Identifying the genetic changes driving adaptive variation in natural populations is key to understanding the origins of biodiversity. The mosaic of mimetic wing patterns in *Heliconius* butterflies makes an excellent system for exploring adaptive variation using next-generation sequencing. In this study, we use a combination of techniques to annotate the genomic interval modulating red color pattern variation, identify a narrow region responsible for adaptive divergence and convergence in *Heliconius* wing color patterns, and explore the evolutionary history of these adaptive alleles. We use whole genome resequencing from four hybrid zones between divergent color pattern races of *Heliconius erato* and two hybrid zones of the co-mimic *Heliconius melpomene* to examine genetic variation across 2.2 Mbp of a partial reference sequence. In the intergenic region near *optix*, the gene previously shown to be responsible for the complex red pattern variation in *Heliconius*, population genetic analyses identify a shared 65-kb region of divergence that includes several sites perfectly associated with phenotype within each species. This region likely contains multiple cis-regulatory elements that control discrete expression domains of *optix*. The parallel signatures of genetic differentiation in *H. erato* and *H. melpomene* support a shared genetic architecture between the two distantly related co-mimics; however, phylogenetic analysis suggests mimetic patterns in each species evolved independently. Using a combination of next-generation sequencing analyses, we have refined our understanding of the genetic architecture of wing pattern variation in *Heliconius* and gained important insights into the evolution of novel adaptive phenotypes in natural populations.

[Supplemental material is available for this article.]

Natural selection acting on heritable genetic variation has generated much of the extraordinary biological diversity we observe in nature. However, in the 150 years since Darwin and Wallace independently posited the theory of natural selection, we still have only a rudimentary understanding of how adaptive variation arises and spreads in natural populations. The molecular basis of adaptive variation in natural populations has been identified in only a handful of traits (Martin and Orgogozo 2013). These examples provide the foundation for our current understanding of the genetic architecture of adaptation and underpin efforts to unite molecular, developmental, and evolutionary biology into a single evolutionary synthesis (Stern and Orgogozo 2009).

The array of adaptive wing color patterns of *Heliconius* butterflies offers an exceptional opportunity to explore the functional changes that drive complex adaptive traits in natural populations. *Heliconius* butterflies display bright wing color patterns that are under strong natural selection (Benson 1972; Mallet and Barton 1989; Mallet et al. 1990; Kapan 2001)—they warn potential predators that the butterflies are unpalatable (Chai 1986). Selection favoring regional mimicry among these and other noxious butterflies drives the remarkable diversity in wing color patterns—characterized by extreme divergence within species and striking convergence among distantly related species (Turner 1975). This pattern of convergence and divergence is best exemplified by the Müllerian mimics, *H. erato* and *H. melpomene*. Since the divergence of the two species 13–26 million years ago (Pohl et al. 2009), both have undergone parallel radiations, such that the range of each species is composed of an identical patchwork of divergent color pattern races stitched together by a series of narrow hybrid zones. This replicate-rich and highly variable system has become a textbook example of evolution by natural selection and provides a remarkable template to explore the repeatability of evolution.

*Heliconius* show striking variation in complex red color pattern elements across both the forewing and hindwing. Red color patterns in *H. erato* and *H. melpomene* consist of three distinct elements—the color of the forewing band, the presence or absence of the red “dennis” patch on the proximal portion of the forewing, and the presence or absence of red hindwing rays (Sheppard et al. 1985; Papa et al. 2008). These elements comprise two major red phenotypes—“postman” and “rayed” (Fig. 1). Postman races are characterized by a red forewing band and absence of both the red dennis patch and hindwing rays and are found in disjunct pop-
ulations across Central and South America. Rayed races, in contrast, have a yellow forewing band, red dennis patch, and hindwing rays. The rayed races are found throughout the Amazon Basin but not on the Pacific coast of South America or in Central America (Fig. 1).

Substantial progress has been made in understanding the genetic basis of red phenotypic variation in Heliconius, but the causative variant remains elusive. The region was initially described as a complex of three tightly linked loci (Sheppard et al. 1985). However, the region modulating red variation was positionally cloned in both *H. erato* (Counterman et al. 2010) and *H. melpomene* (Baxter et al. 2010) to a single shared 400-kb genomic interval—referred to as the *D* interval in *H. erato* and the *B/D* interval in *H. melpomene*. Targeted resequencing identified an ~150-kb region of divergence between divergent red color pattern races of *H. melpomene* (Nadeau et al. 2012). Gene expression analyses across this interval supported the transcription factor *optix* as the only gene with expression patterns consistent with a role in red pattern formation (Reed et al. 2011). Gene expression differences and the highly conserved amino acid sequence variation in *optix* suggest that variable red patterns are driven by *cis*-regulatory variation (Reed et al. 2011). Phenotypic recombinants between red pattern elements have been occasionally observed (Mallet 1989), implicating the potential involvement of multiple, tightly linked, *cis*-regulatory variants in this region that generate differences in the spatial expression of *optix* and result in diverse red color pattern phenotypes.

