Research Report no. 379
Abstract

A new recursive prediction error routine is compared with the backpropagation method of training neural networks. Results based on simulated systems, the prediction of Canadian Lynx data, and the modelling of an automotive diesel engine indicate that the recursive prediction error algorithm is far superior to backpropagation.

1 Introduction

A neural network is a highly parallel dynamical system with the topology of a directed graph that can carry out information processing by means of its state response. Neural networks have been the subject of intense study by researchers from many diverse disciplines. Neurobiologists, psychobiologists and those who study the brain and memory are working to establish the ground rules of how the central nervous system actually works. Computer scientists and researchers in the cognitive sciences are pursuing the study of intelligence and the massively parallel distributed information processing done by biological systems. The engineering community are more involved in image processing, signal processing, optimisation and control problems. The most important factors in employing neural networks for any application include the choice of architecture for the network and appropriate learning algorithms. Various neural network models and learning algorithms have been reviewed by Lippmann(1987).

The present study investigates the use of neural networks to model nonlinear systems. Nonlinear systems can be modelled using the functional series description of Volterra and Wiener. Alternatively, a more concise representation for a wide class of nonlinear systems can be achieved by using Nonlinear AutoRegressive Moving Average models with eXogeneous inputs or NARMAX models (Leontaritis and Billings,1985). More recently neural networks have been considered as an alternative functional representation (Lapedes and Farber,1987,
Chen, Billings and Grant (1989). The use of neural networks in this context is supported by the results of Cybenko (1989) and Funahashi (1989) who have proved that any continuous function can be uniformly approximated by a neural network with only one internal layer.

The most popular and successful learning algorithm used to train multilayer neural networks in areas such as speech, natural language processing, pattern recognition and system modelling is currently the backpropagation routine (Sejnowski and Rosenberg, 1986, Allen, 1987, Lapedes and Farber, 1987, Rumelhart and McClelland, 1986). Backpropagation however is based on the steepest descent algorithm which is known to be an inefficient optimization procedure and Brady et al. (1989) and Sutton (1986) have recently reported additional problems with this method of training neural networks. In the present study a new recursive prediction error routine which was introduced by Chen, Billings and Grant (1989) and extended to work in parallel by Chen et al. (1989) is extensively tested and compared with the backpropagation routine. The influence of the momentum and the learning rate constants on the convergence of the backpropagation algorithm are studied and model validation methods are introduced as a measure of network performance. Convergence analysis of the recursive prediction error algorithm is discussed and the method is shown to be superior to the backpropagation routine. Simulated examples, the prediction of Canadian Lynx data and the identification of a model relating fuel rack position to engine speed of an automotive diesel engine are used to compare the two algorithms.

2 Nonlinear System Representation

Multilayered neural networks considered in the present study are feedforward networks. A multilayered neural network is made up of one or more hidden layers between the input and output layers. Each layer consists of computing units called nodes or neurons connected together in the structure of a
layered network as illustrated in Fig. 1. The functionality of the network is determined by specifying the strength of the connection paths called weights and the threshold parameter of each neuron.

The input layer usually acts as an input data holder and it distributes inputs to the first hidden layer. The inputs then propagate forward through the network and each neuron computes its output according to

$$x^k_i = g\left(\sum_{j=1}^{n_{k-1}} w^{k-1}_{ij} x^{k-1}_j + b^k_i\right)$$

for $i=1, \cdots, n_k$ and $k=1, \cdots, l$, where $x^k_i$ is the output of the $i$-th neuron in the $k$-th layer, $w^{k-1}_{ij}$ is the weight connection between the $j$-th neuron of the $(k-1)$-th layer and the $i$-th neuron of the $k$-th layer, and $b^k_i$ is the threshold of the $i$-th neuron in the $k$-th layer. As shown in Fig.1, the $l$-th layer is the output layer and the input layer may be labelled as layer zero. Thus $n_0$ and $n_l$ refer to the numbers of network inputs and outputs respectively. $x^0_i$ and $x^l_i$ will also be denoted as $x_i$ and $y_i$. The function $g(\cdot)$ is called the node activation function. The argument

$$z^k_i = \sum_{j=1}^{n_{k-1}} w^{k-1}_{ij} x^{k-1}_j + b^k_i$$

is therefore the activation for the $i$-th neuron in the $k$-th layer. The function $g(\cdot)$ is assumed to be differentiable and to have a strictly positive first derivative.

