Abstract

A new extensive submarine cold-seep area was discovered on the northern shelf of South Georgia during R/V Polarstern cruise ANT-XXIX/4 in spring 2013. Hydroacoustic surveys and video-based sea floor observations documented the presence of 133 individual gas bubble emissions, which were restricted to glacially-formed fjords and troughs. Effective methane transport from these emissions into the hydrosphere was proven by relative enrichments of dissolved methane in near-bottom waters. Stable carbon isotopic signatures of the methane pointed to a predominant microbial origin. Although known from many continental margins in the world’s oceans, this is the first report of an active area of methane seepage in the Southern Ocean. Our finding of substantial methane emission related to a trough and fjord system, a topographical setting that exists commonly in glacially-affected areas, opens up the possibility that methane seepage is a more widespread phenomenon in polar and sub-polar regions than previously thought.

Keywords: Cold seeps, gas bubble emissions, methane seepage, South Georgia

1. Introduction

Sea-floor hydrocarbon seepage occurs at numerous sites on the world’s ocean margins, from the continental shelves to the abyssal depths, in a variety of geological settings\(^1\)\(^,\)\(^2\). Notwithstanding several decades of global methane seep exploration, examples in the Southern Ocean are almost unknown. First videographic evidence of an Antarctic cold seep was obtained by Domack et al.\(^3\) from the seafloor beneath the collapsed Larsen B ice shelf, western Weddell Sea, located in the trough of the Evans and Crane glacier. This site was later revisited by Niemann et al.\(^4\), who classified the seepage as inactive, based on the presence of dead shells of seep-associated chemosymbiotic clams (*Calyptogena* sp.), a geochemical sea floor analysis, and the lack of hydroacoustically detectable gas
emissions. Apart from at this single extinct cold seep site, naturally occurring chemosynthetic organisms\(^5\) have also been found in the Southern Ocean at hydrothermal vents in the Bransfield Straight\(^6,7\) and the South Sandwich back-arc\(^8\), and at a whale fall from the Kemp Caldera\(^9\). The paucity of records of chemosynthesis-based communities in the Southern Oceans can be partly explained by a lack of exploration, due to the challenging and remote conditions in this region\(^10\).

The expanding numbers of seep locations discovered worldwide highlights the importance of methane seepage for the global carbon cycle, and its potential contribution to the oceanic and atmospheric methane inventory, where - in the latter case - methane acts as a potent greenhouse gas. In contrast to deep-water seep sites, where most bubbles dissolve during ascent through the water column and the dissolved methane is oxidized by microbes\(^11-13\), a fraction of gas emitted from shallow water environments may transgress the sea-atmosphere boundary, especially in storm seasons\(^14,15\). Therefore, shelf and upper slope areas such as off Spitsbergen\(^16,17\), in the Black Sea\(^18\), and off East Siberia\(^19\) are of particular interest when considering the role of methane seepage as a possible contributor to concentrations of methane in the atmosphere.

South Georgia belongs to the crustal blocks forming the North Scotia Ridge (Fig. 1a), which were once part of the continental connection between South America and the Antarctic Peninsula\(^20,21\). These crustal blocks were moved during the Cenozoic by backarc spreading and subsequent eastward growth of the Scotia Sea\(^20,22\). There is evidence for active convergence along the western side of the North Scotia Ridge, but convergence has now ceased along its eastern section, which includes the South Georgia block\(^20,23\). However, analyses of an earthquake with its epicenter located south of the South Georgia block (see Fig. 1b) indicates nearly pure thrust faulting, interpreted to represent thrusting of the Scotia Plate beneath South Georgia\(^24\). This tectonic framework shows that South Georgia is part of an isolated microcontinental block, divided by the W-E trending Cooper Bay Shear Zone that crosses the Island (Fig. 1b). This is the major tectonic boundary that displaces the late Jurassic to early Cretaceous basement complexes exposed on South Georgia\(^25\).
In contrast to the knowledge of the geologic and tectonic evolution of South Georgia, the shelf and upper slope area surrounding the Island have been less well studied. However, a recent comprehensive bathymetric compilation aimed at elucidating the paleo-ice sheet drainage of the Island has greatly improved our knowledge of the continental shelf morphology of South Georgia\textsuperscript{26}. Graham et al.\textsuperscript{26} described large eroded troughs linked to the recent fjords around South Georgia (Fig. 1b), and they proposed that these cross-shelf troughs were formed during glacial times and represent former pathways of outlet glaciers and ice streams. While probable Mesozoic sedimentary and volcanic rocks extend beneath the inner shelf of South Georgia, Cenozoic sediments form the outer parts of the continental shelf\textsuperscript{26,27}.

