll (1996)[47]	Unclear. Unclear if recruited consecutively	High. Not blinded to results of other tests	Low. Although 6 out of 27 diagnosed by clinical follow-up	Low. Although 6/27 only had clinical follow-up
Demirev (2014)[48]	Low	High. MRI and PET-CT results not blinded (in 19/27, MRI was performed before PET-CT, and after in 8/27 cases)	Low. Although 15/27 patients had histology/ microbiology confirmed from bone sample (most confirmed positive). Other methods of sample collection included blood sampling (seven), pus aspiration (five), soft tissue debridement (one negative). Clinical follow-up in four patients	Low. Although 15/27 patients had histology/ microbiology confirmed from bone sample (most confirmed positive). Other methods of sample collection included blood sampling (seven), pus aspiration (five), soft tissue debridement (one negative). Clinical follow-up in four patients
Enderle (1999)[49]	Low	Low	Low	Low
Erdman (1991)[50]	Low	Low	Low. A total of 29/110 patients diagnosed by clinical follow-up	Low. Although 29/56 of index test negative patients were confirmed negative by clinical follow-up only
Ertugrul (2006)[51]	Unclear. Unclear if patients were enrolled consecutively and why not all patients received both index tests (MRI: 28/31, scintigraphy: 26/31)	Unclear. No reporting on blinding to index test results	Low	Low
Ezzat (2011)[52]	High. Excluded patients with 'presence of any chronic disease with signs and symptoms similar to acute OM'	Low	Unclear. Most (23/27) patients had surgery, only two had cytology (pus aspiration) and two had 1-week clinical follow-up. It is unclear how many had histology/microbiology	Low
Familiari (2011)[53]	Unclear. Unclear if this was a consecutive or random sample, detail on exclusions lacking	Low. Several cut-off values were considered, but it does not appear that optimal cut-off values were derived a posteriori based on ROC curves	Low	Low
Filippi (2006)[54]	Low	Low	Low	Low
Filippi (2009)[55]	Low	Low	Low	Low. Although 5/17 patients only had clinical follow-up, the duration of follow-up (24 months) and results suggest a low risk of verification bias

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Franceschi (2013)[56]	Unclear. Conference abstract, insufficient information on selection	Low	Low	High. Only participants who received surgery were analysed (17 out of 39 who received PET/CT)
Gemmel (2004)[57]	High. Only patients with final diagnosis confirmed by microbiology and/or pus visible during surgery were included	Low	Low	Low
Guhlmann (1998)[58]	Unclear. Not stated if the sample was consecutive and exclusion criteria not reported	Low	Low	Low for 18F-FDG-PET. High for scintigraphy, owing to exclusion of significant number of inconclusive results (14, of which nine were confirmed positive and five were confirmed negative)
Guhlmann (1998)[59]	Unclear. Unclear if consecutive and no reporting of exclusion criteria	Low	Low	Low
Hakim (2006)[60]	Unclear. Unclear if patients were enrolled consecutively and limited information on selection criteria	Unclear. Unclear if PET and SPECT results were interpreted independently and blinded	Low	Low. Only 4/34 (11.8%) did not have a biopsy
Hartmann (2007)[61]	Unclear. Unclear if consecutively enrolled	Low	Low	Low
Hazenberg (2011)[62]	Unclear (conference abstract, insufficient detail). Unclear because of question 1	Unclear (conference abstract, insufficient detail)	Low	Low (based on limited data from the conference abstract)
Heiba (2017)[63]	Unclear. Not sure why the diagnosis was not included in some patients' records	Low	Low	Low. A total of 12/33 had clinical follow-up only but most were confirmed negative
Horger (2003)[64]	Unclear. Unclear if consecutive with no inappropriate exclusions	High. It appears that interpretation of scintigraphy + SPECT and SPECT/CT were not done blinded	Low	Low. Although 9/29 sites had 6 months' follow-up and no biopsy
Horger (2007)[65]	Low	High. No blinding to results of various index tests	Low. Although 15/31 had surgery/biopsy and 16/31 had clinical, microbiology and/or radiography follow-up	Low. Although 15/31 had surgery/biopsy and 16/31 had clinical, microbiology and/or radiography follow-up, and it is unclear if all confirmed positive (nine) had a biopsy

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Huang (1998)[66]	Low	Low	Low	Low. A total of 10/42 (23.8%, five confirmed positive and five confirmed negative) patients had clinical follow-up only (6 months to 3 years)
Johnson (2009)[67]	Unclear. 'Repeated examinations of the same patient were excluded from the study, as were examinations of patients who had insufficient clinical follow-up to establish the presence or absence of OM.' Unclear how many patients were excluded. Patients with repeated examinations may have been harder to diagnose	Low	Low	Low. Although negative cases confirmed by clinical follow-up (duration unknown) in 85% of cases. Positive cases confirmed by histopathology in 90% of cases
Kaim (2000)[68]	Unclear. Unclear if consecutive	Low	Low. Although 5/18 only had clinical follow-up (> 16 months)	Low. Although 5/18 only had clinical follow-up (> 16 months)
Kim (2017)[69]	Low. Although limited to those who had both scans within 1 week	Low	Low. Nine cases of surgery/histopathology, 12 cases of clinical follow-up, but all positive cases confirmed by bone biopsy	Low. Nine cases of surgery/histopathology, 12 cases of clinical follow-up, but all positive cases confirmed by bone biopsy
La Fontaine (2016)[70]	Unclear. Retrospective chart review, unclear if all eligible patients were included	Low	Low	Low
Larcos (1991)[71]	Unclear. Unclear if consecutive recruitment	Unclear. Unclear if index test results were interpreted blinded to each of the other index tests	Low. It appears that all positives and a significant proportion of negatives were confirmed by histopathology	Low. It appears that all positives and a significant proportion of negatives were confirmed by histopathology
Larson (2011)[72]	Unclear	Unclear. Unclear if index tests were interpreted blinded to one another	Low	Low. Sensitivity and specificity were reported, although the final number of confirmed positive/negative cases were not provided, therefore the 2 × 2 results could not be calculated

