**Does the Stock Market Reward Innovation?
European Stock Index Reaction to Negative News during the Global Financial Crisis**

Abstract

This study uses data on 27 European stock indices over the period from January 2007 to December 2012 to investigate the relationship between innovations and the market reaction to negative news during the financial crisis. We use the bivariate BEKK-GARCH approach to estimate time-varying betas and abnormal returns. We show that index prices of countries in the high (low) innovation groups experience significantly positive (negative) abnormal returns on and following the negative news announcement dates. We also find that index beta changes following the arrival of bad news is negatively associated with a country's innovativeness. This finding suggests that innovations promote economic stability and enhance investors' confidence in a country's ability to cope during difficult times. Thus, policy makers who are concerned with sustainable growth should encourage R&D investments by adopting effective policies and avoid unnecessary cuts in R&D expenditures even during times of crisis. A study of the pre-crisis period from January 2001 to December 2006, using the same methods, indicates that investors value innovation more during difficult times.

JEL classification: G1; O2; O3

Keywords: Innovation; R&D investments; Stock price reaction; Time-varying betas.

1. Introduction

A recent OECD (2009) report suggests that the recession, which began with the financial crisis of 2007, has impacted research and development (R&D) in OECD countries. In the fourth quarter of 2008, a decline in R&D expenditure, or at best slower growth, was apparent. Moreover, R&D expenditure declined by a record 4.5% in 2009 across the OECD, with falls in all major OECD countries except South Korea and France. However, as is shown in this paper, the performance of stock markets in OECD countries during the crisis period has exhibited heterogeneity. The study reported in this paper sheds light on the role of innovation in building investor confidence and in stimulating economic recovery. The argument that motivates this work is that if innovation improves profitability and reduces investment costs, it should also increase investors' confidence in a country's ability to withstand the effect of difficult economic conditions. More specifically, if investors' confidence increases with innovation, the stock markets of innovation-intensive countries would be less adversely affected by negative news about the global economy. We investigate this issue by examining the reaction of European stock market indices to the arrival of major negative news during the recent global financial crisis. We choose to focus our analysis on European markets for several reasons. First, Europe is a significant player in the global economy, with the GDP of the euro-zone area (\$13 trillion) being almost equal to that of the US (\$15 trillion). Secondly, whilst the financial crisis started in the US, its impact was greater and it lasted longer in Europe (Weisbrot, 2014). Thirdly, the European sovereign debt crisis had a significant effect on investors' confidence and was blamed for the slow recovery in the US and the global economy. Finally, the considerable variations in European countries' commitments to innovations and the fact that these countries are not affected in the same way by the financial crisis make Europe a perfect environment to study the link between innovation and a country's ability to cope during difficult times.

This paper is motivated both by theoretical literature and empirical evidence at firm and country level. Chen and Zhang (2009) develop a model in which firms with higher expected profitability and lower investment costs provide higher expected returns. To test whether the market rewards innovation, existing empirical studies focus almost exclusively on the impact of R&D investments and patents on firm value (see for example Griliches, 1981; Jaffe, 1986; Hall et al, 2005), the short-term stock price reaction to R&D announcements (for example Chan et al, 1990; Saad and Zantout, 2009) and the long-term

stock returns associated with past R&D investment (for example Chan et al, 2001; Eberhart et al, 2004). However, the results of these studies are far from conclusive. For example, Chan et al (2001) find firms with higher R&D investment experience no better long-term risk-adjusted excess returns than the rest of their sample firms. However, Porter (1992), Hall (1993) and Hall and Hall (1993) show that investors fail to foresee the rewards from long-term R&D investments and thus undervalue R&D-intensive stocks. Eberhart et al (2004) show that firms exhibit significant positive risk-adjusted excess returns for the five-year period following R&D expenditure increases. They interpret it as an evidence of investors' under reaction to the benefit of R&D increases.

While several studies show that innovations stimulate economic growth (Aghion and Howitt, 1998; Grossman and Helpman, 1991; Solow, 1956) and promote nations' competitive advantage (Porter, 1998), evidence on the relationship between innovations and aggregate stock market returns is relatively scarce. Hsu (2009) argues that if innovation raises the expected productivity and profitability of the representative firm, it should also improve the overall efficiency and reduce investment costs at the aggregate level. Consistent with this prediction, Hsu finds that innovations have positive and distinct predictive power for U.S. and other countries market returns and premiums. The study in this paper also uses country level data to investigate the relationship between innovation and market returns and premiums. However, unlike Hsu (2009), who attempts to explain the time series of market returns using innovation shocks, we investigate the behaviour of market returns and betas following the arrival of negative news about the global economy. This leads to new insights about the relationship between innovation and investor confidence in a country's ability to cope during difficult economic climates. We argue that the productivity and efficiency benefits associated with innovations are likely to be even more crucial during crisis periods, particularly as customers switch to lower-priced products/services providers in order to reduce their expenditure.

This argument suggests that firms and economies with continued investments in innovations are more likely to survive the recession and position themselves well for the recovery periods, whereas others may be forced to cut their R&D expenditure to ensure short-term survival at the expense of the long-term performance (see, for example, Smallbone et al, 1999). Thus, if innovations help firms to respond properly in times of trouble, investors might

be less worried about losing their wealth in times of trouble and may therefore react less adversely, or even positively, to the arrival of negative news about the global economy.

To investigate this issue, we estimate abnormal returns and time-varying betas for 27 European country indices around informed negative shocks. These which are defined as the World index returns in the lowest 5th percentile that can be matched with the timelines of the crisis released by the BBC, European Central Bank (ECB), Federal Reserve Bank of St Louis and The Guardian¹ newspaper. We argue that if innovations enhance investors' confidence, one would expect a positive association between innovation measures and event day abnormal returns, as recessions may have less adverse effect on the competitiveness and profitability of firms in innovation-intensive economies. We also examine the effect of innovation on the co-movement of local stock market indices and the World index during crisis periods. As above, it can be argued that the stability of economies with continuous investments innovations is less likely to be threatened by recession, as firms in these markets are better equipped to cope with the challenges imposed by global economic downturns. Thus, negative news about the global economy should have less impact on the time varying betas, which are a measure of stability and riskiness, of stock markets of highly innovative countries.