South Georgia is located in the path of the Antarctic Circumpolar Current (ACC). The Polar Front is located to the north and the southern ACC front loops anticyclonically around the island from the south before retroreflecting to the east\textsuperscript{28}. The shelf waters of South Georgia often show oceanographic properties that are markedly different from the open waters, indicating that local processes are important in dictating shelf water mass characteristics\textsuperscript{29}. Various shelf-specific processes have been observed, or inferred at South Georgia, and significant interannual variability of the oceanographic conditions on the shelf are known\textsuperscript{29,30}. Whitehouse et al.\textsuperscript{31} reported a surface water warming of up to 2.3°C in 81 years around South Georgia, however, this warming was not recognized in waters deeper than 200 m. In general, the special oceanographic conditions around South Georgia result in a rich ecosystem, with large phytoplankton blooms and related strong atmospheric carbon drawdown\textsuperscript{32,33}, as well as high organic matter sedimentation on the shelf. The seasonally occurring blooms are particularly intense on the northern shelf area of South Georgia and within the adjacent Georgia Basin\textsuperscript{32}.

In this study we performed a comprehensive hydroacoustic survey along the northern shelf of South Georgia, detecting numerous gas flares and analyzing their distribution. Subsequent sea floor visual observations of two of these flares revealed a detailed view of the seep sites. These data were correlated with oceanographic parameters and methane analyses in water column samples that
together illustrate methane-related processes taking place in the local hydrosphere. In addition, gas samples taken from sediment cores from the seep sites were analyzed for their stable carbon isotopic composition, which allowed us infer the source of the methane fueling them.

**Results**

**Hydroacoustic observations**

Hydroacoustic surveys revealed the presence of numerous gas emission sites at water depths between 130 and 390 meters below sea level (mbsl) on the northern shelf of South Georgia in spring 2013. The gas emissions appear as ‘flares’ in the echograms due to the high impedance contrast of free gas emanating as bubbles through the water column, which produce a high-backscatter signal (Fig. 2a). The flares are composed of vertically arranged oblique reflections that image the up-rising individual bubbles or groups of bubbles, and make them discernible from fish schools. In total, at least 133 individual flares were detected during our study (Figs. 3a and b, supplementary table S1). The flares showed largely straight and vertical orientation (e.g. the 170-m high ‘Cumberland Bay Flare’, Fig. 4c), indicating a lack of strong currents that would be expected to deflect the bubbles during their rise through the water column. Roughly ~75 % of the flares were less than 100 m high, with an average of ~70 m (supplementary table S1). However, three flares extended from the sea floor to a height of at least 25 mbsl. The uppermost part of the echograms was disturbed by acoustic noise that hampered differentiation of gas bubbles from plankton and/or fish. In general, the real flare height was difficult to determine using Parasound recordings, as the small ~4° opening angle and a coherent narrowing footprint with decreasing depth impeded the detection of the uppermost part of the flares when the ship did not pass exactly through the center of the bubble train.

Many flares detected were discontinuous or had no connection to the sea floor (Figs. 4a and b). This observation can be attributed to horizontal deflections of a bubble stream that moves in and out of the conical Parasound beam, or to pulsing gas bubble streams where the emissions are spatially and temporally variable. The latter explanation seems to be more likely in this case, as the tall flares
appeared vertical and didn’t show strong lateral deflections, although variable current regimes cannot be ruled out entirely.