Identifying the genomic region responsible for red color pattern variation has allowed reassessment of the history of color pattern diversification in these co-mimics using the region most likely to reflect mimetic history. Phylogenetic reconstruction of the history of color pattern evolution in both *H. erato* and *H. melpomene* found that sequences from the gene *optix* cluster races strongly by color pattern, rather than the clustering by geographic proximity observed with other genomic markers (Hines et al. 2011). This suggests a single origin for geographically disjunct rayed color pattern phenotypes within each species. The evolutionary history between the two co-mimetic species is likely more complex. *Heliconius erato* and *H. melpomene* belong to divergent clades and are not known to hybridize, precluding the hypothesis of adaptive introgression that has been shown between more closely related species within the melpomene/cydno/silvaniform clade (The Heliconius Genome Consortium 2012; Pardo-Díaz et al. 2012). However, the question remains as to whether or not the convergent color patterns have a common origin through the use of ancestral variation or if they evolved independently through unique de novo mutations. Inferring the evolutionary history of this striking mimetic phenotype requires high resolution sequence data across a more finely defined genomic region regulating color pattern variation in both species.

In this study, we use a combination of next-generation sequencing technologies to (1) explore the genetic variation that modulates spatially complex adaptive red wing color pattern variation in natural populations of *Heliconius erato* butterflies; and (2) compare the genomic regions responsible for parallel mimetic color pattern radiations in *H. erato* and *H. melpomene*. We start by using transcriptome sequencing to annotate protein coding genes across the *H. erato* red color pattern interval. We then examine whole genome resequencing data from divergent color pattern races across four geographically distinct *H. erato* hybrid zones. In these admixture zones, gene flow between divergent races homogenizes the genomes, while strong selection on color pattern creates narrow regions of genetic divergence around these genomic targets of selection. We use these hybrid zone data to localize signatures of selection across 1 Mb of the red color pattern locus and identify a noncoding region likely responsible for regulating expression of *optix* and ultimately driving spatially complex patterns of red across the wings. Finally, we use phylogenetic analyses to demonstrate that mimetic red patterns evolved only once within each species but likely evolved independently in the co-mimics *H. erato* and *H. melpomene*. These two distantly related mimetic species appear to generate their convergent phenotypes through different changes in the same genetic architecture. This study refines the regulatory regions driving adaptive phenotypic variation in a classic mimetic radiation and provides an improved understanding of the repeatability of evolution at the genomic level.

**Results**

**Annotation, synteny, and conservation of the *H. erato* red color pattern (*D*) interval**

Using transcriptome alignments, protein homology, and ab initio predictions, we annotated 30 protein coding genes across 1 Mb of the *H. erato* *D* interval (Supplemental Table S4; GenBank accession KC469894). The genes across the *D* interval are in perfect synteny with the corresponding red pattern region of the co-mimic *H. melpomene* (Supplemental Fig. S1). The annotated region contains a 200-kb gene desert that includes a single gene, *optix*. This gene desert contains the 65-kb peak that shows strong signatures of selection and association (described below). Sequence alignments of the *H. erato* *D* interval and the orthologous scaffolds from the *H. melpomene* genome identified 182 highly conserved regions (>90% sequence similarity in a 500-bp window), covering a total of 63 kb of sequence, of which 25 kb is located in noncoding regions. The 65-kb peak we have identified contains 20% of the conserved noncoding regions, but transcriptome alignments show...
no transcriptional activity. Analysis of potential transcription factor binding sites in the 65-kb region revealed binding sites for numerous transcription factors across the region, but no clear candidates for optix regulation (see Supplemental Material section S1; Supplemental Fig. S2).

**Summary of resequencing data and genotyping**

We examined whole genome data from multiple individuals of divergent color pattern races across four geographically distinct *H. erato* hybrid zones and one *H. melpomene* hybrid zone (Fig. 1; Table 1). We resequenced 45 *H. erato* individuals to a median per base coverage between 15× and 35× per individual and aligned sequence reads across 2.2 Mb of the *H. erato* partial reference genome sequence (1 Mb of the D interval and 1.2 Mb from other regions of the genome). For each individual, we identified, on average, one SNP for every 22 bases genotyped (Supplemental Table S6). Additionally, we resequenced six *H. melpomene* individuals to a median per base coverage between 19× and 34× per individual and aligned sequences to the whole *H. melpomene* reference genome (The Heliconius Genome Consortium 2012). For each individual, we identified, on average, one SNP for every 48 bases genotyped across the B/D interval (Supplemental Table S7).