Taking into account different levels of innovation, we provide a direct comparison for 27 European markets. The innovation measures are based on government budget appropriations or outlays on research and development as a percentage of GDP, the actual R&D expenditures as a percentage of GDP, the ratio of knowledge based researchers to total employment and the number of patent applications per million inhabitants. The 27 countries are split into high (30%), medium (40%) and low (30%) innovation groups. Consistent with the investor confidence view, we show that countries with higher innovation measures experience much smaller negative stock price reactions to negative news events. The results also suggest that abnormal returns around days of informed negative shocks are positively related to the cross-country variation in innovation variables. The results are robust to different measures of innovation and after controlling for the effects of other economic

¹ See the following links for further details: <http://www.ecb.int/ecb/html/crisis.en.html>, <http://www.guardian.co.uk/business/2012/aug/07/credit-crunch-boom-bust-timeline>, <http://timeline.stlouisfed.org/index.cfm?p=timeline>, and <http://www.bbc.co.uk/news/business-13856580>

variables. We also show that changes in stock market index betas tend to exhibit a negative association with a country's innovativeness. This relationship is particularly pronounced when government support to R&D activities is used to measure innovation. We attribute the observed decline in the co-movement between innovation-intensive stock indices with the World index to the superior performance of highly innovative firms during global downturns.

To investigate whether these findings are unique to the crisis period, the analysis is also carried out for the period January 2001 to December 2006. We find that the positive reaction of innovation-intensive country indices to the arrival of negative news is unique to the times of crisis. This finding indicates that investors value innovation more during difficult times.

The paper is organized as follows. Section 2 provides a brief review of the literature and develops the hypotheses to be tested. Section 3 presents a brief description of the global financial crisis and its impact on the European countries. Section 4 presents the data, defines the variables and reports the descriptive statistics. Section 5 describes the methodology. Section 6 reports the empirical results and Section 7 discusses the implications of our findings and concludes.

2. Related Literature and Hypothesis Development

Several studies, including Stein (1988), Porter (1992) and Hall (1993), argue that investors focus excessively on short-term profits and under-value firms with long-term investments, such as R&D, which create strategic options for a firm and are a major source of competitive advantage (see, for example, Ansoff, 1995; Porter, 1998). However, Jensen (1993) argues that not all R&D investments are likely to be profitable. If investors overlook this possibility, they are more likely to overvalue the stocks of R&D-intensive firms. Several studies investigate the issue of whether R&D intensive stocks are over- or under-valued by examining the stock price behaviour following the announcement of corporate R&D investments.

One stream of the empirical literature focuses on the short-term stock price reaction to R&D expenditure announcements. Chan et al (1990) and Zantout and Tsetsekos (1994) show that stock markets react positively to increased R&D expenditure announcements by

technology firms. Saad and Zantout (2009) find a negative stock price response to public announcements on discontinuation of R&D programs in science and technology industries. Szewczyk et al (1996) report a positive association between Tobin's q , a measure of investment opportunities, and stock price reaction to the announcement of R&D investments. Using a sample of 157 US firms for the period 1968-1974, Griliches (1981) finds that one additional dollar spent on R&D boosts a firm's market value by \$2 and an additional patent boosts the market value by around \$200,000 over the long term. Hall et al (2005) show that the book value of assets, number of patents per dollar of R&D and number of citations per patent have significant impacts on market value, with an extra citation per patent enhancing a firm's market value by about 3%. Ehie and Olibe (2010) report a positive association between R&D investments and market value for both manufacturing and services industries.

While the majority of studies report a positive short-term price reaction to increased R&D expenditure announcements, others show that the market reaction to R&D investments varies considerably across time and regions. For example, Hall (1993) reports a sharper decrease in the market valuation of R&D investment in the US manufacturing industry during 1986 – 1991 than that observed during 1979 – 1983. She attributes such a decline to a lower rate of return to R&D and a higher discount rate for R&D investments due to uncertainty. Erickson and Jacobson (1992) find that R&D investments do not increase the market value of US firms, after taking into consideration other firm-specific factors. Hall and Oriani (2006) find that R&D is valued by French and German investors, but not by Italian ones. Booth et al (2006) and Karjalainen (2008) find that investors better value R&D expenditures in a market-based financial system than those in a bank-based financial system.

Another stream of empirical studies focuses on the long-term performance of firms with different R&D investments. Pakes (1985) uses a sample of 120 US firms over the period 1968-1975 to investigate the dynamics among patents (measured by the number of successful patent applications), R&D expenditures and stock returns. He finds that the events that lead the market to re-valuate the firm are significantly correlated with unpredictable changes in both R&D and the patents of the firm. Lev and Sougiannis (1996) find a positive and significant coefficient on the R&D variable, defined as the weighted sum of past R&D expenses, in cross-sectional stock returns over the 12 months subsequent to the release of current period accounting information. Eberhart et al (2004) find that US firms with unexpected R&D increases experience significantly positive risk-adjusted excess stock

returns for 5 years following the firm's R&D increase. They argue that investors systematically underreact to R&D increases that are considered as long-term beneficial investments. Similarly, Eberhart et al (2004) show all groups of firms benefit from R&D investments, but R&D expenditures of high-tech firms generate significantly higher abnormal returns than low-tech firms. Their evidence suggests that the market is slow to recognise the full benefit of R&D investments and the delay in incorporating the R&D benefits is greater in the case of high-tech firms. In contrast, Chan et al (2001) do not find any significant difference in average risk-adjusted excess return between US firms with and without R&D investments.

While research on the effectiveness of R&D investments is evident, little attention has been given the impact of innovations, the by-products of R&D investments, on firms' ability to cope during difficult times. This study uses country level data to investigate the relationship between a country's innovativeness and its stock index price reaction to the announcement of major bad news about the global economy. The efficient market hypothesis (EMH) suggests that stock price should reflect all relevant information immediately and accurately. Thus, stock prices are expected to decrease on the days when negative news arrives to the market. However, we argue that the extent of stock market index price reaction to negative news may depend on a country's innovativeness. It has been argued that R&D expenditure creates intangible assets, such as patents and intellectual property (see, for example, Hall, 1993; Sougiannis, 1994; Al-Horani et al, 2003). According to Porter (1998), these intangible assets are considered to be among the most important sources of a nation's competitive advantage. Knowledge management has also been regarded as one of key determinants of a country's ability to exploit its own innovative efforts in order to improve its competitiveness in the global economy (Schwab, 2012). We argue that if investors can foresee the rewards from innovations, their confidence about the country's ability to cope during difficult times will increase. Therefore, we expect stock indices of innovation-intensive countries to be less adversely affected by the arrival of negative news about the global economy. This leads to:

Hypothesis 1: Abnormal returns on the day of the informed negative shock are positively associated with a country's investment in innovations.