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Ledermann (2000)[73]	Low. Although high rate of patients with metal artefacts (11/15) and only included those with a possible relapse of infection in chronic post-traumatic OM	Unclear. Owing to lack of information on blinding to CT results	Low. Final diagnosis was established in 11 patients by intraoperative microbiological and histological examination, although potentially less accurate for clinical follow-up in 4/15 patients	Low. Most (11/15) confirmed by microbiology/histopathology
Levine (1994)[74]	Unclear. Unclear if patients were enrolled consecutively and why there were significant discrepancies in the number of patients receiving each of the four index tests	Unclear. Owing to lack of information on blinding to reference standard and other index test results	Low. Although most confirmed negative patients did not have histopathology (11/16)	Low. Although 9/36 patients were excluded owing to 'no surgical or histological confirmation within 2 weeks of MRI or failure to resolve with nonoperative management'
Lewis (1988)[75]	Unclear. Unclear if the sample was consecutively recruited; selection criteria were not reported	Unclear. Owing to insufficient details on blinding of staff performing index tests	Low	Low. Although nine (14.8%) excluded owing to 'failure to separately examine the bony portion of a pressure sore specimen or misrouting of specimens to microbiology or gematology laboratories'
Lipman (1998)[76]	Low	Low	Low	Unclear. Unclear how many received radiography and scintigraphy
Mahendra (2017)[77]	Low	Low	Low	Low
Malcius (2009)[78]	Unclear. Unclear if consecutively selected. Exclusions or reasons for exclusions were NR	High. Not all patients had the same tests and all results were considered together: scintigraphy performed if unclear diagnosis based on early radiography and/or ultrasound, and MRI/CT performed if unclear diagnosis based on scintigraphy	Unclear. Number receiving histology/microbiology vs. clinical follow-up unknown. Uncertainty about blinding of reference standard assessors to index test results	Unclear. Number receiving histology/microbiology vs. clinical follow-up unknown
Mason (1989)[79]	Low. Authors suggested that there was a selection bias because only patients considered likely to need surgery were studied. Such patients are probably more likely to have infection, although they may not be easier to diagnose	Unclear. Owing to uncertainty about blinding between index tests	Low	Low

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
McCarthy (2017)[80]	High. 'Patients were excluded if they did not have a preoperative MRI, if they did not have intraoperative bone culture data, or if they underwent debridement only without reconstruction'	Low	Low	Low. Only a small proportion of participants (indeterminate results, 8.5%) were excluded from analyses
Meller (2002)[81]	Low	Low	Low. 9/11 positive locations were confirmed by histology or culture. 10/25 negative locations were confirmed negative by histology or culture. Other locations were diagnosed by MRI ($n = 15$) or clinical follow-up ($n = 2$)	Low. 9/11 positive locations were confirmed by histology or culture. 10/25 negative locations were confirmed negative by histology or culture. Other locations were diagnosed by MRI ($n = 15$) or clinical follow-up ($n = 2$)
Miki (2015)[82]	Unclear. Retrospective study, only patients with surgery. Unclear if all eligible patients were recruited	Unclear. No information on blinding to reference standard results	Low	Low
Modic (1985)[83]	Unclear. Unclear if consecutively recruited and limited reporting of selection criteria	High. Owing to lack of blinding to other index tests	Low. Although 14/37 appeared to have not undergone biopsy. Clinical follow-up ranged from 6 weeks to 15 months and included antibiotics use	Low. Although 14/37 appeared to have not undergone biopsy. Clinical follow-up ranged from 6 weeks to 15 months and included antibiotics use
Morales Lozano (2010)[84]	Unclear. Unclear if selection was consecutive	Unclear. No evidence that interpretation of results of index tests were blinded to each other	Low	Low
Morrison (1993)[85]	Unclear. Unclear if consecutively recruited, limited reporting of selection criteria	Unclear. Owing to lack of information on blinding between index test assessments	Low	Low. Although small risk of verification bias (16.3% of patients did not receive histopathology), and it was not clear when histopathology was performed
Morrison (1998)[86]	Unclear. Unclear if significant number of participants were excluded because of lack of participants with no confirmed diagnosis	Low	Low. 34 were confirmed positive by biopsy, although nine confirmed positive with clinical follow-up including blood cultures, and 30 confirmed negative by clinical follow-up (rapid improvement after conservative management)	Low. 34 were confirmed positive by biopsy, although nine confirmed positive with clinical follow-up including blood cultures, and 30 confirmed negative by clinical follow-up (rapid improvement after conservative management)