The temporal variability of the flares was examined by imaging a given location more than once. Four flares became visible at the same location two times within ca. 14 days, whereas seven other flares appeared only once, although crossed twice (supplementary table S2). The observations of the flare appearance and the repeated surveys show that most flares probably are temporally variable on scales of minutes to weeks.

The detected flares were not randomly distributed along the South Georgia margin. They occurred either within the Cumberland Bay fjord system or within the other incised cross-shelf troughs that cut through the broad shelf surrounding the island (Fig. 3a). Two fjord systems were inspected for the occurrence of flares during cruise ANT-XXIX/4: Cumberland Bay was investigated intensively (Fig. 3b), whereas Possession Bay was entered once and inspected along only two survey lines. While numerous flares were observed in the Cumberland Bay region, no indication of gas emissions was found in Possession Bay. In total, more than 75 flares were detected in both branches of Cumberland Bay and within the cross-shelf to which the fjord system connects (designated as Trough 5 in Fig. 3b). Flares were distributed close to the fjord-mouth and within the fjord itself, but were not detected in the innermost parts of the bay close to the glaciers that discharge into the fjord at the coast. A few flares were found within the ~10 km area seaward of the fjord mouth, and one flare was detected as far as ~30 km from land. In addition to cross-shelf Trough 5, gas emissions were also found in four of the seven troughs defined by Graham et al. on the northern shelf of South Georgia (Fig. 3a). The northern shelf was passed for hydroacoustic surveys twice in a roughly two week interval and during both investigations flares were observed to be restricted to the troughs. No flares were detected on the shallower banks between the cross-shelf troughs and, with the exception of Troughs 2 and 7, all of the troughs surveyed showed gas emissions.
Sedimentary strata were not visible in subbottom Parasound SLF profiles of the shallow shelf banks (Fig. 4b), but the troughs were characterized by reflections indicating sediment accumulations of up to ~40 m in their centers (Figs. 4a). The reflections were sub-parallel to the sea floor and presumably reflect accumulations of sediment transported from the fjords to the shelf, and deposition within the cross-shelf troughs. Numerous zones of acoustic blanking or acoustically-transparent chimneys that pierced the horizontal reflections were observed for all of the sediment infills within the troughs (Figs. 2b, 4a, b and c), suggesting upward gas migration at these sites. The acoustic chimneys were positioned directly underneath the acoustic flares in the water column in several areas, strongly suggesting that the chimneys are the conduits for channeling free gas through the sediments towards the sea floor, where gas bubbles escape into the water column and form the flares imaged in the Parasound PHF echograms (Figs. 2b, 4a, b and c).

**Visual sea floor observations at the ‘Cumberland Bay Flare’**

An OFOS deployment was conducted at a flare site designated as the ‘Cumberland Bay Flare’ in order to visually confirm the sea floor origin of the gas flares recorded hydroacoustically (Fig. 4c), and the nature of the surrounding sediments. The sea floor was inspected along an approx. 400 m long track (Fig. 5). Visibility during the OFOS deployment was limited to a few meters because of the highly turbid and sediment-rich meltwater in the fjord and inspections were thus performed with an altitude of ~2 m. The flat sea floor was composed of unconsolidated sediments and detached kelp fronds (Figs. 6a and b), many of which were partially buried. The observed epibenthic invertebrate megafauna included cidaroid and echinoid sea urchins, asteroid starfish, holothurians, hexactinellid sponges, and fish (Fig. 6a).