The extant literature focuses on the riskiness of R&D investment relative to investments in physical assets. Chan et al (2001) argues that payoffs from R&D investments involve a larger degree of uncertainty and their benefits are likely to materialise much later than benefits from investments in physical assets. Consistent with this view, Al-Horani et al (2003) find a positive association between the cross-sectional UK expected returns and R&D expenditure. Their evidence implies that intangible assets resulting from R&D activities are riskier than tangible assets. The main objective of the study reported in this paper is not to compare the relative riskiness of tangible and intangible assets. Instead, we investigate the link between innovations and the change in stock market index betas following the arrival of major negative news. We argue that if innovations help firms to develop competitive advantage, highly innovative firms would be better for disruptive economic conditions and recessions should, therefore, have less adverse impact on their performance and the stability of their cash flows.

The impact of negative news announcements on individual stock betas is widely examined in the literature. Several studies, including Hamada (1972), Appleyard and Strong (1989), Monkhouse (1997), show that the arrival of bad news tends to reduce equity value, increase firm leverage and increase stock betas. Others, such as Kalay and Lowenstein (1985) and Patell and Wolfson (1979), argue that surprises increase uncertainty and stock betas increase following negative news announcements. The uncertain information hypothesis (UIH) of Brown et al (1988) suggests that stock betas increase following both positive and negative news. The authors argue that in incomplete information environment, investors may use the parameters of a conditional probability distribution to estimate the various potential outcomes. Since the full extent and the ultimate impact of the arrival of good or bad news about a firm's future prospects may still be uncertain, risk-averse investors may choose to apply high discount rates and set stock prices significantly below their conditional expected values.

The concept of time varying betas is relevant to this study for two important reasons. First, failure to control for event-induced changes in beta may result in biased abnormal returns estimates. For instance, Benamraoui et al (2013) show that the price patterns following profit warning announcements disappear completely after adjusting for event-induced systematic risk. Similarly, Mazouz and Saadouni (2009) find that the price effects of index revisions are sensitive to the time-varying risk adjustments. Specifically, they show that

OLS-based abnormal returns indicate that the price effect associated with the index revision is temporary, whereas market models with time varying betas imply that both additions and deletions experience permanent price change. Secondly, if innovation-intensive firms cope better during periods of economic distress, the arrival of negative news should have a less adverse impact on the riskiness and value of the stock market in countries that invested more in innovation, leading us to:

Hypothesis 2: Beta changes following informed negative shocks are negatively associated *with a country's* investment in innovation.

3. The Financial Crisis in Europe

The financial crisis began in the summer of 2007 due to the bursting of the US housing bubble. The sharp decline in US house prices caused the value of the securities backed by American real estate to collapse and interbank markets to freeze (Strahan, 2008; Brunnermeier and Pedersen, 2009). This, in turn, caused widespread insolvencies among financial institutions in the US and globally. In 2008, the fourth largest US investment bank, Lehman Brothers, filed for bankruptcy and the US government-sponsored enterprises Fannie Mae and Freddie Mac were placed into conservatorship. During the same year, Northern Rock and the Bradford & Bingley Building Society were nationalised by the British government and the governments of Belgium, France, and Luxembourg had to inject \$9.2 billion to Dexia, the world's largest lender to municipalities. The Belgian, Dutch, and Luxembourg governments also injected \$16.4 billion into banking and insurance company Fortis (Jackson, 2009).

As investor confidence collapsed, financial distress transferred to business and household demand and the economy in Europe entered the steepest downturn on record since the 1930s. The European economy shrank by nearly 4% in 2009, the sharpest contraction in the EU's history (European Commission, 2009). This economic downturn triggered sovereign debt problems in Europe, making it almost impossible for some Eurozone countries, particularly Greece, Ireland, Portugal, Spain and Italy (PIIGS), to service their debt obligations without the assistance of third parties, such as the European Central Bank (ECM) and the International Monetary Fund (IMF). The fears of sovereign debt crisis had severe economic and political consequences in both Europe and globally. The unemployment rate in

European also rose sharply, with Spain and Greece being the worst hit with unemployment rates exceeding 26% (Aridas and Ventura, 2011). In addition to the adverse economic effects, the European crisis saw major political shifts in the leading powers of the worst hit countries, including Greece, Ireland, Italy, Portugal, Spain, Slovenia and Slovakia.

The European countries adopted different policies to stimulate economic growth. Many central banks in Europe, including the ECB and the Bank of England cut interest rates (to 1.5% and 0.5%, respectively), approaching the Federal Reserve rate of 0.25%. In addition, the Bank of England has committed a total of £375 billion to quantitative easing since 2009 (BBC, 2013). However, other European governments, particularly those that received funds from the EC, ECB and IMF, used budget tightening (that is, raising taxes and lowering expenditure) as a means to fight the crisis. Greece, for example, cut its healthcare spending by more than 40% and Portugal reduced the number of private sector workers covered by union contracts from 1.9 million to 300,000 (Weisbrot, 2014). This austerity policy also affected the R&D budget, with R&D expenditure dropping by a record of 4.5% in 2009 across the OCED countries, except South Korea and France.

The fears of contagion risk in Europe began to diminish by the second half of 2012 following the successful policy measures taken by EU leaders and the ECB, which include fiscal consolidation and structural reforms among the worst affected countries. Whilst these actions helped to restore investors' confidence in the Eurozone, some countries, particularly Greece and Cyprus, are still in need for funds from the ECB and IMF to restore recovery and stimulate growth.

4. Data Variable Definitions and Descriptive Statistics

For the crisis period, we analyse 27 European stock market indices² over the period from January 2007 to December 2012. The stock market indices are from Datastream. The proxy for the World market portfolio is the Datastream World index. Yearly innovation measures and macroeconomic variables are obtained from the Eurostat and World Development Indicators, respectively. Informed negative shocks are identified by matching the lowest 5th percentile of the World Index returns during the study period with the timelines of crisis from

² The other European stock markets are excluded due to unavailability of the DS index data.

the BBC, ECB, Federal Reserve Bank of St Louis and The Guardian. To avoid confounding effects when tracking the post-shock abnormal returns, multiple price shocks in a 10-days post the event window are excluded from our analysis. By applying these criteria, we indentified 20 informed negative shocks over the study period, with a mean (median) of -4.54% (-4.51%) and values ranging from highest of -2.2% to the lowest of -6.65%.

Insert Table 1 about here

We use government budget appropriations or outlays on R&D as a percentage of GDP (denoted GBOARD), R&D expenditure as a percentage of GDP (RDEXPEND), personnel and researchers in knowledge-intensive activities to total employment (EMPLOY) and patent applications per million inhabitants (PATENT) to capture different aspects of a country's innovativeness. Specifically, GBAORD measures government's support to R&D activities and the priority of public funding of R&D placed by central governments; RDEXPEND captures the governments' R&D actual expenditure; EMPLOY is a measure of skilled workforce working in technological innovation; PATENT is a measure of innovation output.