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Nath (1992)[87]	Unclear. Unclear whether or not the patients were recruited consecutively and because of limited reporting of selection criteria	Unclear. Unclear blinding to reference standard and between index tests	Low. Although unclear if all samples were taken from fluid from the bone itself	Low. Only three had clinical follow-up only
Nawaz (2010)[88]	Low	Unclear. Unclear if staff were blinded to the results of each of the three index tests performed	Low	Low. Although 33.6% of all patients received histopathology. Most patients with final negative diagnosis (94.5%) were confirmed by clinical examination only. Most (85.2%) with final positive diagnoses were confirmed by histopathology
Newman (1991)[89]	Low	Unclear. Radiography and scintigraphy were interpreted in a blinded fashion, but it is unclear if interpretation of each of the two scintigraphy methods was performed blinded. Bone scans were performed after WBC scans	Low	Low. Although between 35 and 39 out of 41 eligible ulcers were included in the analyses across the different index tests. Reasons for exclusion were not reported
Newman (1992)[90]	Unclear. Unclear why only 12 of 23 patients were included. The scintigraphy data are a subset of Newman 1991[89]	Low	Low	Low
Nigro (1992)[91]	Low. Unclear if selection was consecutive, although it appears that all eligible patients were included	High. Readers were not blinded to the results of the other index tests	Unclear. Duration of clinical follow-up for 13/47 examinations (of which 11 were confirmed negative) was not reported	Low. Although 13/47 had only clinical follow-up of unknown duration, including around 50% (11/21 for MRI) of confirmed negative cases
Park (1982)[92]	High. Only diabetic patients who had radiographs, three-phase bone scans, and histological confirmation of the diagnosis, and surgery < 4 weeks after scan	Low	Low	Low. Although three patients with absent flow were excluded from the analysis for scintigraphy
Rastogi (2016)[93]	Low	Unclear. It is unclear if the results of each of the two index tests were interpreted blinded and independently	Low. Although some concerns about the accuracy of Jamshidi needle biopsy	Low. Reasons for exclusion appeared appropriate

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Remedios (1998)[94]	Unclear. Unclear if consecutively recruited	Low. The comparison of the two scintigraphy tests may have biased the scintigraphy assessment, although the actual comparison between MRI and scintigraphy was blinded	Low. All four positive cases were confirmed by biopsy, although four patients were confirmed negative by clinical follow-up only, and one confirmed negative by biopsy	Low. All four positive cases were confirmed by biopsy, although four patients were confirmed negative by clinical follow-up only, and one confirmed negative by biopsy
Rozzanigo (2009)[95]	Unclear. Retrospective study, unlikely to be consecutive. Limited reporting of selection criteria	High. Radiography performed before MRI to inform conduct of MRI (although the study was primarily designed to evaluate MRI, not to compare radiography with MRI)	Unclear. Diagnostic method and duration of follow-up unknown for confirmation of 5/16	Unclear. Diagnostic method and duration of follow-up unknown for confirmation of 5/16
Şanlı (2011)[96]	Low	Low	Unclear. Unclear how many received histopathology or microbiology: histopathology, or microbiology or observation at surgery, or ≥ 1 year follow-up. Unclear if reference standard interpretation was blinded to index test results	Unclear. Unclear how many received histopathology or microbiology; histopathology, or microbiology or observation at surgery, or ≥ 1-year follow-up
Sarikaya (2003)[97]	Unclear. Unclear if consecutively recruited	Low. For radiography: interpreted blinded to scintigraphy results. High. Owing to lack of blinding between MDP and scintigraphy	Low. Culture with/without histology conducted in 36/55 lesions. Histology and culture conducted in all positive cases. Clinical follow-up only (minimum 4 months) conducted in 19/55	Low. Although clinical follow-up only (minimum 4 months) conducted in 19/55 lesions. 26/55 received culture with/without histology. All positive cases were confirmed by histology
Schlung (2016)[98]	Unclear. Retrospective selection of subgroup of patients with MRI findings	Low	Low	Low
Schwegler (2008)[99]	Low	Low	Low. Although all 13/20 negative cases were confirmed by clinical 2-year follow-up only	Low. Although all 13/20 negative cases were confirmed by clinical 2-year follow-up only
Seabold (1990)[100]	Unclear. Unclear if consecutively recruited patients and limited details about selection criteria	Low. Results of scintigraphy and MRI blinded, although MRI was interpreted in conjunction with radiography	Low	Unclear. Only 7/14 participants were included for the analysis of MRI accuracy, with reasons NR

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Seabold (1995)[101]	Unclear. Retrospective study, insufficient detail on selection	Low	Low	High. Equivocal test results were excluded from analyses (two for SPECT and six for CT in the initial test phase) and MRI was only conducted and analysed in 11 out of 25 patients
Segall (1989)[102]	High. Only those who had histology result within 3 weeks of scan: 83 patients had three-phase bone scan, of whom 23 met the final inclusion criteria. Risk of systematic differences between included and excluded participants	Low	Low	Low
Shemesh (2015)[103]	Unclear. Retrospective study, limited reporting of selection process	Low	Low	Low
Unger (1988)[104]	Low	Low	Unclear. 14/35 (40%) only had clinical follow-up, and it is not clear if any of the patients with surgery had histology/microbiology	Unclear. 14/35 (40%) only had clinical follow-up, and it is not clear if any of the patients with surgery had histology/microbiology
van Vliet (2018)[105]	Low, although retrospective	Unclear. Unclear if multiple diagnostic cut-off points were prespecified	Low. Although 1-year follow-up only was used in some (7/30, including three confirmed positive)	Low
Weber (1995)[106]	Unclear. Retrospective and limited reporting of selection criteria	Low	Low	Low. Despite some limitations (exclusion of three patients, two patients with no culture/histology)
Weinstein (1993)[107]	Low	Low	Low	High. 15 patients with no histology and clinical follow-up only were excluded from the analyses
Wenter (2016)[108]	Unclear	Low for qualitative results High for quantitative test results, owing to post hoc choice of optimal cut-off point based on ROC analysis from the study population	Low	Low
Weon (2000)[109]	Low	Low	Low. Although duration of clinical follow-up was not reported in patients who did not have histology/microbiology (11/37)	Low. Although most confirmed negative patients (10/13) only received clinical follow-up. Duration and criteria for clinical follow-up were not reported