**Genomic divergence and genotype by phenotype association**

The sliding window divergence analysis between subpopulations of the two common *H. erato* phenotypes—the postman and the rayed—showed peaks of genetic divergence at two distinct regions within a 200-kb stretch of the D interval (Fig. 2). The first region (the second peak in Fig. 2 spanning ~40 kb [650–690 kb]) had moderate levels of differentiation (0.3 < $\theta_s$ < 0.4) (Fig. 2) and reduced nucleotide diversity (Fig. 3A). This region was centered immediately 3' of the transcription factor *optix*, which is the only gene located within the peaks of divergence. The second region spanned ~65 kb of noncoding sequence more distally 3' of *optix* (515–580 kb). This 65-kb region had very high levels of differentiation (0.6 < $\theta_s$ < 0.7) between hybridizing races, low levels of nucleotide diversity within races (Fig. 3A), and elevated linkage disequilibrium relative to other regions of the genome (Supplemental Fig. S3), which are all indicative of recent positive selection driving the fixation of haplotypes. Of these two regions that showed signatures of selection in *H. erato*, only the 65-kb peak, which is furthest from *optix*, contained SNPs that were perfectly associated with color pattern phenotype across our entire sampling of individuals (Fig. 2).

Overall, the patterns of divergence and association in the gene desert near *optix* were consistent across the geographically distinct *H. erato* hybrid zones. All hybrid zones between rayed and postman phenotypes (Ecuador, French Guiana, and Peru) showed strong genetic differentiation ($\theta$ > 0.6) and numerous fixed differences between phenotypes in the region 3' of *optix* (Supplemental Fig. S4). In the 40-kb peak, which includes *optix*, only the hybrid zones in Ecuador and Peru showed strong differentiation and fixed differences between races. Individuals from French Guiana showed only moderate genetic differences and no perfectly associated SNPs in this region. The Panama hybrid zone is between two different postman phenotypes and, as expected, contained no indication of genetic divergence between phenotypes across the D interval and no regions of consistent association with phenotype (Supplemental Fig. S4D).

There were striking similarities in patterns of differentiation and association between *H. erato* and *H. melpomene*, two species that show identical shifts in their mimetic wing patterns across their geographic ranges (Turner 1975). The same two peaks of population differentiation and phenotypic association were seen when examining *H. erato* and *H. melpomene* in the Peruvian hybrid zone (Supplemental Fig. S1). The major peak of divergence and association identified in the *H. erato* hybrid zones (Fig. 2) perfectly coincides with the region of peak divergence and association identified in *H. melpomene* hybrid zones (Fig. 4; Supplemental Fig. S1).

**Haplotypede structure and recombination under the divergence peak**

To investigate what might be driving the high divergence in the 65-kb peak, we looked for evidence of chromosomal rearrange-

![Figure 2](image-url)
region of peak divergence and association identified in the co-mimic size (subpopulation differentiation ($k = 2$)) (colored red and gray). A horizontal white row separates the two clusters. Blocks where the two color pattern races share haplotypes are represented by regions where individuals of a single color pattern race are assigned to more than one cluster (red columns with light and dark shading; gray columns with light and dark shading). SNPs with fixed allelic differences between color patterns are denoted by red hash marks below the haplotype clustering (data from Fig. 2). (C) Correlation plot of linkage disequilibrium ($r^2$) among 3187 biallelic SNPs across the 500–600 kb window on the $D$ interval.

We more closely examined haplotypes and linkage disequilibrium (LD) across the 65-kb peak of divergence for patterns of recombination. In genomic regions unlinked to color, LD decayed very rapidly, falling to background levels within a few thousand bases (Supplemental Fig. S3). Across the three hybrid zones between rayed and postman races, LD was consistently higher across the 65-kb peak of divergence than across other regions of the $D$ interval (Supplemental Fig. S3).

Although recombination in the 65-kb peak region appears to be substantially reduced, haplotype reconstruction suggests that recombination is present. In the Peruvian hybrid zone, clustering of reconstructed haplotypes into two groups does not support a single large haplotype block distinguishing the two color pattern races. Rather, the clustering revealed several smaller blocks with haplotypes fixed between the color pattern races that were intervened by narrow regions where both races shared the same haplotypes. Similar to the LD analyses, haplotypes clustered more strongly by color pattern races in the $H. erato$ and $H. melpomene$ genomic data across this region. These analyses have limited power due to the necessity of having good coverage across inversion breakpoints from read pairs with one pair in the inverted region and the other outside. Despite these limitations, these results, along with the perfect gene synteny between species, suggest that divergent color pattern races are collinear and can recombine across the $D$ locus.