For the neurons in the hidden layers, the activation function is often chosen to be

$$g(z) = \frac{1}{1 + e^{-z}}$$

Since in system modelling applications the dynamic range of the output data may be greater than 1, the activation function of the output nodes is chosen to be linear. Thus the $i$-th output node performs a weighted sum of its inputs as follows

$$y_i = \sum_{j=1}^{n_{l-1}} w^{l-1}_{ij} x^{l-1}_j$$

Only networks with one hidden layer are considered in the present study.
because the results of Cybenko(1989) and Funahashi(1989) show that this is sufficient to approximate all continuous functions. Let $\Theta = [\theta_1 \cdots \theta_{n_\theta}]^T$ represent all the unknown weights and thresholds of the network. A network with a single layer of hidden units can then be defined by the model

$$\hat{y}(t, \Theta) = \sum_{j=1}^{n_1} w_{j}^{2} \varphi \left( \sum_{i=1}^{n_2} w_{i}^{2} \varphi \left( \sum_{k=1}^{n_0} w_{k}^{2} x_{k}(t) + b_{j} \right) + b_{j} \right) , \quad 1 \leq j \leq n_2$$  \hspace{1cm} (5)

where $x(t) = [x_{1}(t) \cdots x_{n_{0}}(t)]^T$ is the input vector to the network.

3 Learning Algorithms

Two learning algorithms are considered. The backpropagation algorithm is a gradient algorithm designed to minimize the mean square error between the actual output of the network and the desired output. The recursive version of this algorithm is discussed in the present study. The recursive prediction error or RPE algorithm is based on the class of unified recursive parameter estimation methods which minimize the prediction error over the model set using an approximation of the Gauss Newton search direction. Both approaches require differentiable nonlinearities, and the backpropagation algorithm can be viewed as a simplified version of the RPE algorithm.

3.1 Backpropagation Algorithm

The backpropagation algorithm has been described in Rumelhart and McClelland(1986). Define the energy function as

$$J = \frac{1}{2} \sum_{i}(y_i(t) - \hat{y}_i(t))^2$$  \hspace{1cm} (6)

where $y_i(t)$ is the $i$-th desired output. This energy function is to be minimized with respect to all the unknown parameters. In the steepest descent approach the parameter vector $\Theta$ is adjusted using the increment vector $[\Delta \theta_1 \ \Delta \theta_2 \ \cdots \ \Delta \theta_{n_\theta}]^T$ defined along the negative gradient direction of $J$

$$\Delta \theta_i = - \eta \frac{\partial J}{\partial \theta_i} = - \eta \nabla_i J$$  \hspace{1cm} (7)
Although the one-hidden-layer model is used in the present application it is useful to derive the gradient of $J$ for the general case and the result for the one-hidden-layer model can readily be obtained as a special case.

Starting from the top of the network, the application of the chain rule gives rise to

$$\frac{\partial J}{\partial w_{ij}} = \frac{\partial J}{\partial y_i} \times \frac{\partial y_i}{\partial w_{ij}} \quad (8)$$

From eqn.(6)

$$\frac{\partial J}{\partial y_i} = -(y_i - \hat{y}_i) = -\delta_i^i \quad (9)$$

where $\delta_i^i$ is called the error signal of the $i$-th neuron in the $i$-th layer. From eqn.(4)

$$\frac{\partial y_i}{\partial w_{ij}} = x_j^{i-1} \quad (10)$$

Thus

$$\frac{\partial J}{\partial w_{ij}} = -\delta_i^i x_j^{i-1} \quad (11)$$

Next consider the $(i-1)$-th layer. Using the chain rule yields

$$\frac{\partial J}{\partial w_{ij}} = \sum_k \frac{\partial J}{\partial y_k} \times \frac{\partial y_k}{\partial x_j^{i-1}} \times \frac{\partial x_j^{i-1}}{\partial w_{ij}} \quad (12)$$

It is easy to see that

$$\frac{\partial y_k}{\partial x_j^{i-1}} = w_{kj} \quad (13)$$

$$\frac{\partial x_j^{i-1}}{\partial w_{ij}} = g'(x_j^{i-1}) \quad (14)$$

$$\frac{\partial y_k}{\partial w_{ij}} = x_j^{i-2} \quad (15)$$

where

$$g'(s) = \frac{\partial g(s)}{\partial z} \quad (16)$$

By defining the error signal for the $i$-th neuron of the $(i-1)$-th layer as

$$\delta_i^{i-1} = \sum_k \left[ -\frac{\partial J}{\partial y_k} \right] \times \frac{\partial y_k}{\partial x_j^{i-1}} \times \frac{\partial x_j^{i-1}}{\partial w_{ij}} = g'(x_j^{i-1}) \sum_k \delta_k w_{kj} \quad (17)$$
eqn.(12) can be rewritten as

$$\frac{\partial J}{\partial w_{ij}^l} = -\delta_i^{l-1}x_j^{l-2}$$  \tag{18}$$

Similarly it can be shown that

$$\frac{\partial J}{\partial b_i^{l-1}} = -\delta_i^{l-1}$$  \tag{19}$$

By carrying on this procedure the following general results are obtained for $m=l,l-1,\ldots,2$

$$\delta_i^{m-1} = g'(c_i^{m-1})\sum_k\delta_k^m w_{ik}^m$$  \tag{20a}$$

$$\frac{\partial J}{\partial w_{ij}^{m-1}} = -\delta_i^{m-1}x_j^{m-2}$$  \tag{20b}$$

$$\frac{\partial J}{\partial b_i^{m-1}} = -\delta_i^{m-1}$$  \tag{20c}$$

Eqn.(20a) indicates how the error signals propagate down the network, hence, the name of "backpropagation".