Numerous centimetre-sized holes were visible in the sea floor along the OFOS track, which were probably produced by endobenthic organisms or may represent the orifices of emanating gas bubbles. Rising gas bubbles were observed at two seep sites during the OFOS deployment, which was guided by flare observations in the water column. Our observations document single gas bubbles emanating from the sea floor without forming continuous bubble streams. During an observation...
period of about 40 minutes at the southeastern located seep site (Figs. 5 and 6a), we documented more than 50 events (roughly about each minute), where a single bubble or small groups of 2 or 3 bubbles rose from the seabed. We observed individual rising gas bubbles again at a northwestern seep site, which is located ~50 m distant from the other and corresponded to a different water column flare (Figs. 5 and 6b).

At both seep sites the sea floor was covered by centimeter to decimeter-sized, subcircular, whitish material (Fig. 6a and b), occurring either as coherent patches or as collections of several smaller patches (Figs. 5 and 6a). These patches most probably represent microbial mats indicative of fluid flow from below. However, we did not see taxonomically higher chemosymbiotic organisms typically associated with cold seeps in other regions, such as bathymodiolin mussels or vesicomyid clams. The sea floor in two locations where whitish material was observed was slightly elevated and formed topographic mounds up to a few decimeters high (Fig. 6a). Fig. 5 illustrates that the whitish material is restricted to two areas a few meters in extent, both of which are located at the central foci of the two flares detected hydroacoustically.

**Water column characteristics in Cumberland Bay**

Three hydrocasts revealed a general water column stratification and specific differences in hydrological conditions in Cumberland Bay (station CTD-1 close to the ‘Cumberland Bay Flare’; CTD-2 close to the ‘Grytviken Flare’; see Fig. 3b) and a station seaward of the fjord (CTD-3). A pronounced surface layer (upper ~20 mbsl) was present at stations CTD-1 and CTD-2 in Cumberland Bay, characterized by relatively low salinities (<33 PSU), temperatures (<2.8 °C) and beam transmissions (<80 %). These characteristics suggest that this water mass (not observed at the seaward station; Figs. 7, supplementary Fig. S3) represents plumed meltwater and originates from the melting marine terminating glaciers that feed the bay (Fig. 3b). Physico-chemical properties varied only slightly with increasing depth throughout the midwater section. The lower limit of this water mass was found at ~165 mbsl for CTD-2 (located relatively deep within the fjord) and at ~190 mbsl for CTD-1 (located close to the fjord mouth), suggesting that its vertical extent is spatially variable and may reflect
topographically-controlled circulation patterns. Similar water characteristics at all three investigated stations indicate water exchange between Cumberland Bay and the shelf area of South Georgia. The lowermost water mass within and outside Cumberland Bay was characterized by relatively low temperatures (~2.4 – 1.7°C) and relative depletions in dissolved oxygen concentrations (6.5 – 5.2 mL/l), but with the highest salinities (up to 34.2 PSU). A markedly lower beam transmission (as low as 80% at the bottom) recorded for the near-bottom water mass within the bay, if compared to that at the outer shelf station, might be the result of a higher particulate matter load (see also chapter 4.2).

Strong enrichments in dissolved methane of up to 25.4 nmol/l and 55.6 nmol/l, respectively, were measured in the lowermost water mass characterized by low-beam transmission at the two CTD stations taken in close proximity to the ‘Cumberland Bay Flare’ and the ‘Grytviken Flare’ (Figs. 3b and 7). At these stations concentrations of dissolved methane decreased significantly with decreasing depth within the lower 100-120 meters of the water column down to ca. 5 nmol/l (Fig. 7), which is still slightly elevated in contrast to the atmospheric equilibrium (3-3.3 nmol/l). At the outer shelf station, where flares were not detected, dissolved methane concentrations of <5 nmol/l were measured though the whole water column.

**Stable carbon isotopic composition of methane**

Stable carbon isotopic analysis of methane in the gas samples extracted from the two sediment cores taken in close proximity to flares (GC-1 within cross-shelf Trough 6; GC-2 in the Cumberland Bay; Figs. 3a and b) revealed strong depletions in $^{13}$C, with $\delta^{13}$C-CH$_4$ values ranging between −80.2 and −88.9‰ (V-PDB). The greatest depletion came from a methane sample extracted at ~6.5 mbsf from the sediment core GC-2 at the ‘Grytviken Flare’.