We more closely examined haplotypes and linkage disequilibrium (LD) across the 65-kb peak of divergence for patterns of recombination. In genomic regions unlinked to color, LD decayed very rapidly, falling to background levels within a few thousand bases (Supplemental Fig. S3). Across the three hybrid zones between rayed and postman races, LD was consistently higher across the 65-kb peak of divergence than across other regions of the $D$ interval (Supplemental Fig. S3).

Although recombination in the 65-kb peak region appears to be substantially reduced, haplotype reconstruction suggests that recombination is present. In the Peruvian hybrid zone, clustering of reconstructed haplotypes into two groups does not support a single large haplotype block distinguishing the two color pattern races. Rather, the clustering revealed several smaller blocks with haplotypes fixed between the color pattern races that were intervened by narrow regions where both races shared the same haplotypes. Similar to the LD analyses, haplotypes clustered more strongly by color pattern races in the $H. erato$ and $H. melpomene$ genomic data across this region. These analyses have limited power due to the necessity of having good coverage across inversion breakpoints from read pairs with one pair in the inverted region and the other outside. Despite these limitations, these results, along with the perfect gene synteny between species, suggest that divergent color pattern races are collinear and can recombine across the $D$ locus.
This large proportion of polymorphic sites private to a specific hybrid zone indicates that alleles and haplotypes shared between hybridizing races across the 65-kb peak likely result from recent gene flow at each hybrid zone, rather than incomplete sorting of ancestral variation among the different races.

**The evolutionary history of red wing patterns**

We examined phylogenetic relationships across the D interval using two methods—a sliding window likelihood tree preference and optimally partitioned phylogenetic topologies (Fig. 5). We identified a major shift in evolutionary history across the 200-kb region supported by the divergence and association analyses. Likelihood scores strongly support a tree that clusters samples by color pattern phenotype, rather than the tree that clusters samples by geographic population (Fig. 5). Additionally, the optimally partitioned phylogenetic topologies showed a partition encompassing the 200-kb region where the tree perfectly clusters by color. Moving away from this 200-kb region, phylogenetic topology shifted to a transitional topology between color-based and geography-based trees before transitioning to a geography-based tree on the far edge of the interval (Fig. 5). The tree in the color partition supports a single origin of the rayed color pattern, clustering rayed phenotypes separate from nonrayed phenotypes, as does a tree inferred from the 65-kb region of highest divergence (Supplemental Fig. S5). Branch lengths across topologies show a signature of reduced gene flow, whereby color pattern alleles have reduced gene flow among races and less variation among individuals relative to markers further from the color pattern locus (Fig. 5; Supplemental Fig. S5).

We compared the evolutionary history of the red color pattern interval between the two co-mimics, *H. erato* and *H. melpomene*, which showed concordant peaks of divergence, indicating that they use the same genetic architecture to generate their convergent phenotypes. We aligned 71 regions showing high conservation between the two reference sequences within a 300-kb window that included both peaks of divergence. Phylogenetic analyses of 69 of the 71 fragments support complete monophyly of each species, rather than the clustering of samples by phenotype that would be expected if the phenotypes shared a common origin. Nonmonophyly in the two remaining fragments was driven by poor alignments of a few samples with extensive missing data. We more closely examined histories of SNPs within the 65-kb peak of divergence. After manual removal of regions with poor alignment and SNPs with missing data for more than 25% of samples, we obtained 1164 SNPs. *Heliconius erato* and *H. melpomene* share allelic variation across 73 of these 1164 SNPs, none of which show patterns of association with phenotype across both species. Phylogenetic analysis of the 1164 SNPs resolved *H. erato* and *H. melpomene* as separate lineages with high support, while clustering races by phenotype within each species (Supplemental Fig. S6). Results from these data support an independent origin of red patterns within each species.

**Discussion**

The high definition genomic data sets provided by next-generation sequencing techniques can give important insights into how different ecological pressures, complex genetic architectures, and evolutionary histories shape patterns of genomic variation. In this