Thus the steepest-descent minimization of the energy function defined in eqn.(6) produces the following increments for updating $\Theta$

$$\Delta w_{ij}^l(i) = \eta_w\delta_i^l x_j^{l-1}(i)$$  \tag{21a}$$

$$\Delta b_i^l(i) = \eta_b\delta_i^l(i)$$  \tag{21b}$$

where

$$\delta_i^l(i) = y_i(i) - \hat{y}_i(i)$$  \tag{22a}$$

and

$$\delta_i^k(i) = g'(x_i^k(i))\sum_m\delta_m^{k+1}(i)w_{im}^{k+1}(i-1) \quad k=l-1,\ldots,2,1$$  \tag{22b}$$

The constants $\eta_w$ and $\eta_b$ represent the learning rates for the weights and thresholds respectively. In practice, a large value of the learning rate would be preferable because this would result in rapid learning. Unfortunately a large value of learning rate can also lead to oscillation or even divergence. To overcome this problem, a momentum term is usually included so that eqns.(21a) and (21b) become

$$\Delta w_{ij}^l(i) = \eta_w\delta_i^l x_j^{l-1}(i) + \alpha_w\Delta w_{ij}^l(i-1)$$  \tag{23a}$$

$$\Delta b_i^l(i) = \eta_b\delta_i^l(i) + \alpha_b\Delta b_i^l(i-1)$$  \tag{23b}$$
where $\alpha_w$ and $\alpha_b$ are momentum constants which determine the effect of past weight changes to the current direction of movement in the weight space. This effectively filters out high frequency variations in the error surface.

To summarize, the backpropagation algorithm updates the weights and thresholds of the network according to

$$w^j_k(t) = w^j_k(t-1) + \Delta w^j_k(t) \tag{24a}$$
$$b^j_k(t) = b^j_k(t-1) + \Delta b^j_k(t) \tag{24b}$$

with the increments $\Delta w^j_k(t)$ and $\Delta b^j_k(t)$ given in eqns.(23a) and (23b).

3.1.1 Implementation

The implementation of the backpropagation algorithm involves two phases. Weights and thresholds are usually initialized with small random values. In the first phase, inputs are presented to the first hidden layer and these signals then propagated through the network to the output layer. The actual network outputs obtained from the output neurons are compared with the desired outputs to produce the prediction errors or residuals. The second stage involves propagating error signals backwards from the output layer to the first layer. Weights and thresholds are updated based on these error signals. This process is repeated until weights and thresholds converge.

For the activation function defined in eqn.(3) it can be shown that

$$g'(x^i) = x^i(1 - x^i) \tag{25}$$

The implementation for the one-hidden-layer model eqn.(5) can be summarised as follows:

(i) Initialise weights and thresholds for the network with small random values and select values for the learning rates $\eta_w$ and $\eta_b$ and the momentum constants $\alpha_w$ and $\alpha_b$.

(ii) Present the input data to the network and compute the outputs of the network according to
\[ y_i(t) = \sum_{j=1}^{n_1} \sum_{k=1}^{n_2} w_{jk}(t) g(\sum_{k=1}^{n_2} w_{jk}(t-1)x_k(t) + b_i(t-1)) \]

(iii) Compare the outputs of the network with the desired outputs to produce the prediction errors \( \varepsilon_i(t) \) which are equal to the error signals \( \delta_i(t) \) for the output neurons

\[ \varepsilon_i(t) = \delta_i(t) = (y_i(t) - \hat{y}_i(t)) \]

(iv) Update the weight connections between the hidden layer and the output layer

\[ \Delta w_{jk}^2(t) = \eta_w \delta_i(t)x_j(t) + \alpha_w \Delta w_{jk}^2(t-1) \]

\[ w_{jk}^2(t) = w_{jk}^2(t-1) + \Delta w_{jk}^2(t) \]

(v) Compute the error signals for the hidden neurons. As an example consider hidden neuron \( j \) whose output is transmitted to 2 output neurons as illustrated in Fig. 2. The error signal for this hidden neuron is then given by

\[ \delta_j^2(t) = x_j^1(t)(1 - x_j^1(t))(\delta_i^2(t)w_{jk}^2(t-1) + \delta_i^2(t)w_{jk}^2(t-1)) \]

(vi) Update the weights and thresholds for the hidden neurons according to

\[ \Delta w_{jk}^1(t) = \eta_w \delta_j^1(t)x_j(t) + \alpha_w \Delta w_{jk}^1(t-1) \]

\[ w_{jk}^1(t) = w_{jk}^1(t-1) + \Delta w_{jk}^1(t) \]

\[ \Delta b_j^1(t) = \eta_b \delta_j^1(t) + \alpha_b \Delta b_j^1(t-1) \]

\[ b_j^1(t) = b_j^1(t-1) + \Delta b_j^1(t) \]

Step (ii) to (vi) are repeated until convergence.