Table 1 reports the descriptive statistics of the different innovation measures. We split the 27 European countries into high (30%), medium (40%) and low (30%) groups according to each of these four innovation measures and report the results in Panel A of Table 1³. Panel B of Table 1 suggests the presence of wide discrepancies in the level of innovativeness across the sample countries. Specifically, the GBAORD averages 0.60%, with values varying from a minimum of 0.15% for Malta to a maximum of 1.16 % for Finland. Similarly, the RDEXPEND values range from 3.9% for Finland to 0.43% for Cyprus with a mean (median) of 1.60% (1.48%). Finland has the highest EMPLOY of 3.27%, while Romania has the lowest EMPLOY value of 0.42%. It also shows that the average PATENT is 104.95, with Switzerland and Russia having 429.82 and 1.49 patent applications per million inhabitants, respectively. Standard t-tests suggest that the variations in innovations across the three groups are significantly different from zero.

³ To save space, each country's group classifications in 2007 are illustrated in Panel A of Table 1. Yearly group classifications and more detailed descriptive statistics are available upon request.

After discussing innovation measures, we consider other potential determinants of the variations in cross-country stock returns. These variables include openness of goods trading, that is imports plus exports as a percentage of GDP (TRADEOPEN), local inflation rate (INFLATION), official exchange rate to US\$ (EXRATE), the size of financial intermediaries relative to the same of the whole economy, that is domestic credit provided by the banking sector as a percentage of GDP (Credit/GDP) and the size of the stock market relative to size of the whole economy, that is the market capitalisation of listed companies as percentage of GDP (MV/GDP). Our choice of these variables is guided by the findings of relevant studies in the literature. For example, Darrat and Zhong (2005) and Li et al (2004) show that trade openness increases co-movement across stock markets. Fama (1981) predicts a negative association between inflation and stock returns, as inflation is known to have an adverse effect on the real economy. Dornburch and Fisher (1980) argue that the currency movements affect international competitiveness and thus affecting the future cash flows of firms and their stock returns. Allen and Gale (2003) show that stock returns are positively related to the development of a country's financial system, as a sufficiently liquid banking system allows stock market traders to smooth their trades and minimise price volatility. Finally, Martin and Rey (2000) argue that assets with larger demand have a higher price. They find that larger financial areas exhibit higher asset prices, implying a positive association between MV/GDP and stock returns.

Table 2 reports descriptive statistics and the correlations between the various variables used in our analysis. Panel A of Table 2 shows that TRADEOPEN has an average of 107.65%, with values ranging from 47.97% for Turkey to 333.53% for Luxembourg. The average inflation rate during the crisis across 27 European countries is 3.8%. Ireland experienced a deflation of -3.18%, while Russia has the highest inflation rate of 17.96%. Norway (Cyprus) has the smallest (largest) Credit/GDP. Romania (Luxembourg) has the smallest (largest) MV/GDP. Panel B of Table 2 presents the correlation matrix of the variables used in our analysis. The correlations among the four innovation measures range from 0.61 between PATENT and GBAORD to 0.85 between PATENT and RDEXPEND. It indicates that governments' R&D expenditures have a positive impact on patent applications. Thus, policy makers who are concerned with competitive success and wealth creation should encourage R&D investments by adopting effective policies, such as providing fiscal incentives, grants and subsidies of private R&D projects. INFLATION is also highly

correlated with CREDIT/GDP, with a correlation coefficient of -0.54. This finding is consistent with Boyd et al's (2000) argument that an increase in inflation drives down the real rate of return and exacerbates credit market frictions. This, in turn, will have adverse effects on both financial intermediation and capital investments. The correlation between the remaining variables is relatively low (that is, less than 0.5 in absolute value) numerically, even though many of the estimated coefficients are significantly different from zero.

Insert Table 2 about here

5. Methodology

This section describes the methods used to estimate abnormal returns and time varying betas around informed negative shocks. It also outlines the multiple regression models used to investigate the impact of investment in innovations on stock market reactions and its systematic risks.

5.1 The BEKK-GARCH based event study

It has been widely documented in the literature that stock betas vary considerably over time, as firms' leverage, investment opportunities and other characteristics change (see, for example, Black, 1976 and Christie, 1982). Several studies, including Mandelbrot (1963) and Fama (1965), show that daily stock return series are heteroskedastic. The Lagrange Multiplier (LM) test suggests the presence of the Autoregressive Conditional Heteroskedasticity (ARCH) effect in the residuals of the market model of all 27 stock market indices included in our analysis⁴. Following McKenzie et al (2000), we employ the cumulative sum of recursive residual squares (CUMSUMSQ) test to determine whether beta coefficients are constant or time varying. Our results show that the recursive residuals from CUMSUMSQ tests for all 27 stock market indices fall outside the 5% bounds, indicating the parameters of the market model are time varying. Figure 1 provides a typical example of a graphical illustration of the CUMSUMSQ test results⁵.

⁴ Further details on the LM test are available from the corresponding author on request.

⁵ Graphical illustrations of the CUMSUMSQ test of the remaining sample countries are also available upon request.

Insert Figure 1 about here

The time varying nature of the beta coefficients and the presence of heteroskedasticity in the index returns impair the power of the traditional market model in an event study⁶. To overcome this problem, we use the bivariate form of Engle and Kroner's (1995) BEKK-GARCH (1,1) model, which allows the market model betas to vary systematically over time and for the residual errors to be heteroskedastic. This model has also been used by Tsui and Yu (1999), Choudhry (2005) and Choudhry et al (2010), among others, to estimate abnormal returns. The conditional bivariate mean model is specified as

$$R_{it} = \alpha_i + \gamma_{it}, R_{mt} = \alpha_m + \gamma_{mt}, \quad (1)$$

where $\gamma_{i,t}$ and $\gamma_{m,t}$ are random error terms. The conditional covariance matrix of the residual series allows the conditional variance and correlation of both country and World index returns to vary over time

$$Var(\gamma_t \equiv \begin{bmatrix} \gamma_{it} \\ \gamma_{mt} \end{bmatrix} | \Psi_{t-1}) = H_t = \begin{bmatrix} h_{it}^2 & h_{mit} \\ h_{imt} & h_{mt}^2 \end{bmatrix}, \quad (2)$$

$$H_t = C'C + A'\gamma_{t-1}\gamma'_{t-1}A + B'H_{t-1}B, \quad (3)$$

where Ψ_{t-1} is the information set of the past values of the error term γ_t ; h_{mit} is the conditional covariance between country index and World index returns; h_{it}^2 and h_{mt}^2 are conditional variances of country index and World index returns, respectively. A , B and C are 2 x 2 matrices of parameters. Estimated values are indicated with a hat, for example $\hat{\beta}_{it}$. The time-varying beta of index i, β_{it} , is defined in the usual way and is estimated by

$$\hat{\beta}_{it} = \hat{h}_{mit} / \hat{h}_{it}^2. \quad (4)$$

⁶ Although the market model abnormal returns are generally higher than those of BEKK-GARCH (1, 1), our conclusions are not sensitive to the abnormal return estimation technique. More details of these results are available upon request.