---

**Figure 5.** Phylogenetic trees across the D interval. The top panel is the likelihood preference for color-based versus geography-based tree models (inset). Pink bars beneath the plot represent the region where neighbor-joining trees in this sliding window have a monophyletic lineage for the rayed phenotype. These peaks are shown relative to the annotated genes in the interval. The gray bar in the middle represents the five most optimal topological splits used for phylogenetic tree reconstruction, colored by the general history inferred, with black representing a tree clustering by color pattern, light gray a tree clustering by geographic region, and medium gray for transitional topologies. Tree topologies for these divisions are shown below, excluding the tree for the fourth interval, which does not differ substantially from the fifth tree. Nodes supported by a posterior probability $>0.95$ are represented with bold branches preceding them. Phenotypes are represented by branch color and geographic regions by terminal node color. Internal branches are colored only in cases of clade monophyly of that pattern, otherwise branches are represented in gray. All unrooted tree topologies were arbitrarily rooted at the Panamanian lineage for presentation.
study, we used whole genome resequencing to successfully narrow the region modulating adaptive red color pattern variation in \textit{H. erato} to a 65-kb interval of peak divergence that showed strong signatures of selection and included almost all of the SNPs perfectly associated with wing pattern phenotype (Fig. 2). There were no predicted genes or any evidence of transcriptional activity across this region, which strongly supports the assertion that red pattern variation is caused by \textit{cis}-regulatory changes controlling gene expression during wing development (Reed et al. 2011). Although this genetic architecture appears to be highly conserved across the \textit{Heliconius} genus, it most likely arose independently in the co-mimics \textit{H. erato} and \textit{H. melpomene}.

Signatures of strong selection and recombination across the 65-kb region

The patterns of genomic variation across the \textit{H. erato} D interval reflect a history of high rates of gene flow coupled with strong selection. Across most of the 2.2 Mb of the genome we analyzed, gene flow has homogenized genomic variation between hybridizing species, implicating a regulatory mechanism modulating red variation (Reed et al. 2011). We see strong signatures of selection across a 200-kb gene desert that contains only the gene \textit{optix}. We believe that the major 65-kb peak of divergence, which is located in the gene desert – 130 kb 3’ of \textit{optix}, contains multiple \textit{cis}-regulatory elements of \textit{optix}.

The \textit{D} locus segregates with a simple Mendelian inheritance pattern (Mallet 1989; Kapan et al. 2006); however, phenotypic patterns from \textit{H. erato} hybrid zones suggest that different red color pattern elements are genetically distinct. Phenotypic hybrid forms having a red forewing dennis patch but no red hindwing rays should not exist if the same genetic variant at the \textit{D} locus controls both those red pattern elements. Yet such individuals have been found on very rare occasions in hybrid zones (Mallet 1989), and they exist as naturally occurring color pattern races in both \textit{H. erato} (\textit{amaflreda}) and \textit{H. melpomene} (\textit{meriana}) (Sheppard et al. 1985).

We hypothesize that the 65-kb divergence and association peak actually contains a cluster of tightly linked \textit{cis}-regulatory elements of \textit{optix}, each controlling one of the three distinct red pattern elements. There is increasing evidence in other systems that some loci, originally thought to be single large effect loci, are actually clusters of tightly linked genetic changes (Rebeiz et al. 2009; Franken et al. 2011; Studer and Doebley 2011; Loehlin and Werren 2012; Linnen et al. 2013). Our haplotype analysis supports this hypothesis because the 65-kb peak is rather broad and contains a number of haplotype blocks that are perfectly associated with phenotype, with haplotype blocks of low association interspersed between them. Although this could be a consequence of the history of recombination alone, it could also be indicative of several conserved subregions that control different aspects of phenotypic variation (Fig. 3).

In \textit{Heliconius}, these clustered regulatory elements may bind different upstream regulatory genes that control the spatially specific expression patterns of \textit{optix} and ultimately determine scale coloration across the wings. The region could thus act as an evolutionary hotspot, with the flexibility to generate diverse phenotypes, but where strong selection and physical linkage ensure that mimetic patterns are inherited as a whole.

Independent origins of a shared genetic architecture between co-mimics

The genetic architecture driving color pattern convergence and divergence appears to be highly conserved across the \textit{Heliconius} genus. The \textit{D} interval showed strikingly consistent differentiation across replicate \textit{H. erato} hybrid zones between divergent color pattern races (Supplemental Fig. S4). Moreover, the 65-kb divergence
and association peak identified in our *Heliconius erato* analysis is nearly identical to the peak of divergence in the co-mimic, *H. melpomene* (Fig. 4; Supplemental Fig. S1). These observations raise some interesting questions about the broader evolutionary history of this region. Did the alleles responsible for mimetic patterns in *H. erato* and *H. melpomene* evolve independently or do they share a common origin, through either adaptive introgression or shared ancestral variation?

The history of color pattern evolution within *H. erato* indicates that races with similar red wing patterns likely share a common origin. Consistent with a previous gene-based study (Hines et al. 2011), sliding window phylogenetic analyses and inferred phylogenetic trees for the 65-kb region strongly support a common origin of the rayed pattern in *H. erato* (Fig. 5; Supplemental Fig. S5).