3.1.2 Convergence

It is well-known, from standard nonlinear optimisation theory, that the block-data version of the backpropagation algorithm will converge to a local minimum of the mean square error surface. The backpropagation algorithm discussed in the present study is a recursive version. Notice that this algorithm is known as the smoothed stochastic algorithm in system identification. If the learning rates \( \eta_w \) and \( \eta_b \) are made \( t \)-dependent and tend to zero as \( t \to +\infty \), a unified
method developed by Ljung(1977) for convergence analysis of recursive algorithms can readily be applied. Under the above assumption on learning rates, it can be shown that the recursive version of the backpropagation algorithm has the same convergence properties as its off-line counterpart. This means that the parameter vector \( \hat{\Theta}(t) \) will converge to a local minimum of the mean square error surface as the sample points \( t \rightarrow \infty \). Furthermore convergence of the backpropagation algorithm can be discussed within the same framework for the RPE algorithm. However it is generally true that the convergence of the backpropagation algorithm is fairly slow compared with the RPE algorithm. It is reasonable to believe that these results will have relevance for the case of smaller constant learning rates.

If all the neurons have a linear activation function, the network will degenerate to a linear one. In this extreme case, the convergence results for the adaptive linear combiner (Widrow and Stearns, 1985) are valid.

3.2 Recursive Prediction Error (RPE) Algorithm

The off-line prediction error algorithm (PEM) is derived based on the criterion

\[
J(\Theta) = \frac{1}{N} \sum_{n=1}^{N} Q(e(t), \Theta)
\]

(26)

where \( Q(.,.) \) is the measure of fit and \( e(t) \) is the prediction error vector. A good measure of fit is a quadratic function of \( e(t) \) (Ljung, 1981)

\[
Q(e(t), \Theta) = \frac{1}{2} e^T(t, \Theta) \Lambda^{-1} e(t, \Theta)
\]

(27)

where \( \Lambda \) is some \( n_f \times n_f \) symmetric positive definite matrix and \( n_f \) is the number of output nodes. If the prediction errors are Gaussian with zero mean, \( Q(.,.) \) can be chosen as the negative log likelihood function

\[
Q(e(t), \Theta) = \text{constant} + \frac{1}{2} \log |\Lambda| + \frac{1}{2} e^T(t, \Theta) \Lambda^{-1} e(t, \Theta)
\]

(28)

When the covariance matrix \( \Lambda \) is known (independent of \( \Theta \)), the first two terms in
\( Q(\cdot \cdot) \) have no effect on the minimization which then becomes equivalent to eqn.(27). In this case the prediction error estimate is equal to the maximum likelihood estimate with the advantage that the estimation accuracy satisfies the Cramer-Rao bound. In general the prediction error will not be Gaussian. However the asymptotic properties of PEM with \( Q(\cdot \cdot) \) given in eqn.(27) are very similar to those of maximum likelihood and it can be shown that under weak assumptions the PE estimates are consistent, asymptotically normally distributed and asymptotically efficient.

The minimization of the criterion (26) can be performed using the Gauss-Newton algorithm

\[
\Theta^{(k)} = \Theta^{(k-1)} + \mu(\Theta^{(k-1)})
\]

where superscript \((k)\) denotes the iteration step, \(\mu(\Theta)\) is the Gauss-Newton search direction defined by

\[
\mu(\Theta) = -[H(\Theta)]^{-1}VJ(\Theta)
\]

\(VJ(\Theta)\) is the gradient of \(J(\Theta)\) and \(H(\Theta)\) is the second derivative, known as the Hessian matrix of \(J(\Theta)\). The gradient of \(J(\Theta)\) can be derived by substituting eqns.(27) into the criterion (26) to yield

\[
VJ(\Theta) = -\frac{1}{N} \sum_{m=1}^{N} \Psi(t, \Theta) \Lambda^{-1}e(t, \Theta)
\]

where

\[
\Psi(t, \Theta) = \left[ \frac{d\hat{y}(t, \Theta)}{d\Theta} \right]^T
\]

is the first derivative of the one step ahead prediction with respect to \(\Theta\). The Hessian of \(J(\Theta)\) is obtained by differentiating \(VJ(\Theta)\)

\[
H(\Theta) = \frac{\partial^2 J}{\partial \Theta^2} = \frac{1}{N} \sum_{m=1}^{N} \Psi(t, \Theta) \Lambda^{-1} \Psi^T(t, \Theta) + \frac{1}{N} \sum_{m=1}^{N} \frac{d\Psi(t, \Theta)}{d\Theta} \Lambda^{-1} e(t, \Theta)
\]