To account for the potential effect of beta changes on the abnormal returns around informed negative shocks, beta adjusted abnormal returns, AR_{it} , are estimated as

$$AR_{it} = R_{it} - \hat{\alpha}_{it} - \hat{\beta}_{it}R_{mt} . \quad (5)$$

For N indices, the average beta adjusted abnormal returns and the cumulative beta adjusted abnormal returns are calculated in the usual way as

$$\overline{AR}_t = \frac{1}{N} \sum_{i=1}^N AR_{it}, \quad \overline{CAR}_S = \frac{1}{N} \sum_{i=1}^N CAR_{iS}, \quad (6)$$

where CAR_{iS} is the cumulative abnormal return of stock index i over a window of S days starting on the day of the event, that is $CAR_{iS} = \sum_{t=0}^S AR_{it}$. The two test statistics used to assess the statistical significance of \overline{AR}_t and \overline{CAR}_S , are as follows

$$T_1 = N^{1/2} \overline{AR}_t / \hat{\sigma}_{AR}, \quad T_2 = N^{1/2} \overline{CAR}_S / \hat{\sigma}_{CAR}, \quad (7)$$

where $\hat{\sigma}_{AR}$ and $\hat{\sigma}_{CAR}$ are the estimated standard deviations of the $AR_{i,t}$ and $CAR_{i,S}$, respectively, and are estimated as

$$\hat{\sigma}_{AR} = \sqrt{\frac{1}{N-1} \sum_{i=1}^N (AR_{i,t} - \overline{AR}_t)^2}, \quad \hat{\sigma}_{CAR} = \sqrt{\frac{1}{N-1} \sum_{i=1}^N (CAR_{i,S} - \overline{CAR}_S)^2}. \quad (8)$$

When standard assumptions hold, T_1 and T_2 follow Student t-distributions with $N - 1$ degrees of freedom.⁷ Following Benamraoui et al (2013), the impact of negative news announcements on country index betas is estimated using the following equation

$$\hat{\beta}_{it} = \hat{\beta}_{i,pre} + \hat{\beta}_{in} D_{in} + \omega_i, \quad (9)$$

where $\hat{\beta}_{i,pre}$ is index i's estimated pre-event beta, measured over [-201,-1] window prior to the announcement date. The subscript $n \in [1, +N]$ of D_{in} denotes the number of days after the event day t. $D_{i1}, D_{i2}, \dots, D_{iN}$ are dummy variables with a value of unity if $t \in [0, +1]$,

⁷ For robustness purposes, we also use Newey-West Heteroskedasticity and Serial Correlation Consistent estimator and J-Statistic of Campbell et al (1997). The conclusions are unchanged.

$t \in [0, +2], \dots, t \in [0, +N]$, respectively, and zero otherwise. $\hat{\beta}_{in}$ is the estimated change in the beta measured over the window of length n after the event date. The standard paired t-test and the non-parametric Wilcoxon Signed Rank Test are used to test if the pre-event and post-event betas are significantly different.

5.2 Multiple regression analysis

The following panel regression model is used to examine the relationship between investments in innovations and stock market reaction to the announcement of major bad news about the global economy

$$Y_{it} = \delta_0 + \delta_0 IV_{it} + \rho^T X_{it} + \tau_{it}. \quad (10)$$

To test our hypotheses, we estimate Equation (10) using the announcement day abnormal return AR_{i0} and then beta changes $\hat{\beta}_{in}$ as the dependent variables. Hypothesis 1 is tested by using AR_{i0} as the dependent variable in Equation (10). This hypothesis predicts that δ_0 will be positive and statistically significant. Furthermore, hypothesis 2 is tested by using $\hat{\beta}_{in}$ as the dependent variable. If this hypothesis holds, the parameter δ_0 will be negative and statistically significant. A specific innovation variable is denoted by IV and X represents the vector of control variables, namely TRADEOPEN, EXRATE, INFLATION, Credit/GDP and MV/GDP. All these variables are as previously defined (see Section 4) and their values are taken at the yearend prior to a given event. To avoid multi-collinearity related issues, the inclusion of highly correlated variables in the same regression model is avoided.

6. Empirical Results

The empirical results are presented in three subsections. Sections 6.1 and 6.2 are concerned with the crisis period from 2007. Section 6.1 discusses abnormal return estimates around informed negative shocks. Section 6.2 reports the changes in stock index betas following the announcements of negative news about the global economy. Section 6.3 presents the analogous results for the pre-crisis period 2001 to 2006.

6.1 Abnormal returns analysis

Table 3 reports the event day average abnormal returns and the post-event cumulative abnormal returns for all 27 countries in the study and for the four subsamples of countries classified using the four different innovation measures described above. The event day abnormal return is negative (-0.08%), but is not statistically significant different from zero. The cumulative abnormal return over the windows [0, 10], [0, 20] and [0, 30] following informed negative shocks are also not significantly different from zero. This suggests that on average the national stock indices of the 27 European countries in the study were not vulnerable to the announcement of negative news about the global economy during the recent financial crisis.

To test whether innovations affect stock market reactions to news about the global economy, we divided the 27 countries into three groups, high (30%), medium (40%), and low (30%), based on each of the innovation measures described in Section 4. Table 3 shows that event day abnormal returns increase with innovation. The event day abnormal return for countries in the low innovation groups are negative and significantly less than zero⁸ for three out of the four measures. The cumulative abnormal returns over the windows [0, 10], [0, 20] and [0, 30] associated with this particular group of countries are also negative and statistically significant, indicating that such a negative reaction is long-lived. The significantly negative cumulative abnormal returns observed over the windows [1, 10], [1, 20] and [1, 30] imply the presence of price continuation patterns following the arrival of bad news about the global economy. This finding is consistent with Lasfer et al (2003), who show that large negative index price changes are followed by negative abnormal price performance. It should be noted, however, that there is some evidence in Panels A and C of Table 3 that the effect is weakening by day 30.