TABLE 16 The QUADAS-2 risk-of-bias decisions (*continued*)

First author and year of publication	Could the selection of patients have introduced bias?	Could the conduct or interpretation of the index test have introduced bias?	Could the reference standard, its conduct or its interpretation have introduced bias?	Could the patient flow have introduced bias?
Williamson (1989)[110]	Unclear. Only small number of patients with recent radiography and scintigraphy	Unclear. No evidence of blinding between index tests and with reference standard. Plausible that the CT results were not interpreted blinded to radiography and scintigraphy	Low. Although only clinical follow-up was used for patients with negative CT (3/7)	Low. Although only clinical follow-up was used for patients with negative CT (3/7)
Yang (2016)[111]	Low	Low	High. Unlikely that clinical follow-up (reference standard for 22/48 patients) was done blinded to PET test results. Concerns about the reliability of follow-up as the reference standard: patients were considered OM positive if resolution of symptoms was observed after systematic antibiotic treatment	High. Clinical follow-up was the reference standard for 22/48 (45.8%). Patients were considered OM positive if resolution of symptoms was observed after systematic antibiotic treatment
Yuh (1989)[112]	Low	Low	Low. Nearly all positive cases were confirmed by histopathology. 14/24 patients had histopathology. However, 10 had clinical follow-up only (unknown duration), and it is unclear if reference standard (including follow-up) was performed blinded to index test results	Low. Nearly all positive cases were confirmed by histopathology. 14/24 patients had histopathology. However, 10 had clinical follow-up only (unknown duration)
Zaiton (2014)[113]	Low	Low	Low	Low

NR, not reported; OM, osteomyelitis.

TABLE 17 The QUADAS-2 applicability decisions

First author and year of publication	Are there concerns that the included patients and setting do not match the review question?	Are there concerns that the index test, its conduct or interpretation differ from the review question?	Are there concerns that the target condition as defined by the reference standard does not match the review question?
Abdel Razek (2017)[37]	Low	Low	Low
Al-Khawari (2005)[38]	Low	Low	Low
Al-Sheikh (1985)[39]	Low	Low	Low
Aragón-Sánchez (2011)[40]	Low. Note: diabetic foot referral centre, high prevalence of OM	Low	Low
Aslangul (2013)[41]	Low	Low	Low
Blume (1997)[42]	Low	Low	Low
Bohchelian (2002)[43]	Low	Low	Low
Bolouri (2013)[44]	Low	Low	Low
Brunel (2016)[45]	Low. Although extrapolation to patients with no spinal chord injury may be limited	Low	Low
Chacko (2003)[46]	Low	Low	Low
Croll (1996)[47]	Low	Low	Low
Demirev (2014)[48]	Low	Low	Low
Enderle (1999)[49]	Low	Low	Low
Erdman (1991)[50]	Low	Low	Low
Ertugrul (2006)[51]	Low	Low	Low
Ezzat (2011)[52]	Low. Although excluded patients with 'presence of any chronic disease with signs and symptoms similar to acute OM'	Low	Low
Familiari (2011)[53]	Low	Low	Low
Filippi (2006)[54]	Low	Low	Low
Filippi (2009)[55]	Low	Low	Low
Franceschi (2013)[56]	Unclear. Conference abstract, insufficient information about participants	Low	Low
Gemmel (2004)[57]	Unclear	Low	Low
Guhlmann (1998)[58]	Low	Low	Low
Guhlmann (1998)[59]	Low	Low	Low
Hakim (2006)[60]	Low	Low	Low
Hartmann (2007)[61]	Low	Low	Low
Hazenberg (2011)[62]	Low	Low	Low
Heiba(2017)[63]	Low	Low	Low
Horger (2003)[64]	Low	Low	Low
Horger (2007)[65]	Low	Low	Low
Huang (1998)[66]	Low	Low	Low
Johnson (2009)[67]	Low	Low	Low

TABLE 17 The QUADAS-2 applicability decisions (*continued*)

First author and year of publication	Are there concerns that the included patients and setting do not match the review question?	Are there concerns that the index test, its conduct or interpretation differ from the review question?	Are there concerns that the target condition as defined by the reference standard does not match the review question?
Kaim (2000)[68]	Low. Although highly selected patient population: only long-standing, post-traumatic OM with suspected recurrent OM	Low	Low
Kim (2017)[69]	Low	Low	Low
La Fontaine (2016)[70]	Low	Low	Low
Larcos (1991)[71]	Low	Low	Low
Larson (2011)[72]	Unclear. Only some may have been referred for suspected OM (numbers unknown)	Low	Low
Ledermann (2000)[73]	Low. No significant concerns, although high proportion of patients with metal artefacts (11/15) and highly selected patient group. Only included those with a possible relapse of infection in chronic post-traumatic OM	Unclear. MRIs performed in a high proportion of patients with metal artefacts (11/15). Of these 11, four rated as 'metal artefact renders film interpretation considerably more difficult; two rated as 'metal artefact impairs complete evaluation of film because of major obscuring artefacts'	Low
Levine (1994)[74]	Low. Although limited reporting of patient characteristics	Low	Low
Lewis (1988)[75]	Unclear. Selection criteria and participant characteristics NR	Low	Low
Lipman (1998)[76]	Low	Low	Low
Mahendra (2017)[77]	Low	Unclear. No reporting on use of antimicrobials before MRI	Low
Malcius (2009)[78]	Low	Low	Low
Mason (1989)[79]	Low	Low	Low
McCarthy (2017)[80]	Low	Low	Low
Meller (2002)[81]	Low	Low	Low
Miki (2015)[82]	Low	Low	Low
Modic (1985)[83]	Unclear	Low	Low
Morales Lozano (2010)[84]	Low. Although high prevalence of OM (79.5%)	Low	Low
Morrison (1993)[85]	Low. All suspected OM	Low	Low
Morrison (1998)[86]	Low	Low	Low
Nath (1992)[87]	Low	Low	Low
Nawaz (2010)[88]	Low	Low	Low
Newman (1991)[89]	Low	Low	Low
Newman (1992)[90]	Low	Low	Low