At a minimum point of the criterion (26), the prediction errors form an uncorrelated sequence, and it can be shown that the expected value of the last term in eqn.(33) goes to zero so that eqn.(33) can be approximated as
\[ H(\Theta) = \frac{1}{N} \sum_{i=1}^{N} \Psi_i(\Theta)\Lambda^{-1}\Psi_i^T(\Theta) \]  
(34)

In case the matrix \( H(\Theta) \) may be close to singular, the following approximate Hessian can be taken

\[ H(\Theta) = \frac{1}{N} \sum_{i=1}^{N} \Psi_i(\Theta)\Lambda^{-1}\Psi_i^T(\Theta) + \beta I \]  
(35)

where \( I \) is the identity matrix and \( \beta \) is a non-negative small scalar. \( \lambda^{(k)} \) is obtained by minimizing \( J(\Theta^{(k-1)} + s\mu(\Theta^{(k-1)})) \) over \( 0 < s < 1 \) using a linear search technique.

The off-line recursive prediction error algorithm can be used as a basis to derive a recursive algorithm to minimize the criterion (26). The derivation is given by Ljung(1981), Ljung and Soderstrom(1983) and yields the standard recursive prediction error algorithm

\[ \varepsilon(i) = y(i) - \hat{y}(i) \]  
(36)

\[ R(i) = R(i-1) + \gamma(i)[\Psi(i)\Lambda^{-1}\Psi_i^T + \beta I - R(i-1)] \]  
(37)

\[ \hat{\Theta}(i) = \hat{\Theta}(i-1) + \gamma(i)R^{-1}(i)\Psi(i)\Lambda^{-1}\varepsilon(i) \]  
(38)

where \( \hat{\Theta}(i) \) is the estimate of the parameter vector and \( \gamma(i) \) is the gain at sample \( i \).

The gradient of \( Q(\varepsilon(i)) \) is \( \Psi(i)\Lambda^{-1}\varepsilon(i) \) which is a stochastic gradient and \( R^{-1}(i)\Psi(i)\Lambda^{-1}\varepsilon(i) \) can be regarded as an approximation of the Gauss-Newton search direction.

The simplest choice of \( \Lambda \) is \( I \). In practice the RPE algorithm is not implemented with an inversion of \( R(i) \) in each step, but the algorithm is updated in terms of

\[ P(i) = \gamma(i)R^{-1}(i) \]  
(39)

to give for \( \beta = 0 \)

\[ \varepsilon(i) = y(i) - \hat{y}(i) \]  
(40)

\[ P(i) = \frac{1}{\lambda(i)} \left( P(i-1) - P(i-1)\Psi(i)[\lambda(i)I + \Psi_i^T(i)P(i-1)\Psi(i)]^{-1}\Psi_i^T(i)P(i-1) \right) \]  
(41)

\[ \hat{\Theta}(i) = \hat{\Theta}(i-1) + P(i)\Psi(i)\varepsilon(i) \]  
(42)

where

\[ \lambda(i) = \frac{\gamma(i-1)}{\gamma(i)}(1 - \gamma(i)) \]  
(43)
\( \lambda(t) \) is called the forgetting factor. When it is required to weight out the old data, it is required that \( \lambda(t) < 1 \). It is desirable to set \( \lambda(t) < 1 \) at the initial stage so that rapid adaptation takes place and then to let \( \lambda(t) \rightarrow 1 \) as \( t \rightarrow \infty \) (Ljung and Soderstrom, 1983). These objectives can be achieved using the scheme

\[
\lambda(t) = \lambda_0 \lambda(t-1) + (1 - \lambda_0)
\]

where \( \lambda_0 \) and the initial forgetting factor \( \lambda(0) \) are design values.

The gradient \( \Psi(t, \Theta) \) is an \( n_0 \times n_1 \) matrix. For networks with a single hidden layer \( (n_1 = n_2) \), the number of parameters to be estimated is given by

\[
n_q = (n_0 + 1) \times n_1 + n_1 \times n_2
\]

The elements of \( \Psi \) for the one-hidden-layer model can be obtained by differentiating eqn.(5) with respect to \( \theta_i \) to yield

\[
\psi_{ij} = \frac{d\tilde{y}_j}{d\theta_i} = \begin{cases} 
  x_i^2 & \text{if } \theta_i = w_{jk}^2 \quad 1 \leq k \leq n_1 \\
  x_i^2(1-x_i^2)w_{jk}^2 & \text{if } \theta_i = b_j^2 \quad 1 \leq j \leq n_1 \\
  x_i^2(1-x_i^2)w_{jk}^2x_m & \text{if } \theta_i = w_{km} \quad 1 \leq k \leq n_1, 1 \leq m \leq n_0 \\
  0 & \text{otherwise}
\end{cases}
\]

where the activation function \( g(\cdot) \) is assumed to be eqn.(3). If the output layer consists of a single neuron, \( n_2 = 1 \), the index \( j \) in eqn.(46) can then be removed. Consider for example the network shown in Fig. 3 where \( n_0 = 3, n_1 = 2, n_2 = 1 \) and the input vector is given by

\[
x(t) = [x_1(t) \quad x_2(t) \quad x_3(t)]^T = [u(t-1) \quad u(t-2) \quad y(t-1)]^T
\]