Table 3 shows that the abnormal returns associated with the countries in the medium innovation groups are not significantly different from zero. However, countries in the highest innovation groups react positively to the arrival of negative news about the global economy. Specifically, the event day abnormal returns associated with countries with the 30% highest values of the classifiers GBAORD, RDEXPEND, EMPLOY and PATENT are 0.11%, 0.25%,

⁸ To allow for the time difference between locations, we also estimate cumulative abnormal returns in the event window [0, 1]. The conclusions remain largely unchanged.

0.29% and 0.19%, respectively. The cumulative abnormal returns over longer event windows [0, 10], [0, 20] and [0, 30], are positive and, with a few exceptions, statistically significant at the 1% level. This evidence suggests that positive market reaction to negative news about the global economy is long-lived. We also find positive price continuation patterns in the indices of countries in the high innovation groups with positive abnormal returns on event days followed by positive price performance in the windows up to 20 days.

Table 3 also provides the t-statistics for differences in cumulative abnormal returns between different innovation groups. Cumulative abnormal returns associated with countries in the high innovation groups are significantly higher than those in the low innovation groups. We also show that countries in the medium innovation groups tend to outperform those in the low innovation groups around the announcement of bad news about the global economy. These findings are robust to the different innovation measures.

Insert Table 3 about here

We use multiple fixed effects panel data regressions, Equation (10), with abnormal return on the event day as the dependent variable to verify the validity of the results after accounting for the effect of other well known determinants of country level returns.⁹ The Hausman test suggests that the use of fixed effects is more appropriate than a random effects specification for our data. Table 4 reports the coefficients of panel data regressions on the event day abnormal returns. The t-statistics are shown in parentheses. Consistent with the investors' confidence view, the coefficients on the innovation measures in Models 1 through 8 are positive and statistically significant. The coefficient of MV/GDP, which measures the relative size of the financial market, is negative and statistically significant. This finding is similar to the small firm effect but contradicts Martin and Rey's (2000) view that larger financial markets ought to exhibit higher asset prices. The remaining control variables are not significantly related the abnormal returns.

Overall, the results suggest that the index price reaction to negative shocks is positively associated with a country's innovativeness. While the positive association between

⁹ Our conclusions remain consistent when cumulative abnormal returns over longer windows post the informed negative shocks are used as the dependent variables in equation (10).

innovations and firm value is well documented in the literature (see Chan et al, 1990; Zantout and Tsetsekos, 1994; Eberhart et al, 2004, among others), this study is the first to show that stock markets in innovation-intensive markets react favourably to stressful economic circumstances. We argue that this evidence is consistent with Hypothesis 1, which suggests investments in innovations enhances investors' confidence in firms' ability to compete effectively during difficult times. This finding is also consistent with several other studies in the literature, which suggest that innovations can create future opportunities to provide firms with distinct competitive advantage. Rhodes and Stelter (2009), among others, posit that turbulent times bring with them opportunities and threats. Hartman (2009) argues that innovations increase the flexibility and the speed at which firms respond to changing conditions. Several studies argue that firms adapt to economic downturns by implementing business strategies centred on innovations. For example, Clifford (1977) and Picard and Rimmer (1999) posit that firms tend to respond to recession conditions by developing new products and targeting new market niches. Chou and Chan (2002) argue that innovations enable firms to attract customers by improving their quality and brand or maintaining low prices in price-sensitive markets. Thus, the positive abnormal returns observed in the case of stock indices of innovation-intensive countries following the arrival of bad news about the global economic may reflect the distinct competitive advantage and ability of innovative-intensive firms to adapt quickly and effectively to disruptive economic conditions.

Insert Table 4 about here

6.2 Changes in betas analyses

Table 5 presents the changes in market index betas following informed negative shocks. Panel A shows that the average pre-event beta is 0.8185. The paired-test suggests that the pre- and post-event betas are not significantly different from each other, except for the window [0, 30] in which a significant beta decrease is observed after informed negative shocks.¹⁰ This finding implies that, on average, the arrival of bad news about the global economy does not affect the uncertainty and the index betas of our sample countries.

¹⁰ Similar results are obtained when the non-parametric Wilcoxon signed rank test is used to test the statistical significance of the beta changes.

To investigate the relationship between the index betas and investment in innovations, countries are divided into high (30%), medium (40%) and low (30%) groups based on each of our four innovation measures. Consistent with Jensen's (1993) view that investment in innovations carries higher uncertainty, Table 5 shows that pre-event index betas increases with a country's innovativeness. For example, the average pre-event beta associated with countries in the high, medium and low GBOARD groups are 0.9765, 0.8366 and 0.63, respectively. Similarly, the average pre-event betas for countries in the high, medium and low RDEXPEND groups are 0.9588, 0.8407 and 0.6477, respectively. Similar, although weaker, patterns are also observed when countries are split according to EMPLOY and PATENT. The differences in the pre-event index betas between countries in the high and low innovation groups are statistically significant, irrespective of innovation measures.

Insert Table 5 about here

Table 5 also compares the pre- and post-event betas associated with the different innovation groups. The results suggest that innovations are important determinants of the index betas reaction to the arrival of negative news about the global economy. We show that changes in index betas tend to exhibit a negative association with a country's innovativeness. This relationship is particularly more pronounced in the cases of GBOARD and RDEXPEND and when post-event betas are measured over longer windows. For example, the average index betas of countries in the high GBOARD group exhibits a significant decline from 0.9765 over the window [-201, -1] to 0.9212 over the window [0, 30]. However, the average index beta associated with countries in the medium and low GBOARD groups experience a consistent increase up to 20 days after the event. This increase is statistically significant in the case of countries in the medium GBOARD group for event windows [0, 5] and [0, 10]. Similar findings are reported when RDEXPEND is a proxy for innovation. Specifically, the group of countries with the highest RDEXPEND experience a consistent decline in index betas over a 30-day period after informed negative shocks. This decrease is significant for windows [0, 20] and [0, 30] following the event. Countries in the medium RDEXPEND group exhibit significant average beta increase for up to 20 days post-informed negative shocks. However, the average betas of countries in the low RDEXPEND also declines in the post-event periods, but the decrease is only significant for windows [0, 20] and [0, 30]. The

variations of betas across different groups are much less pronounced when EMPLOY and PATENT are used as proxies for innovation.