Adaptive introgression of red color pattern alleles between species could be argued to explain a shared origin of mimetic phenotypes across *Heliconius*, as it does within the *H. melpomene* clade (The *Heliconius* Genome Consortium 2012; Pardo-Diaz et al. 2012). Similarly, ancestral variation, shared between the co-mimics, could also be elicited to explain the shared mimetic phenotypes. Yet, in our comparative analysis across the 65-kb peak that we have identified as responsible for red patterning, we found no evidence for a common origin of shared color pattern variation in these co-mimics. No SNPs were perfectly associated with color pattern in both species, and all geneologies from this region were reciprocally monophyletic for both species. These results are consistent with the deep genetic divergence (Pohl et al. 2009) and lack of hybridization between *H. erato* and *H. melpomene*.

Although color patterns likely have a single origin within each species, patterns of variation suggest similar red patterns evolved independently in the co-mimetic species. Analyses between color pattern races within a species show numerous shared SNPs and strong phylogenetic clustering—indicating a shared origin or the rayed phenotype. Analyses between co-mimetic species show no shared SNPs and no phylogenetic clustering—indicating that it is most likely that the two parallel radiations independently evolved mimetic red patterns through changes in the same regulatory regions.

Although we found no evidence for a shared history of red color patterns between the co-mimics *H. erato* and *H. melpomene*, it is important to point out several caveats. Foremost, we are only beginning to understand the evolutionary dynamics of this region. Patterns of variation, including SNPs and insertions/deletions, across this noncoding genomic interval are complex, and our strategy of mapping short sequencing reads onto a static reference sequence may miss variation that is functionally important. In addition, mapping of these data onto different species-specific references may introduce some bias. The improvement of algorithms for de novo assembly from short read sequence data (Miller et al. 2010; Schatz et al. 2010), coupled with emerging technologies for generating long sequencing reads from single molecules (Schatz et al. 2010), will allow more detailed dissection of the evolutionary dynamics of this region in the future. Resolution of the question of the origin of mimicry in *Heliconius* awaits final discovery of the precise functional changes regulating phenotypic variation in both species.

In conclusion, using genomic sequencing of a small number of individuals from multiple admixed hybrid zones, we were able to confidently localize the noncoding genetic switch modulating an adaptive phenotype. We showed that both distantly related co-mimics used this same genetic architecture, but although regulatory alleles appear to have a single origin within species, mutations were most likely independently acquired in the co-mimetic species to produce the shared phenotypes. This study highlights how next-generation sequencing techniques can be leveraged to identify functional variation and to understand the evolutionary history of adaptive radiations.

**Methods**

**Annotation, synteny, and conservation**

We annotated 2.2 Mb of *Heliconius erato petiverana* BAC sequences from the ~400-Mb *H. erato* genome (see Supplemental Material section S1 for further details). Approximately 1 Mb of this reference sequence, called the *D* interval, was previously identified as being involved in red wing color pattern elements (Counterman et al. 2010). We masked repetitive elements in this partial reference genome using RepeatMasker v3-2-9 (Smit et al. 2010) and a *Heliconius* repetitive elements database (The *Heliconius* Genome Consortium 2012).

We generated a partial reference transcriptome for *H. erato* wing tissue using reference-based assembly of Illumina RNA-seq short-read data. We obtained whole transcriptome short-read sequences from hindwing cDNA for 18 individuals, including two divergent *H. erato* color pattern races and three developmental stages. Transcripts were generated from these pooled samples using the Bowtie/TopHat/Cufflinks pipeline. We aligned each sample to the masked reference sequence using TopHat v1.2.0 (Trapnell et al. 2009) and Bowtie v0.12.7.0 (Langmead et al. 2009), with stringent mapping parameters to minimize false alignments. We generated transcripts by analyzing alignments with Cufflinks v1.0.1 (Trapnell et al. 2010).

We produced automated gene annotations across the *H. erato* partial genomic reference sequence using the MAKER pipeline v2.09 (Holt and Yandell 2011). This analysis involved masking repetitive elements in the reference sequence, aligning peptide sequences from the UniRef90 (Suzek et al. 2007) and *Bombyx mori* (Duan et al. 2010) protein databases, and aligning transcripts from the RNA-seq data and previously published EST sequences from wing tissues of *H. erato* and *H. himea* (Papanicolaou et al. 2009). MAKER generated ab initio gene models for both the masked and unmasked reference using AUGUSTUS v2.5.5 (Stanke et al. 2006) trained for *H. melpomene* (The *Heliconius* Genome Consortium 2012) and SNAP v2010-07-28 (Korf 2004) trained for *Bombyx mori*. MAKER generated gene predictions by promoting ab initio models with enough supporting evidence from protein homology or transcriptome alignments. We manually curated the predicted genes within the *D* interval based on the supporting evidence and alignments to annotated *Heliconius* proteins and curated insect proteins.