**Discussion**

We detected 133 gas flares at the northern shelf of South Georgia (Fig. 3a) during R/V Polarstern cruise ANT-XXIX/4 in 2013. Visual sea-floor inspections with the high-resolution video camera of the OFOS system confirmed active seepage at the ‘Cumberland Bay Flare’ in the form of rising gas
bubbles and white sea-bed patches (Figs. 6a and b) interpreted as microbial mats fueled by methane emission. Hydroacoustically-imaged flares originated from sea floor locations that showed acoustically-blanked chimneys in the underlying sediments. In addition, water samples taken in bottom waters within two flares showed elevated concentrations of dissolved methane (Fig. 7), that proved methane transport by gas bubbles from the sea floor into the hydrosphere.

This new finding of methane seepage adds to the long and steadily growing list of seep areas in the world’s oceans\(^1,2,34\). At high latitudes, seeps are known in the Arctic and sub-Arctic, which have recently sparked particular scientific interest because of their links to permafrost settings\(^16\) with potential global warming effects\(^16\). Hydrothermal vents and cold seeps are known to host specialized faunal communities which are based on chemosynthesis\(^5,35\). In the Southern Ocean to date only a few chemosynthetic ecosystems are known\(^10\), including the presently inactive cold seep in the western Weddell Sea, hydrothermal vent fields and a natural whale fall\(^3,4,6–9\). The epibenthic invertebrate megafauna observed in the Cumberland Bay area comprises species commonly found around South Georgia\(^36–38\). Except for the inferred microbial mats chemosynthetic organisms usually found at cold seep sites were not found at the seeps investigated in this study. This might be because of the relatively shallow water depth (\(~250\) mbsl), since the typical animals obligate at cold seeps (e.g. species of vesicomyid clams, bathymodiolin mussels and siboglinid tubeworms) are restricted to aphotic habitats. Explanations for their absence on the continental shelves include the abundance of predators in shallower waters, or competitive exclusion by primary consumers limiting the presence of species dependent on chemoautotrophic symbionts\(^39\). The exact depth limit is not precisely resolved\(^40\), but the shallowest seep communities with the typical obligate species found so far are reported from the Eel River basin, offshore California in \(~350\) mbsl\(^41\) and in the Sea of Okhotsk in \(~370\) mbsl\(^39\). In our study we detected gas bubble seepage using hydroacoustics in the same depth range (ca. 380 mbsl), but did not investigate these sites visually. Thus, it remains a possibility that typical obligate cold seep animals are present on the deeper shelves around South Georgia.
As noted above, the flares detected during ANT-XXIX/4 along the northern shelf of South Georgia are not randomly distributed, but are restricted to the fjords and glacial troughs along the shelf (Fig. 3a), the latter accounting for ~15% of the total shelf area surrounding the island of South Georgia. Detailed surveys are required to determine further distribution and total abundance of such methane seep sites, which is probably significantly higher than the 133 flares we detected during the detailed but still spatially-limited surveys of R/V Polarstern cruise ANT-XXIX/4. A similar observation was made in a hydrocarbon seep area on the Baffin Bay shelf region, where oil and gas seeps were found within glacially-formed troughs seaward of fjord systems. In addition, seepage was inferred to occur in fjords in Spitsbergen and Norway, based on the presence of sea floor pockmarks. Fjords generally appear to represent favorable settings for methane seepage as they are commonly characterized by high sedimentation rates (due to high input from inflowing glaciers or meltwater streams). In addition, in some cases shallow water sills hamper water exchange with open seawater areas and ventilation, favouring anoxic conditions and protecting organic material from rapid microbial decomposition under aerobic conditions, which finally leads to large accumulations of refractory organic matter in the sediments. During our study we observed various sill structures in the high-resolution bathymetric maps of the South Georgia fjords, probably representing fjord moraines. However, these do not appear to fully restrict flow (Fig. 3b), as temperature, salinity and concentrations of dissolved oxygen are indeed lower in the bottom waters than in overlying water masses, but the values where similar in magnitude for all three stations, both within and outside the fjord. Therefore, there is no apparent isolation of the deep waters in Cumberland Bay (Figs. 7, supplementary Fig. S3). Bottom water oxygen concentrations within and outside the bay were ~5 mL/l (corresponding to ~220 µmol/l), indicating well-oxygenated conditions.