We run multiple fixed effects panel data regressions (Equation 10 with $\hat{\beta}_{in}$ as the dependent variable) to investigate whether the results are robust after accounting for the effect of the control variables. The use of fixed effects regressions rather than random-effects are justified by Hausman tests. Table 6 reports the coefficients of panel data regressions on changes in betas for the window [0, 20] following the arrival of negative news about the global economy.¹¹ The t-statistics are shown in parentheses. Models 1 through 8 indicate the presence of negative association between index betas and innovation measures. However, this relationship is only statistically significant when GBOARD is used as a proxy for innovation. The coefficient on TRADEOPEN in Table 6 is positive and statistically significant, reflecting the fact that openness increases co-movements across stock markets (Li et al, 2004). The coefficient on INFLATION is also positive and statistically significant, implying that high inflation increases riskiness of firm's capital investment and stock beta (Pindyck, 1984). Finally, the significantly negative association between index beta changes and CREDIT/GDP indicates that stock market systematic risk is lower in countries with more developed banking systems. The statistical significance of the remaining explanatory variables, namely MV/GDP and EXRATE, is sensitive to the model specification. Furthermore, when the estimated coefficients of these variables are significantly different from zero, it is only at the 5% level.

The results of time varying beta analysis provide a partial support for Hypothesis 2, which predicts that the announcement of negative news has less negative impact on the riskiness of stock markets of the countries in the high innovation groups. The support is particularly more pronounced, when GBOARD is used as an innovation measure. While existing studies show that the arrival of negative surprises increases uncertainty and increase stock betas (see, for example, Brown et al, 1998; Kalay and Lowenstein, 1985; Patell and Wolfson, 1979), our results indicate that innovations may reduce uncertainty around negative surprises by enabling firms to exploit the opportunities and overcome the threats imposed by the global economic downturns. Thus, the reduced co-movement between stock indices of innovation-intensive countries and the World market portfolio may reflect the superior performance of highly innovative firms during crisis periods.

¹¹ The regressions are also run using betas for windows [0, 5], [0, 10], [0, 30] post the informed shocks. The results are consistent.

Insert Table 6 about here

6.3 The pre-crisis results

Thus far, the results suggest that innovation helps to restore investors' confidence and that stock indices of innovation-intensive countries react positively to the arrival of negative news during the financial crisis. To examine whether these results are unique to the crisis period, we investigate the stock market index reaction to the arrival of negative news prior the US subprime crisis that is from January 2001 to December 2006. In line with the earlier analysis, we use the bivariate BEKK GARCH-based event study methodology to estimate abnormal returns and time-varying betas. We also match the lowest 5th percentile of the DataStream World index returns with news announcements by the ECB to identify our events (that is, informed negative shocks). This matching resulted in 18 events over the pre-crisis period, with a mean (median) of -1.81% (-1.58%) and values ranging from -3.38% to -1.08%.

Table 7 presents the post-event abnormal returns associated with the entire sample and the three subsamples of countries ranked on their innovation measures. Panel A shows that the average abnormal return associated with the 27 European indices on the event day is significantly negative. The cumulative abnormal returns are also significantly negative up to 30 day following bad news announcements, implying that European stock indices underreact to the arrival of negative news. This finding is consistent with Lasfer et al (2003), who find that stock market indices underreact to both negative and positive shocks in the short-term. Table 7 also shows that the post-shock cumulative abnormal returns associated with high- and medium-innovation countries are not significantly different from zero. However, the cumulative abnormal returns of low-innovation countries remain negative and statistically significant up 30 days following the negative news announcements. This finding suggests innovation helps stock indices to absorb negative news more quickly. The stock indices of low innovation group exhibit larger price drops than those of high innovation group. The t-statistics indicate that the presence of some differences in the reaction between high- and low-innovation countries, but the statistical significance of difference is not consistent across innovation measures and estimation windows. Specifically, the differences in the cumulative abnormal returns of high and low innovation groups are only significant in the cases of

GBAORD and REDEXPEND over the windows [0, 20] and [0, 30], respectively. We also estimate Equation (10) using data from the pre-crisis period. We find GBAORD is the only innovation measure that affects the index price reaction to negative news. The coefficient on GBAORD is positive and statistically significant, implying that stock indices of countries with high GBAORD exhibit lower negative reaction to negative news than those in the low GBAORD category. The details of these results are omitted from the paper to save space, but are available from the corresponding author on request.

Insert Table 7 about here

We also examine the link between innovation and the changes in the stock index betas following the arrival of negative news in the pre-crisis period. The results in Table 8 indicate that the average index beta of the sample countries increase significantly from 0.5889 over the window [-201, -1] to 0.6875 over the window [0, 30]. The post-shock index betas increase significantly for the high-, medium- and low-innovation groups. This finding is robust to different innovation measures and estimation windows. Contrary to the results from the crisis period, the t-statistics in Table 8 also suggest that the index betas of high innovation countries increase more than those in the low innovation category. We estimate the pre-crisis data using multiple fixed effect panel data regressions, Equation (10), with $\hat{\beta}_{in}$ over the window [0, 20] as the dependent variable. We find that GBAORD is the only innovation measure that affects index beta changes. Specifically, the coefficient on GBAORD is negative and significant, after controlling for the country fixed effect and other determinants of the beta changes. This finding implies that the index betas of high GBAORD countries are less adversely affected by the negative news announcement. As above, these results are available on request.

Insert Table 8 about here

Overall, the pre-crisis data analysis provides some evidence that innovations may help to reduce the adverse effect of bad news announcement on the index prices and betas. However, the positive cumulative abnormal returns and the beta declines associated with

innovation-intensive country indices following negative news are unique to the times of crisis. This finding suggests that investors value innovation more during difficult times.

7. Implications and conclusions

The study uses country level data to test whether stock markets reward innovations. It contributes to the literature by linking innovations to investors' confidence in a country's ability to cope during times of economic and financial turmoil. We argue that if innovations enable firms and economies to develop distinct competitive advantage, which helps them to cope with difficult economic conditions and if investors can anticipate the rewards of innovations from a long-term prospective, the riskiness and value of stock market indices of highly innovative countries should be less vulnerable to the announcement of negative news about the global economy. We use the bivariate form of Engle and Kroner's (1995) BEKK model to investigate the price and beta reaction of the European stock market indices to arrival of major bad news during the recent global financial crisis.

The results of this study suggest that the stock market reaction to the arrival of negative news about the global economy do depend on a country's innovativeness. Specifically, we find that stocks in innovation-intensive economies offer higher returns and lower risk during crisis episodes. This evidence implies that innovation helps firms and economies to cope better during crisis. It also implies that assets in highly innovative economies offer investors opportunities to protect their wealth in crisis times. Further analysis suggests that the positive cumulative abnormal returns and the beta declines observed in the case of innovation-intensive country indices following negative news are unique to the crisis periods. This evidence suggests that investors value innovation more during difficult times.