We assigned gene descriptions and putative functions based on homology with known proteins and protein domains. In addition to protein coding genes, we predicted transcription factor binding sites using the Transcription Element Search System (TESS) (Schug and Overton 1997), searching against known *Drosophila* binding sites from the TRANSFAC and JASPAR databases.

We examined gene synteny across the *D* interval between the curated *H. erato* peptide sequences and *H. melpomene* v1.0 peptide sequences (The *Heliconius* Genome Consortium 2012) (see Supplemental Material section S2 for further details). We used Inparanoid v4.3 (Ostlund et al. 2010) to identify one-to-one orthologs and examined genes for consistent order and orientation using OrthoCluster release 2 (Vergara and Chen 2009).

We examined the level of sequence conservation between *H. erato* and *H. melpomene* across the *D* interval (see Supplemental Material section S2 for further details). We used mVista LAGAN and Overton 1997), searching against known *Drosophila* binding sites from the TRANSFAC and JASPAR databases.
(Brudno et al. 2003) to globally align the \textit{H. erato} interval sequence and the \textit{H. melpomene} scaffolds containing the orthologous genes identified by the Inparanoid analysis. We examined sequence conservation in 500-bp windows across the interval, identifying regions of $>90\%$ similarity.

**Sequencing and genotyping**

To determine where in the \textit{D} interval different red phenotypes diverge genetically, and therefore where the genetic control of the red phenotype is most likely located, we examined genomic sequence data for divergent red color pattern races of \textit{H. erato} (see Supplemental Material section S3 for further details). We collected 45 individual \textit{H. erato} butterflies from hybrid zones in Peru ($n=14$), French Guiana ($n=13$), Ecuador ($n=10$), and Panama ($n=8$) (Fig. 1; Supplemental Table S6). We collected phenotypically pure individuals of each color pattern race from admixed populations where the ranges of two color pattern races overlap. For dissecting red color pattern variation, the hybrid zones in Peru, French Guiana, and Ecuador are considered replicate hybrid zones since each involves hybridization between rayed and postman races. The Panamanian hybrid zone serves as a control in that both races are postman phenotypes, showing variation only in the yellow phenotypic elements, which are under independent genetic control from the red elements (Mallet 1986). Additionally, we collected six \textit{H. melpomene} individuals near a hybrid zone in eastern Colombia, three samples representing each of the two major red phenotypes—the postman and the rayed (Supplemental Table S7). We assessed variation across a second \textit{H. melpomene} hybrid zone in Peru, which is also represented by postman and rayed phenotypes, using published targeted resequencing data (Nadeau et al. 2012).

We sequenced the whole genome of each sample on the Illumina platform, producing 100-bp paired-end reads. We aligned the \textit{H. erato} sequencing reads to our unmasked \textit{H. erato} partial reference genome and \textit{H. melpomene} reads to the \textit{H. melpomene} genome v1.1 (The Heliconius Genome Consortium 2012) using BWA v0.5.9-r16 (Li and Durbin 2009) with relaxed mapping parameters. We called multisample genotypes across samples for each race using GATK’s (DePristo et al. 2011; McKenna et al. 2010) UnifiedGenotyper with heterozygosity set to 0.025 and filtered genotype calls for quality using GATK’s VariantFilter, applying both site and individual sample filters to remove low quality genotypes, low coverage regions, and hypercoverage regions indicative of repetitive elements. We used BreakDancer v1.2.6 (Chen et al. 2009) to identify regions of the reference sequence that showed paired end alignments with incorrect orientations and unexpected distances between pairs, indicating possible structural rearrangement.

**Divergence and association analyses**

We examined signatures of selection and genotype by phenotype association between divergent color pattern races (see Supplemental Material section S4 for further details). We calculated sliding window genomic divergence between pairs of \textit{H. erato} color pattern races at each hybrid zone independently and across all hybrid zones combined, with samples classified as either postman or rayed phenotypes. We used a model for diploid data with populations as random effects ($\theta$) (Weir 1996) and no simplifying assumptions regarding sample sizes or number of populations (Weir and Cockerham 1984). For analyzing all hybrid zones combined, we incorporated the geographic structure of the populations by using a three-level hierarchy method ($\theta_3$) (Weir 1996). For all comparisons, we calculated divergence at a position only if at least 75\% of the individuals were genotyped for each phenotype. We evaluated 15-kb sliding windows at 5-kb steps across the genomic intervals and required a window to have divergence calculated for at least 20\% of the positions in the window. We calculated a baseline level of divergence for each comparison as the level of divergence observed across intervals unlinked to color pattern (\textit{H. erato}: three unlinked BACs; \textit{H. melpomene}: 38 unlinked scaffolds).