For Cumberland Bay, Platt estimated the sedimentation rate at $2.8 \times 10^3$ g m$^{-2}$ yr$^{-1}$ and an organic matter input of 60 g carbon m$^{-2}$ yr$^{-1}$, providing an ideal setting for shallow biogenic methane production. A biogenic methane source is proven by $\delta^{13}$C-CH$_4$ values $< -80$ ‰ (V-PDB) for all gas samples collected from the two sediment cores we investigated. Methanogens preferentially
consume substrates depleted in $^{13}$C, whereas thermogenic light hydrocarbons by non-selective hydrocarbon cracking are not affected by significant isotope fractionation effects. For a microbial hydrocarbon formation and accumulation both high sedimentation rate and the presence of sufficient amount of organic matter in the sediments is required. South Georgia lies in the eastward flowing ACC, creating a morphological high in the largest meander modifying the Southern ACC front. Due to this particular hydrographic configuration, intensive and regular phytoplankton blooms develop in the area north and northwest of the South Georgia shelf, leading to both a rich food web, and a high carbon production, which is either exported or ultimately deposited at the sea floor. Although there is no indication for deeply buried reservoirs of thermogenic gas fueling the gas emission sites investigated in this study, thermogenic gas migration through deep-rooted faults cannot be entirely excluded as the fjords and connecting cross-shelf troughs may have established along lines of structural weakness that could have evolved in association to faults zones. Unfortunately, there are currently no seismic data imaging the deeper structure of the South Georgia block to test such a hypothesis.

Due to the nature of our survey, most of the imaged flares were not centered directly under the vessel, thus, precluding a quantitative assessment of their intensities. However, our observations revealed that (1) most flares are only few tens of meters high, (2) flares often appear episodically and are characterized by discharge in pulses, and (3) flares indicative for individual bubbles or bubble groups are occasionally tilted, so that their sea floor origin could not always be traced (Figs. 4a and b). These data suggest that most of the flares are rather weak and represent discontinuous releases of gas bubble emissions. Visual inspection of the ‘Cumberland Bay Flare’ one of the most intense flares we imaged (Fig. 4c), showed sporadic gas bubble discharge from the projected flare origin, but also indicated that the sporadic release of individual gas bubbles was sufficient to cause a relatively intense signature in the corresponding echogram. Because our data demonstrate that the flares are temporally variable over minutes to weeks it may be possible that the activity and intensity of the gas emissions may also change seasonally or annually.
The quantity of bubbles and the intensity of seepage on the northern shelf of South Georgia seems to be rather weak in comparison to other seep areas, e.g. Hydrate Ridge, the Makran continental margin, Santa Barbara channel, as well as several seepage areas in the Black Sea, where vigorous gas bubble emissions and/or strong flares have been documented. However, the large number of emission sites as revealed from our flare imaging, in combination with the strong enrichments in dissolved methane, suggests injection of significant quantities of methane into the bottom water in fjords and the cross-shelf troughs of South Georgia, even though each individual seep may contribute only a small amount of methane.