TABLE 17 The QUADAS-2 applicability decisions (*continued*)

First author and year of publication	Are there concerns that the included patients and setting do not match the review question?	Are there concerns that the index test, its conduct or interpretation differ from the review question?	Are there concerns that the target condition as defined by the reference standard does not match the review question?
Nigro (1992)[91]	Low	Low	Low
Park (1982)[92]	Low	Low	Low
Rastogi (2016)[93]	Low	Low	Low
Remedios (1998)[94]	Low	Low	Low
Rozzanigo (2009)[95]	Low	Low	Low
Şanlı (2011)[96]	Low	Low	Low
Sarikaya (2003)[97]	Low. Patients with initial normal bone scan were excluded	Low	Low
Schlung (2016)[98]	Low	Low	Low
Schwegler (2008)[99]	Low	Low	Low
Seabold (1990)[100]	Low	Low	Low
Seabold (1995)[101]	Unclear. Retrospective study, insufficient detail on selection	Low	Low
Segall (1989)[102]	Low	Low	Low
Shemesh (2015)[103]	Low	Low	Low
Unger (1988)[104]	Low	Low	Low
van Vliet (2018)[105]	Low. Although only for differentiation between aseptic and septic delayed union in lower extremity	Low	Low
Weber (1995)[106]	Low. Although combines preoperative and follow-up scans	Low	Low
Weinstein (1993)[107]	Low	Low	Low
Wenter (2016)[108]	Low	Low	Low
Weon (2000)[109]	Low	Low	Low
Williamson (1989)[110]	Low	Low	Low
Yang (2016)[111]	Low	Low	Low
Yuh (1989)[112]	Low	Low	Low
Zaiton (2014)[113]	Low. Plain radiography (no radiological changes suggesting OM), patients scheduled for surgical management	Low	Low

NR, not reported; OM, osteomyelitis.

Appendix 3 Participant selection criteria in diagnostic accuracy studies

TABLE 18 Participant selection criteria in diagnostic accuracy studies

First author and year of publication	Criteria	
	Inclusion	**Exclusion**
Abdel Razek (2017)[37]	Suspected acute diabetic foot OM	Previous foot surgical intervention
Al-Khawari (2005)[38]	Suspected ankle and/or foot infection	NR
Al-Sheikh (1985)[39]	Suspected bone infection	NR
Aragón-Sánchez (2011)[40]	Diabetic foot infection	Toe necrosis caused by critical ischaemia
Aslangul (2013)[41]	Chronic foot ulcer with over bony prominence, relapsing infection, or slow healing despite adequate blood flow and care	Received systemic antibiotic in past 14 days or requiring surgery
Blume (1997)[42]	Pre-existing pedal abnormalities and clinical suspicion of OM	NR
Bohchelian (2002)[43]	Diabetic foot ulcer	NR
Bolouri (2013)[44]	High suspicion of OM of the jaw	NR
Brunel (2016)[45]	Pressure ulcer (stage III/IV) with unfavourable evolution despite optimal management, referred for surgical debridement	Antibiotics within 2 weeks before biopsies, or no biopsy
Chacko (2003)[46]	Soft tissue infection overlying bone, including decubitus ulcers, cellulitis or foot ulcer (87.5%), and recent surgery (41.1%)	NR
Croll (1996)[47]	Admitted with diabetic foot infection	Obvious gangrene or a fetid foot requiring immediate surgery
Demirev (2014)[48]	All consecutive patients who underwent ^{18}F-FDG-PET/CT as well as MRI scanning for diagnosis of OM. Referred because of inconclusive previous evaluations test (including radiography), or inconclusive standard radiography and CT, or to identify location and expansion of infection before surgery	NR
Enderle (1999)[49]	Patients with type 2 diabetes only, suspected of chronic OM with a foot lesion $\geq$ grade 2 in accordance with the classification of Wagner (Wagner[173]). Impaired wound healing, despite pathogenesis-adapted therapy for > 4 weeks	Patients with acute infection
Erdman (1991)[50]	Suspected acute or chronic OM, with clinical follow-up or histopathologic data	Motion artefact or metallic artefact
Ertugrul (2006)[51]	Suspected diabetic foot lesion with Wagner grade of $\geq$ 3 ulcer	NR
Ezzat (2011)[52]	Children with clinical suspicion of AOM, negative or equivocal conventional plain radiography and presenting within 2 weeks of symptoms onset	COM, 'presence of any chronic disease with signs and symptoms similar to acute OM'

TABLE 18 Participant selection criteria in diagnostic accuracy studies (*continued*)