We estimated genotype by phenotype association at each \textit{H. erato} hybrid zone independently and across all four \textit{H. erato} hybrid zones combined. We examined each biallelic SNP using a two-tailed Fisher’s exact test based on allele counts. Positions were excluded if $<75\%$ of individuals were genotyped for each phenotype.

To look for signatures of selection, we calculated sliding window values for the proportion of segregating sites and heterozygosity for the \textit{H. erato} Peruvian hybrid zone. We calculated estimates of these parameters for a genomic position only if at least 75\% of individuals were genotyped and then looked at 15-kb windows with a 5-kb step size, for windows with at least 20\% of positions with parameter estimates. To explore linkage disequilibrium (LD), we examined all biallelic SNPs with at least 75\% of individuals genotyped. We calculated correlations ($r^2$) between all pairwise SNPs using PLINK (Purcell et al. 2007), which for unphased data is based on genotype allele counts.

We assessed divergence and association in the \textit{H. melpomene} hybrid zones as described above. Additionally, for each \textit{H. erato} fixed SNP, we attempted to identify an orthologous SNP in \textit{H. melpomene} and determined if the SNP was associated with phenotype in both species.

**Linkage disequilibrium and haplotype clustering**

We explored haplotype structure in the Peruvian hybrid zone by estimating haplotypes across a 100-kb window of the \textit{D} interval (500–600 kb) containing the 65-kb peak of divergence and flanking regions using fastPHASE v1.2 (Scheet and Stephens 2006) (see Supplemental Material section S6 for further details). We filtered biallelic SNPs across this 100-kb region to remove sites that had genotypes from $<75\%$ of the individuals of each race, resulting in 3227 SNPs. Haplotypes were clustered during phase estimation into two clusters ($K=2$) and the proportion of rayed and postman individuals assigned to each cluster at each SNP was determined. We used Haploscope (San Lucas et al. 2012) to visualize regions where the two races had fixed haplotype block differences and where individuals from both races shared the same haplotypes. Using the haplotype estimations from fastPHASE, for each SNP, Haploscope visualizes the portion of individuals from a race (light vs. dark) assigned to each cluster (red vs. gray) across the 100-kb region (San Lucas et al. 2012).

**Phylogenetic analyses**

We constructed phylogenetic trees across sliding windows in the \textit{D} interval, sampling 15 kb of sequence every 5 kb (see Supplemental Material section S5 for further details). For each window, we tested the log likelihood of the data with two alternative trees: The geographic tree assumes samples cluster by geographic hybrid zone and the color based tree groups races with a similar color pattern (rayed or postman) (Fig. 5). Likelihood values were calculated for each interval and tree topology using scripts in PAUP* 4b10 (Swofford 2002), using a GTR + G model inferred for the interval as a whole using Modeltest v3.7 (Posada and Crandall 1998). Neighbor-joining trees across these sliding windows constructed in PAUP* were used to infer regions of monophyly by color phenotype.

To summarize variation in phylogenetic topology across the interval, we constrained division of the interval into the five most distinct topologies using the MLT method, raising the likelihood...
score penalty until five clusters of SNP blocks were reached (Ané 2011). Tree topologies for each of these five regions of the interval were constructed using MrBayes v3.1.2 (Ronquist and Huelsenbeck 2003). Analyses involved three runs for 3 million generations each, sampling every 500 generations and removing 33% burn-in and runs that did not converge (as assessed in MrBayes and Tracer v1.5 [Rambaut and Drummond 2007]). Models were assigned using MrModeltest v2.3 (Nylander 2004) and included the GTR model for the second and third regions of the interval and GTR + G for the remaining regions. In addition to these phylogenies, phylogenetic and network-based trees were constructed for both the 65-kb peak region of population differentiation and unlinked genetic regions.

To test whether shared color patterns between the mimics could result from a common origin, we also performed phylogenetic analyses combining H. erato and H. melpomene sequences along this interval. We focused on regions of high conservation between H. erato and H. melpomene (>80% conservation in a 500-kbp window) from our mVista alignment within the 515–580 kb region of peak divergence. We used ClustalW2 (Larkin et al. 2007) and manual edits to align sequences from all 45 H. erato individuals (Supplemental Table S6) and 14 H. melpomene individuals (Supplemental Table S7). After filtering, 1134 SNPs were concatenated and used for a Bayesian analysis using the same parameters above and a GTR model.