Our hydroacoustic data additionally indicate that most gas bubbles released into the water column probably did not reach the upper water layer and atmosphere, but instead dissolved entirely during their ascent. With three exceptions, all 133 flares detected disappeared from the SBES echograms well below the sea surface. Although the geometric limitation of the SBES coverage, particularly at shallow depths, has to be considered, the fraction of methane transported as gas bubbles is not limited only by the maximum bubble rising height, but mainly depends on the effectiveness of gas exchange processes taking place when entering the hydrosphere, due to concentration differences. The proportion of methane initially contained in the bubble is rapidly replaced by dissolved nitrogen and oxygen from the ambient water. The rapidity of this process strongly depends on the bubble size, the rising velocity, as well as the composition and conditions of the surrounding medium and the presence of upwelling flows. Several studies have demonstrated that methane escapes the bubbles well before final bubble dissolution. Our suggestion that most of the methane discharged from the South Georgia northern shelf does not reach the upper water column is additionally strengthened by the relatively low concentrations of dissolved methane (about 5 nmol/l) in the intermediate to uppermost water masses at two hydrocast stations, deliberately acquired close to recorded flares in the Cumberland Bay area (Figs. 3b and 8). Most probably, the strong stratification of the water column, as evidenced by the T-S diagram (supplementary Fig. S3), impedes a regular vertical mixing within Cumberland Bay and the released methane therefore remains within
the bottom water, leading to the observed profiles. A fraction of this methane may be oxidized by microbial activity\textsuperscript{62}, so the measured concentrations reflect a balance between methane input and sea-floor consumption within Cumberland Bay and water exchange with the outer shelf water. It is hard to directly correlate water column data with flare strength, but our data agrees with our assumption that the methane transported via gas bubbles rapidly dissolves in the water body, so that most of the dissolved methane remains in the bottom water and that bubbles producing the hydroacoustic flares visible at that sites and reaching 50 m higher into the water column may have been depleted in methane.

We argue that the seepage around South Georgia is spatially related to the glacial trough and fjord system, a setting often occurring in sub-Antarctic regions that need further exploration to characterize the nature, distribution and magnitude of hydrocarbon seepage in this region. Research questions about methane seepage around South Georgia following from our study include: 1) unraveling the relationships between seepage, methane sources and rates of sediment accumulation, as well as the type and amount of organic carbon; 2) evaluating the potential contribution of thermogenic gas in some areas; 3) documentation of the biosphere and biogeochemical processes supported by the methane input; 4) establishing whether some of the deeper seeps support chemosynthetic fauna, and, if present, do they serve as ‘stepping stones’ for larval distribution of chemosynthesis-based organisms in the Southern Ocean; 5) constructing a carbon budget for the region, which includes source and consumption terms as well as the effect of circulation within and outside the fjords, and the circumstances under which this methane may reach the atmosphere.

**Methods**

**Hydroacoustic systems**

The data used for this study were acquired during R/V Polarstern cruise ANT-XXIX/4 in March and April 2013\textsuperscript{61}. Bathymetric mapping was performed using an ATLAS Hydrosweep Deep-Sea 320-beam echosounder operating at a frequency of \textasciitilde15 kHz and covering a swath width about four times the
water depth. Raw data were processed with CARIS 7.0 HIPS and SIPS and the MB-System software and the grids produced were visualized with ESRI ArcMap 10.0, which allowed for inclusion of additional relevant data to be plotted (e.g. track lines, locations of gas emissions). The cleaned Hydrosweep data were gridded with a cell size of 25 m. We combined our results with additional data from earlier cruises of the British Antarctic Survey (available at http://www.antarctica.ac.uk/bas_research/data/online_resources/sgbd/) and the GEBCO dataset (http://www.gebco.net/).

We used the ship-mounted parametric single beam echosounder (SBES) ATLAS PARASOUND for shallow subbottom imaging. The secondary low frequency (SLF) of about 4 kHz was recorded and processed online with the software ATLAS PARASTORE. The resulting PS3-files were imported to SENT (H. Keil, University of Bremen) and the data plotted. In addition, the SBES ATLAS PARASOUND was used for flare detection and imaging, using the primary high frequency (PHF) of about 18 kHz (Fig. 2a). The transducer opening angle is 4°, resulting in a footprint size of about 7% of the water depth. PARASOUND data as well as metadata are available at the PANGAEA data repository.