Using eqn.(45), the number of parameters to be estimated is ten. The parameter vector \( \Theta \) is then

\[
\Theta = [\theta_1 \quad \theta_2 \quad \cdots \quad \theta_{10}]^T
\]

If the following equivalences

\[
\theta_1 = w_{11}, \quad \theta_2 = w_{12}, \quad \theta_3 = w_{13}, \quad \theta_4 = b_1, \quad \theta_5 = w_{21}, \\
\theta_6 = w_{22}, \quad \theta_7 = w_{23}, \quad \theta_8 = b_2, \quad \theta_9 = w_1^2, \quad \theta_{10} = w_2^2
\]

are introduced, the elements of \( \Psi \) in this case are given by

\[
\psi_1 = x_1^2(1-x_1^2)w_1^2x_1, \quad \psi_2 = x_1^2(1-x_1^2)w_2^2x_2, \quad \psi_3 = x_1^2(1-x_1^2)w_3^2x_3, \\
\psi_4 = x_1^2(1-x_1^2)w_4^2, \quad \psi_5 = x_2^2(1-x_2^2)w_2^2x_1, \quad \psi_6 = x_2^2(1-x_2^2)w_3^2x_2,
\]
\[ \psi_7 = x_2^2(1 - x_2^2)w_2^2x_3, \quad \psi_8 = x_2^2(1 - x_2^2)w_2^3, \quad \psi_9 = x_1^2, \quad \psi_{10} = x_2^2 \]

Finally it is worth pointing out that, if \( P(t) \) in eqn.(42) is replaced by the identity matrix \( I \), the RPE algorithm reduces to the backpropagation algorithm written in a vector form. This can be verified easily. The matrix \( P(t) \) determines the asymptotical accuracy of the estimate and therefore is also called the covariance matrix.

### 3.2.1 Implementation

The implementation of the RPE algorithm involves two phases. The first phase is the same as that of the backpropagation algorithm, that is to obtain the output \( \hat{y}(t) \). The second phase includes computing the covariance matrix \( P(t) \) and the gradient \( \Psi(t)e(t) \) and updating the parameter vector. The matrix \( P(t) \) in particular requires matrix algebra. The RPE algorithm is therefore computationally more demanding than the simple backpropagation method. The RPE algorithm for one-hidden-layer model eqn.(5) can be summarized as follows:

(i) Initialise the weights and thresholds with small random values; choose \( P(0) \) as a diagonal matrix with large diagonal values typically in the range of \( 10^2I \) to \( 10^4I \); assign values to \( \lambda_0 \) and \( \lambda(0) \) typically \( \lambda_0 = 0.99 \) and \( \lambda(0) = 0.95 \).

(ii) Present inputs to the network and compute the network outputs.

(iii) Compare the network outputs with the desired outputs to give the prediction errors \( e(t) \); then compute elements of \( \Psi(t) \) according to eqn.(46). Notice this is done from the top output layer down to the hidden layer.

(iv) Compute \( P(t) \) according to eqn.(41).

(v) Adjust parameter vector \( \Theta \) according to eqn.(42).

Steps (ii) to (v) are repeated until convergence.
3.2.2 Convergence

It has been shown (Ljung, 1977) that the RPE algorithm used in linear systems identification has the same convergence properties as its off-line counterpart. One of these properties is that the estimate $\hat{\theta}(t)$ converges with probability one either to a local minimum of $E[e^T(t, \Theta)e(t, \Theta)]$ or to a boundary point of the set of the parameter vector describing the model set as $t$ tends to infinity, where $E[.]$ is the expectation operator. The proof of convergence is based upon the differential equation associated with the RPE algorithm

$$\frac{d}{dt} \hat{\Theta}(t) = R^{-1}(t) f(\hat{\Theta}(t)) \quad (47a)$$

$$\frac{d}{dt} R(t) = G(\hat{\Theta}(t)) - R(t) \quad (47b)$$

where

$$f(\hat{\Theta}) = E[\Psi(t, \Theta)e(t, \Theta)] \quad (48a)$$

$$G(\hat{\Theta}) = E[\Psi(t, \Theta)\Psi^T(t, \Theta)] \quad (48b)$$

The convergence of the RPE algorithm is connected with the stability of the above differential equations. The stability of eqns. (47a) and (47b) can be proved by applying Lyapunov stability theory. It can also be shown that the estimate $\hat{\theta}(t)$ should follow the trajectories of the above differential equations asymptotically. These results can be extended to nonlinear systems (Chen and Billings, 1989 and Chen, Billings and Grant, 1989).