First author and year of publication	Criteria	
	Inclusion	**Exclusion**
Familiari (2011)[53]	High clinical suspicion of foot OM based on the presence of signs and symptoms of infection (exposed bone, $n = 7$)	NR
Filippi (2006)[54]	Suspected OM	NR
Filippi (2009)[55]	Diabetes, foot lesions, abnormal laboratory tests and clinical signs of infection	NR
Franceschi (2013)[56]	Chronic diabetic foot infection	NR
Gemmel (2004)[57]	Suspected spinal infection after previous spinal surgery with a final diagnosis based on microbiology and/or intraoperative findings of macroscopic pus	Recently undergone surgery (no patients with interval of < 2 months were included)
Guhlmann (1998)[58]	Recurrent OM or symptoms of OM for > 6 weeks. Trauma or surgery dating back at least 2 years	NR
Guhlmann (1998)[59]	Suspected COM with symptoms of infection lasting > 6 weeks or presence of recurrent OM	NR
Hakim (2006)[60]	Provisional chronic suppurative OM diagnosis referred for scintigraphy, with no previous COM diagnosis	NR
Hartmann (2007)[61]	Suspected COM with symptoms of infection lasting > 6 weeks or presence of recurrent OM, with histopathology or microbiology results	Trauma or surgical intervention on affected bone during the 6 months prior to the PET/CT examination
Hazenberg (2011)[62]	Persistent OM despite antibiotics therapy	Peripheral arterial disease
Heiba (2017)[63]	Clinically suspected OM	No SPEC/CT data or definitive diagnosis
Horger (2003)[64]	Suspected reactivated post-traumatic COM	NR
Horger (2007)[65]	Clinical suspicion of acute or chronic OM	NR
Huang (1998)[66]	Paralysed with clinically suspected acute OM of the pelvis/hip, equivocal radiography	NR
Johnson (2009)[67]	MRI of the foot for evaluation of suspected OM	Repeated examinations of the same patient, insufficient clinical follow-up for OM diagnosis
Kaim (2000)[68]	Suspected relapse of bone infection in leg, recurrent OM	Patients with orthopaedic devices (although three with metal artefacts were included)
Kim (2017)[69]	Suspected OM and patients for whom time interval between the two index tests was < 1 week	NR
La Fontaine (2016)[70]	Received either MRI or SPECT-CT and a biopsy within 8 weeks for suspected diabetic foot OM	NR
Larcos (1991)[71]	Suspected pedal OM, with final diagnosis proved by surgery or clinical follow-up	Patients with multisystem disorders and inadequate documentation for the foot
Larson (2011)[72]	Stage IV pressure ulcers undergoing surgical debridement with intraoperative bone culture and prior radiography. Only some may have been referred for suspected OM	Those without surgical debridement, or treated but lacking bone culture and/or radiography were excluded
Ledermann (2000)[73]	Suspected relapse of infection in chronic (at least 1.5 years) post-traumatic OM of lower extremities with complete MRI examination on admission	NR

TABLE 18 Participant selection criteria in diagnostic accuracy studies (*continued*)

First author and year of publication	Criteria	
	Inclusion	**Exclusion**
Levine (1994)[74]	Suspected OM because of diabetic foot ulcer	'No surgical or histological confirmation within 2 weeks of MRI or failure to resolve with non-operative management'
Lewis (1988)[75]	Spinal cord injury patients with pressure sores	NR
Lipman (1998)[76]	Peripheral neuropathy, high clinical suspicion of OM	NR
Mahendra (2017)[77]	Diabetic foot ulcer	'Previously operated cases with persistent ulcer'
Malcius (2009)[78]	Pain in bone area, fever, functional disorder, and/or signs of infection. Scintigraphy performed if unclear diagnosis based on early radiography and/or ultrasound, and MRI/CT performed if unclear diagnosis based on scintigraphy	NR
Mason (1989)[79]	Clinical history of suspected bone infection, soft tissue infection, or both; a completed MR imaging study; prior trauma, surgery, or both; and documented operative, pathologic, microbiologic and clinical follow-up	Incomplete MRI examination, MRI after resection, lack of follow-up data
McCarthy (2017)[80]	Surgical reconstruction of pressure ulcer with preoperative MRI and intraoperative bone cultures	No MRI, no intraoperative culture data, debridement only without reconstruction
Meller (2002)[81]	Non-diabetic, suspected COM based on positive scintigraphy	NR
Miki (2015)[82]	Diabetic foot ulcer, undergone surgery and histopathology, type 2 diabetes	NR
Modic (1985)[83]	Strong suspicion of vertebral OM based on symptoms, laboratory abnormalities, abnormal or suspicious radiographic assessment and predisposing factors	NR
Morales Lozano (2010)[84]	Diabetic patients with infected foot ulcer attending a diabetic foot clinic with suspicion of OM based on ulcer specimen culture, radiography and probe-to-bone test. Single ulcer (neuropathic or neuroischemic), previous surgery for OM or unresolved ulcer following local or antibiotic treatment	Critical ischaemia or due for an operation unrelated to OM
Morrison (1993)[85]	Suspected OM	NR
Morrison (1998)[86]	Suspected foot OM with minimum 6 weeks' follow-up	NR
Nath (1992)[87]	Pain and swelling of the affected limb, suspected OM	NR
Nawaz (2010)[88]	Diabetic foot disease and/or diabetes with suspected deep-seated infection(s) of the lower extremity(or extremities). Serum glucose levels of < 200 mg/dl	NR
Newman (1991)[89]	Diabetic foot ulcer, inpatients and outpatients	Myocardial infarction, severe peripheral vascular disease, ongoing antibiotic treatment of > 7 days or patient declined to participate

TABLE 18 Participant selection criteria in diagnostic accuracy studies (*continued*)