Our findings also have important implications for both managers and policy makers. The positive index price reaction of innovation-intensive countries to the negative global economic outlook suggests that investors reward innovation. In other words, while commitments to R&D expenditures may hurt current earnings, they are necessary for competitive success (or even survival) during economic downturns. Thus, managers who are seeking to maximise shareholder wealth should continue to invest in innovation without fearing short-term negative effects on the stock price. Furthermore, as innovations contribute

to economic stability, policy makers who are concerned with sustainable economic growth should encourage R&D investments by adopting effective policies, such as R&D tax credits and direct subsidies of private R&D projects. Governments should also avoid unnecessary cuts in R&D expenditures even during the crisis periods, as cutting R&D expenditure may have a significant negative impact on competitiveness the long-term. Becker and Pain (2008), for example, show that the poor performance of the UK manufacturing sector during the 1990s was caused by the decline in UK government financing of R&D projects in the preceding periods.

The evidence reported in this study opens several other paths for future research. For example, it may be useful to investigate the relationship between investments in innovation and stock market liquidity during crisis episodes. This analysis may shed some light on the extent to which investors perceive innovative economies as places for safety during global economic downturns. Other extensions could shift the focus from stocks to other asset classes. For instance, it can be argued that if innovations promote economic stability, default risk of bonds and borrowing costs should exhibit a negative association with a country's innovativeness.

T-stat (M/L)	-10.57**	-14.57**	-12.75**	-8.48**

This table provides summary statistics for a sample of 27 European countries. Government budget appropriations or outlays on R&D as a percentage of GDP (GBOARD %), R&D expenditure as a percentage of GDP (RDEXPEND %), personnel and researchers in knowledge-intensive activities to total employment (EMPLOY %), and patent applications per million inhabitants (PATENT) are country level innovation measures. The variables are measured as yearend values 1-year ahead of each of the 20 informed negative shocks during the crisis. The 27 European countries are split into high (30%), medium (40%) and low (30%) groups according to these four innovation measures. The standard t-test is used to test the differences in innovations across the three groups. ** and * denote statistical significance at the 1% and 5% significance levels, respectively.

Table 2 Descriptive Statistics for Control Variables and Correlation Matrix during the Crisis Period

Panel A: Descriptive statistics

INFLATION	-0.41**	-0.37**	-0.44**	-0.36**	-0.07	-0.54**	-0.17**	0.12**	1

Panel A of Table 2 provides a summary statistics for the control variables, other than innovation measures, in equation (2). TRADEOPEN is measured by import plus export as a percentage of GDP; EXRATE is the US Dollar value of the local currency; INFLATION is the annual inflation rate; CREDIT/GDP is measured by domestic credit provided by the banking sector as a percentage of GDP; MV/GDP is measured by the market capitalization of listed companies as percentage of GDP. The variables are measured as yearend values 1-year ahead of 20 informed negative shocks during the crisis. Panel B presents the correlation matrix of these variables. ** and * denote statistical significance at the 1% and 5% significance levels, respectively.

This table reports average abnormal returns around and following the informed negative shocks by high/medium/low government budget appropriations or outlays on R&D as a percentage of GDP (GBOARD %), R&D expenditure as a percentage of GDP (RDEXPEND %), personnel and researchers in knowledge-intensive activities to total employment (EMPLOYMENT %) and patent applications per million inhabitants (PATENT). The t-statistics calculated using Equation (7) are used to test whether the CARs are significantly from zero. The standard t-tests are employed to test the differences between groups. ** and * denote statistical significance at the 1% and 5% significance levels, respectively.

This table shows the results of fixed effects panel regressions of the abnormal returns on the day of informed negative shocks for all the 27 European countries. Government budget appropriations or outlays on R&D as a percentage of GDP (GBOARD %), R&D expenditure as a percentage of GDP (RDEXPEND %), personnel and researchers in knowledge-intensive activities to total employment (EMPLOYMENT %), and patent applications per million inhabitants (PATENT) are innovation measures. TRADEOPEN is measured by import plus export as a percentage of GDP; EXRATE is the US Dollar value of the local currency; INFLATION is the annual inflation rate; CREDIT/GDP is the domestic Credit provided by banking sector as a percentage of GDP. MV/GDP is the market Capitalization of listed companies as a percentage of GDP. The t-statistics are shown in parentheses. ** and * denote statistical significance at the 1% and 5% significance levels, respectively.

This table reports average index betas before/after the informed negative shocks by high/medium/low government budget appropriations or outlays on R&D as a percentage of GDP (GBAORD %), R&D expenditure as a percentage of GDP (RDEXPEND %), personnel and researchers in knowledge-intensive activities to total employment (EMPLOYMENT %) and patent applications per million inhabitants (PATENT). The paired t-tests are used to judge whether the pre-event beta is significantly different from the post-event betas. The standard t-tests are used to test the differences in pre-event betas and changes in betas across the three groups. ** and * denote statistical significance at the 1% and 5% significance levels, respectively.

This table shows the results of fixed effects panel regressions of the Beta changes for [0, 20] post the informed negative shocks for all the 27 European countries. Government budget appropriations or outlays on R&D as a percentage of GDP (GBAORD %), R&D expenditure as a percentage of GDP (RDEXPEND %), personnel and researchers in knowledge-intensive activities to total employment (EMPLOYMENT %), and patent applications per million inhabitants (PATENT) are innovation measures. TRADEOPEN is measured by import plus export as a percentage of GDP; EXRATE is the US Dollar value of the local currency; INFLATION is the annual inflation rate; CREDIT/GDP is the domestic Credit provided by banking sector as a percentage of GDP. MV/GDP is the market Capitalization of listed companies as a percentage of GDP. The t-statistics are shown in parentheses. ** and * denote statistical significance at the 1% and 5% significance levels, respectively.

This table reports average abnormal returns around and following the informed negative shocks by high/medium/low government budget appropriations or outlays on R&D as a percentage of GDP (GBOARD %), R&D expenditure as a percentage of GDP (RDEXPEND %), personnel and researchers in knowledge-intensive activities to total employment (EMPLOYMENT %) and patent applications per million inhabitants (PATENT) during the period of Jan 2001 to Dec 2006. The t-statistics calculated using Equation (7) are used to test whether the CARs are significantly from zero. The standard t-tests are employed to test the differences between groups. ** and * denote statistical significance at the 1% and 5% significance levels, respectively.

Figure 1: Example of a CUMSUMSQ Test for Parameter Stability

The results of the CUMSUMSQ test indicates that the parameters generated from regressing Austrian stock market index returns against World index returns are not stable over time.