Under the assumption that the learning rates tend to zero as $t \to +\infty$, the convergence properties of the backpropagation algorithm can be similarly analysed. The differential equation associated with the backpropagation algorithm in this case can easily be obtained by replacing $R(t)$ in eqn. (47a) with the identity matrix to yield

$$\frac{d}{dt} \hat{\Theta}(t) = f(\hat{\Theta}(t)) \quad (49)$$
4 Model Validity Tests

The main objective in system modelling is to produce an acceptable model which accurately represents the system. The identified model will only produce acceptable predictions over different data sets if it is unbiased. If the model structure and the estimated parameters are correct then the prediction error sequence $\varepsilon(t)$ should be unpredictable from all linear and nonlinear combinations of past inputs and outputs. This condition will hold if and only if (Billings and Voon, 1986)

\[
\begin{align*}
\phi_{ee}(\tau) &= 0, \quad \tau \neq 0 \\
\phi_{eu}(\tau) &= 0, \quad \text{for all } \tau \\
\phi_{eeu}(\tau) &= 0, \quad \tau \geq 0 \\
\phi_{uu}(\tau) &= 0, \quad \text{for all } \tau \\
\phi_{uu}(\tau) &= 0, \quad \text{for all } \tau
\end{align*}
\]  

(50)

where $\phi$ represents the standard correlation function. If these functions fall within the 95% confidence intervals ($\pm 1.96/\sqrt{N}$), the model can be regarded as adequate.

5 Simulation Study

Five examples of nonlinear systems were considered. The first three examples called S1, S2 and S3 represent simulated nonlinear systems. The fourth example is the prediction of Canadian Lynx data and the fifth example is the identification of an automotive diesel engine. The fourth example is a scalar time series and the rest of the examples are all single-input single-output systems. Therefore the output layer of neural networks requires only one neuron ($n_2 = 1$).

5.1 Simulated systems: S1, S2 and S3

Neural network models with a single layer of hidden units were used to model these systems. The hidden layer consisted of 5 hidden neurons, ($n_1 = 5$) and the network input vector is defined by

$$x(t) = [u(t-1) \ u(t-2) \ u(t-3) \ y(t-1) \ y(t-2)]^T$$

giving $n_0 = 5$. In each of the three cases, the input $u(t)$ was a zero mean uniformly
distributed white noise sequence and 500 data points were generated. The backpropagation routine and the RPE algorithm were used to train the networks. Comparisons of these algorithms were made using the following models:

S1: \[ y(t) = 0.8y(t-1) + 0.4u(t-1) + u^2(t-1) + u^3(t-1) \]

S2: \[ y(t) = 0.4y^2(t-1) + 0.2u(t-1) + 0.6u^2(t-1) \]

S3: \[ y(t) = 0.8y(t-1) + 0.5u^2(t-1)y(t-1) + u^2(t-1) \]

These polynomial models are chosen such that S1 contains power nonlinearities in the input, S2 contains power nonlinearities both in the input and output and S3 contains a cross-multiplication term and power nonlinearity.

The measure of closeness between the predicted output and the measured output used is the error index defined as the normalised root mean square of the residual given by

\[
Error\ index = \sqrt{\frac{\sum(y(t) - \hat{y}(t))^2}{\sum y^2(t)}}
\]

The main result obtained from the simulations was that the RPE algorithm converged faster and gave a better prediction than the backpropagation algorithm. This is shown in Figs. 4, 5 and 6 for simulations S1, S2 and S3 respectively. The error index curves obtained for the RPE algorithm were smoother than those of the backpropagation algorithm. This is easily understood because the covariance matrix \( P(t) \) has the effect of smoothing the random variations in the gradient vector.

It was found that the choice of learning rates and the momentum constants for the backpropagation algorithm influenced the evolution of the error indexes and their corresponding final values. Normally, small values of learning rates, \( \eta_w \) and \( \eta_b \) are chosen and momentum constants, \( \alpha_w \) and \( \alpha_b \) are chosen to be less than but near to 1. The effect of varying one of these parameters whilst keeping the
others constant is illustrated in Fig. 7. The final values of the error indexes were
0.487, 0.165, 0.312, 1.292 and 0.243 for the cases A, B, C, D and E respectively.
This shows the sensitivity of the backpropagation algorithm to the user selectable
parameters.

For each example considered, a different combination of these parameters
was needed. If an inappropriate choice was made, there was a possibility that the
model would not produce a satisfactory prediction for the same amount of training
data. This sensitivity can create difficulties whenever backpropagation routine is
employed.

It was also difficult to satisfy the model validity tests of eqn.(50) using the
backpropagation routine. Figs. 9b, 10b and 11b illustrate the tests for simulations
S1, S2 and S3 respectively using the backpropagation algorithm. Whilst neither
RPE nor backpropagation satisfy these tests completely the results for the latter
algorithm are inferior to those for RPE. Larger networks may well have produced
improved results but a longer training period will be required. The selection of the
number of nodes in a network is still an open question which will not be
addressed in the current study.