First author and year of publication	Criteria	
	Inclusion	**Exclusion**
Newman (1992)[90]	Clinical suspicion of OM by referring physician	Myocardial infarction, severe peripheral vascular disease, ongoing antibiotic treatment for > 7 days or patient declined to participate
Nigro (1992)[91]	Patients with foot inflammation and possible OM referred for MRI	NR
Park (1982)[92]	Diabetic patients who had radiographs, three-phase bone scans, and histological confirmation of the diagnosis	Surgical procedure performed more than 4 weeks after the bone scan
Rastogi (2016)[93]	Diabetic Charcot neuroarthropathy, suspected diabetic foot OM, foot ulcer or discharging sinus	Unfit for PET/CT or MRI, previous antibiotic treatment for foot infections for > 72 hours, peripheral vascular disease
Remedios (1998)[94]	Peripheral neuropathy chronic foot ulcers and clinical signs of OM	NR
Rozzanigo (2009)[95]	Infected ulcer affecting the forefoot/midfoot/hindfoot	NR
Şanlı (2011)[96]	Suspected bone or orthopaedic implant infection based on clinical signs	NR
Sarikaya (2003)[97]	Clinically suspected OM, diabetes, non-healing ulcers or gangrene	Normal scintigraphy, antibiotics within 1 week of imaging and culture
Schlung (2016)[98]	Septic hip (presumed likely or confirmed) with joint aspirate or culture data following treatment with irrigation and debridement and antibiotics who underwent preoperative MRI	No septic hip (presumed or confirmed) with joint aspirate or culture data, no preoperative MRI
Schwegler (2008)[99]	Diabetes, non-healing chronic foot ulcer for at least 8 weeks; absence of antibiotic pretreatment and of clinical signs or symptoms of local or systemic infection	Clinical signs of local infection, antibiotic treatment at time of PET or within 1 month
Seabold (1990)[100]	High clinical suspicion of OM in or around neuropathic joint(s)	NR
Seabold (1995)[101]	Suspected cranial OM undergoing diagnostic imaging	NR
Segall (1989)[102]	Histological test for OM within 3 weeks of bone scan	NR
Shemesh (2015)[103]	Cases suspected of deep infection following osteosynthesis for fractures of the tibia, treated surgically and had preoperative PET/CT scan	NR
Unger (1988)[104]	Clinical suspicion of acute OM	NR
van Vliet (2018)[105]	Underwent 18F-FDG-PET/CT at level 1 trauma centre between March 2010 to October 2014	Surgery within 3 months of PET/CT
Weber (1995)[106]	Clinically suspicious postoperative initial persistent or recurrent OM	NR
Weinstein (1993)[107]	Clinical suspicion of OM, non-healing foot ulcer or soft tissue infection of the foot	NR
Wenter (2016)[108]	Suspected chronic OM treated in major trauma centre. Pain, absence of clear clinical or laboratory markers for acute local infection, non-conclusive radiography and MRI	NR

TABLE 18 Participant selection criteria in diagnostic accuracy studies (*continued*)

First author and year of publication	Criteria	
	Inclusion	**Exclusion**
Weon (2000)[109]	Suspected OM	NR
Williamson (1989)[110]	Suspected OM based on radiography	NR
Yang (2016)[111]	Suspected diabetic foot OM, consecutively included	NR
Yuh (1989)[112]	Diabetes with clinical suspicion of OM and/or non-healing foot ulcers	NR
Zaiton (2014)[113]	Foot ulcers with sign of infection, normal radiography with no sign of OM, scheduled for surgical management	Recurrent or long-standing OM with evident radiographic changes, ischaemic foot ulcers, minor abrasion or laceration, presence of contraindication to surgery or MRI examination

NR, not reported; OM, osteomyelitis.

Appendix 4 Results of diagnostic meta-analyses

TABLE 19 Summary of diagnostic accuracy studies

First author and year of publication	Population	Cause	Diagnostic tests used
Al-Khawari (2005)[38]	Adults	Diabetic foot ulcers	MRI
Al-Sheikh (1985)[39]	Adults	NR	Scintigraphy and radiography
Aragón-Sánchez (2011)[40]	Adults	Diabetic foot ulcers	Radiography
Aslangul (2013)[41]	Adults	Diabetic foot ulcers	SPECT/CT
Blume (1997)[42]	Adults	Diabetic foot ulcers	Scintigraphy and radiography
Bolouri (2013)[44]	Mixed	Multiple	CT, scintigraphy, SPECT/CT and radiography
Brunel (2016)[45]	Adults	Pressure ulcers	MRI
Chacko (2003)[46]	NR	Multiple	PET
Croll (1996)[47]	Adults	Diabetic foot ulcers	MRI, scintigraphy and radiography
Demirev (2014)[48]	Adults	Multiple	MRI and PET-CT
Enderle (1999)[49]	Adults	Diabetic foot ulcers	MRI, scintigraphy, ultrasound and radiography
Erdman (1991)[50]	Mixed	Multiple	MRI
Ertugrul (2006)[51]	NR	Diabetic foot ulcers	MRI and scintigraphy
Familiari (2011)[53]	Adults	Diabetic foot ulcers	PET-CT and scintigraphy
Filippi (2006)[54]	Adults	Multiple	SPECT/CT
Filippi (2009)[55]	Adults	Diabetic foot ulcers	SPECT/CT
Franceschi (2013)[56]	Adults	Diabetic foot ulcers	PET-CT
Gemmel (2004)[57]	Mixed	Surgical	Scintigraphy and SPECT
Guhlmann (1998)[58]	Adults	Trauma or surgery	PET and scintigraphy
Guhlmann (1998)[59]	Adults	Trauma or surgery	PET
Hakim (2006)[60]	Adults	Dental infection, trauma, others	PET and SPECT
Hartmann (2007)[61]	Adults	Trauma	PET-CT
Hazenberg (2011)[62]	NR	Diabetic foot ulcers	MRI
Heiba (2017)[63]	Adults	NR	Scintigraphy and SPECT/CT
Horger (2003)[64]	Adults	Trauma	SPECT/CT
Horger (2007)[65]	Adults	Multiple	SPECT/CT ($n = 15$), MRI ($n = 6$) and radiography ($n = 20$)
Huang (1998)[66]	Adults	Skin ulceration	MRI
Johnson (2009)[67]	Adults	Diabetes, other	MRI
Kaim (2000)[68]	Adults	Trauma	MRI and scintigraphy
La Fontaine (2016)[70]	Adults	Diabetic foot ulcers	MRI and SPECT/CT
Larcos (1991)[71]	Adults	Diabetic foot ulcers	Scintigraphy and radiography
Ledermann (2000)[73]	Adults	Trauma	MRI
Levine (1994)[74]	Adults	Diabetic foot ulcers	MRI, scintigraphy and radiography

TABLE 19 Summary of diagnostic accuracy studies (*continued*)

| First author and year of publication	Population	Cause	Diagnostic tests used
Lewis (1988)[75]	Adults	Skin ulceration	CT, scintigraphy and radiography
Lipman (1998)[76]	Adults	Diabetes (85%), peripheral neuropathy (100%)	MRI
Mahendra (2017)[77]	Adults	Diabetic foot ulcers	MRI
Mason (1989)[79]	NR	Trauma (93%), other (7%)	MRI and scintigraphy
McCarthy (2017)[80]	Adults	Skin ulceration	MRI
Meller (2002)[81]	Adults	Multiple	PET and scintigraphy
Miki (2015)[82]	Adults	Diabetic foot ulcers	MRI
Modic (1985)[83]	Adults	Multiple	MRI, scintigraphy (and SPECT $n = 5$) and radiography
Morales Lozano (2010)[84]	NR	Diabetic foot ulcers	Radiography
Morrison (1993)[85]	Mixed	Multiple	MRI
Morrison (1998)[86]	Adults	Diabetes (85%), others (15%)	MRI
Nath (1992)[87]	Mixed	NR	Ultrasound and radiography
Nawaz (2010)[88]	Adults	Diabetic foot ulcers	MRI, PET and radiography
Newman (1992)[90]	NR	Diabetic foot ulcers	Scintigraphy and radiography
Newman (1991)[89]	NR	Diabetic foot ulcers	MRI and scintigraphy
Nigro (1992)[91]	Adults	Diabetic foot ulcers, foot ulcers or inflammation	MRI, scintigraphy and radiography
Park (1982)[92]	NR	Diabetic foot ulcers	Scintigraphy and radiography
Rastogi (2016)[93]	Adults	Diabetic foot ulcers	MRI and PET-CT
Remedios (1998)[94]	Adults	Diabetic foot ulcers	MRI and scintigraphy
Rozzanigo (2009)[95]	Adults	Diabetic foot ulcers	MRI and radiography
Sarikaya (2003)[97]	Adults	Diabetic foot ulcers	Scintigraphy and radiography

TABLE 21 Summary of studies of scintigraphy

First author and year of publication	Number of participants	Type or cause of osteomyelitis	Isotope and scintigraphy type
Included in main meta-analysis			
Al-Sheikh (1985)[39]	22	Multiple	^{67}Ga
			^{99m}Tc-MDP
			^{99m}Tc-MDP/^{67}Ga
			^{111}In WBC
Blume (1997)[42]	27	Diabetic foot ulcers	^{99m}Tc-HMPAO WBC
			^{99m}Tc-MDP
Bolouri (2013)[44]	42	Jaw/head	^{99m}Tc-DPD
Croll (1996)[47]	22	Diabetic foot ulcers	^{99m}Tc-MDP
			^{111}In WBC
Enderle (1999)[49]	16	Diabetic foot ulcers	^{99m}Tc-MDP
Ertugrul (2006)[51]	26	Diabetic foot ulcers	^{99m}Tc-WBC and ^{99m}Tc-MDP
Familiari (2011)[53]	13	Diabetic foot ulcers	^{99m}Tc-HMPAO WBC
Gemmel (2004)[57]	22	Surgical in spine	^{99m}Tc-ciprofloxacin (Infection; Bayer plc, Newbury, UK)
Guhlmann (1998)[59]	37	Contiguous (multiple locations)	^{99m}Tc-AGAb/^{99m}Tc-MDP
Heiba (2017)[63]	33	Pelvis/hip	Not reported
Kaim (2000)[68]	19	Long bone trauma	^{99m}Tc-DPD/^{99m}Tc-Mab
Larcos (1991)[71]	49	Diabetic foot ulcers	^{99m}Tc-MDP
Larcos (1991)[71]	51	Diabetic foot ulcers	^{111}In WBC
Levine (1994)[74]	11	Not reported	^{99m}Tc-HMDP
			^{111}In WBC

TABLE 21 Summary of studies of scintigraphy (*continued*)

First author and year of publication	Number of participants	Type or cause of osteomyelitis	Isotope and scintigraphy type
Lewis (1988)[75]	52	Skin ulceration	99mTc-WBC
Mason (1989)[79]	11	Long bone trauma	111In WBC
Meller (2002)[81]	34	Multiple	111In WBC
Modic (1985)[83]	20	Multiple	67Ga
			99mTc-HMDP
Newman (1991)[89]	39	Diabetic foot ulcers	99mTc-MDP
			111In WBC
Newman (1992)[90]	16	Diabetic foot ulcers	111In WBC
Nigro (1992)[91]	39	Diabetic foot ulcers	99mTc-HMDP
Park (1982)[92]	36	Diabetic foot ulcers	99mTc-MDP
Remedios (1998)[94]	9	Diabetic foot ulcers	99mTc-NA
Sarikaya (2003)[97]	55	Diabetic foot ulcers	99mTc-MDP
			99mTc-dextran