For the RPE algorithm, it is known that while the choice of the initial
covariance matrix $P(0)=\rho I$, $\rho>0$ affects the initial stage of parameter estimation it
should not significantly influence the final parameter estimates. A larger $\rho$ will
generally produce a more rapid change at the initial stages. These expectations
were confirmed in the simulation as shown in Fig.8. The recursive prediction error
algorithm produced model validity tests which were closer to the 95% confidence
limits for the same structure of network and gave better predictions compared
to the backpropagation algorithm as indicated in Figs. 4 to 11. These advantages
of the RPE algorithm are achieved at the expense of more computations at each
iteration. Notice that the RPE algorithm described above can be reformulated into
a parallel algorithm (Chen et al., 1989) so that the parallel computing potential of the
network is exploited whilst maintaining the efficiency of RPE.

5.2 Canadian Lynx data

The fourth example concerns the modelling of a time series which representing Canadian lynx data. A neural network model with \( n_0 = 7 \) and \( n_1 = 5 \) was fitted using both the backpropagation and the RPE algorithms. The input vector in this case is

\[
x(t) = [y(t-1) \ y(t-2) \ \cdots \ y(t-7)]^T
\]

The lynx data consists of the annual record of the numbers of Canadian lynx trapped in the Mackenzie River district of North-Western Canada. This data was collected over a period of 114 years between 1821-1934 (Rao and Gabr, 1984). It has been noticed that the data exhibits an apparently regular ten year cycle. Since the peaks of the data are sharp, while the troughs are relatively smooth, Moran (1953) recommended that the logarithm to the base ten of the data should be used for estimation.

For the lynx data, the backpropagation routine failed to give a reasonable model using the data set consisting of 114 data points although many combinations of learning rates, momentum constants and initial weights and thresholds were tried. This failure was probably due to the slow convergence of the backpropagation routine. A length of 114 data points might not be enough for the backpropagation algorithm to train such a network of 45 parameters so that significant changes to the initial parameter values were obtained.

Fig. 12 shows the logarithmically transformed lynx data, the one step ahead prediction and the residuals obtained from the model trained by the RPE algorithm using the data set of 114 points. The one step ahead prediction superimposed on the actual data is illustrated in Fig. 13, where it is shown that the resulting model was capable of predicting the observations reasonably well. Various alternative network structure were trained but no significant improvement was achieved.
5.3 A turbocharged automotive diesel engine

The fifth example involves the identification of a model of a turbocharged automotive diesel engine. A neural network with \( n_p = n_i = 5 \) was used to model this system. The input vector was defined by

\[
x(t) = [u(t-1) \ u(t-2) \ u(t-3) \ y(t-1) \ y(t-2)]^T
\]

The description of the experimental procedure and data collection are described in Billings et al (1989). The low engine speed data set, b6shv2.dta was used in the present analysis. The input to the system was fuel rack position and the observed output was engine speed. The fuel rack was perturbed by a square wave signal of large amplitude with a superimposed PRBS.

The input and output data together with the predicted outputs and the residuals of the model trained by the RPE algorithm are shown in Fig. 14. Fig. 15 shows the one step ahead predicted output superimposed on the actual output. The correlation validity tests shown in Fig. 16 suggest the model is inadequate. Increasing the number of hidden neurons from 5 to 7 gave the validity tests shown in Fig. 17 which compared with Fig. 16 show no significant improvement. However on increasing the number of input nodes from 5 to 7 that is the input vector was now defined by

\[
x(t) = [u(t-1) \ u(t-2) \ u(t-3) \ u(t-4) \ y(t-1) \ y(t-2) \ y(t-3)]^T
\]

the correlation tests were improved as shown in Fig. 18. The data set was shown to be highly nonlinear (Billings et al., 1989). 400 points of data might not be sufficient for the RPE algorithm to obtain a finely tuned parameter estimate so that the model validity tests are all within the confidence bands. Presenting the same set of data to the network for a second time resulted with more acceptable model validation plots of Fig. 19. It is therefore not surprized that for this system, despite many attempts, the backpropagation routine failed to produce a reasonable estimate.
A NARMAX polynomial model has been estimated for the diesel engine but a direct comparison of these results with the neural network model are not possible because a noise model was estimated as part of the NARMAX analysis.

6 Conclusions

A new recursive prediction error estimator (RPE) has been compared with backpropagation as a method of training neural network models of nonlinear systems. It has been demonstrated that the recursive prediction error algorithm often yields better predictions and faster convergence than backpropagation. The backpropagation algorithm appears to be dependent on the user selectable parameters to the extent that if an inappropriate combination of the learning rates and momentum constants are chosen the algorithm performs badly. The new RPE algorithm appears to provide an effective method of training neural networks at the expense of increased computational load compared with backpropagation.