Seafloor observations
The Ocean Floor Observation System (OFOS), a towed underwater system equipped with a high-resolution digital camera (ISITEC, CANON EOS 1Ds Mark III), was used to visually inspect the sea floor in areas where flares were detected. The camera was programmed to take high-resolution (21 megapixels) photographs of the sea floor every 30 seconds at an altitude of about 1.5 – 2 m relative to the seabed. Underwater-navigation was achieved using the shipboard IXSEA Posidonia ultra short baseline system, with an accuracy of 5 – 10 m, and these data were used to establish the OFOS tracks and the positions of each photograph taken.

Water column analyses
Water column properties were studied by repeated hydrocasts with a 24-Niskin water bottle rosette and a CTD (Seabird, SBE 911+). Using the sensors of the CTD-unit, salinity, temperature, and pressure data were measured and, in addition, a Sea-Tech transmissometer recorded beam transmission and a SBE 43 sensor concentrations of dissolved oxygen. For quantification of methane concentrations in
the water column, 750 ml of sampled seawater were transferred from the Niskin bottles into pre-evacuated 1000 ml glass bottles immediately after recovery, followed by gas extraction according to the modification of the vacuum degassing method described by Rehder et al. The extracted gas samples were analyzed with a 6890N gas chromatograph (Agilent Technologies) equipped with a capillary column and connected to a Flame Ionization Detector, as described in Pape et al. Calibrations and performance checks of the analytical system were conducted regularly using commercial pure methane standards. The coefficient of variation determined for the analytical procedure was less than 2%.

**Stable carbon isotope signatures**

Three sedimentary gas samples each extracted from two gravity cores taken close to flare origins (GC-1: station PS81/280-1 in cross-shelf Trough 6, Fig. 3a; GC-2: station PS81/284-1 in Cumberland Bay, Fig. 3b) were analyzed for stable carbon isotope ratios of methane. The samples were obtained from depths between 6 and 9 meters below sea floor (mbsf), which was below the actual depth of the sulfate-methane transition (Chapter 9 in Bohrmann), and, thus, should not have been influenced by potential anaerobic oxidation of methane processes. Sediment (3 ml) was sampled from the bottom of each of the freshly cut core sections using cut-off syringes and transferred into 20 ml glass vials prefilled with 5 ml of 1 M NaOH. The gas was sampled for onboard methane concentration analyses and shore-based measurements of its stable isotope signature. Analysis of stable C isotope signatures of CH4 was conducted in the commercial GEO-data GmbH laboratory (Garbsen, Germany). Stable C isotope signatures are reported in δ-notation in parts permil (%o), relative to the Vienna PeeDee Belemnite (V-PDB) standard for carbon isotopes. The reproducibility of stable carbon isotope determinations is estimated at ±0.1‰.

**Acknowledgements**

We greatly appreciate the shipboard support from the master and crew of the research vessel Polarstern during cruise ANT-XXIX/4. This work was supported by the Deutsche Forschungsgemeinschaft (DFG) in the framework of the priority program ‘Antarctic Research with comparative investigations in Arctic ice areas’ by a grant to BO 1049/19 and through the DFG-Research Center / Cluster of Excellence „The Ocean in the Earth System“. AGCG was supported by Natural Environment Research Council (NERC) New Investigator Grant, NEK0005271, and by a fieldwork grant from the UK Quaternary Research Association (QRA) Research Fund. KL was supported by the ChEsSo programme (Consortium Grant NE/DO1249X/1) funded by NERC. CTSL acknowledges travel funds from the Earth Surface Sciences Institute, University of Leeds.

**Author contributions**

M.R. led the authorship of the paper. G.B. was principle scientist of R/V Polarstern ANT-XXIX/4. P.W. and A.G.C.G. took care of the processing of MBES data. G.K. and M.R. operated and analyzed the SBES data. S.M., P.G., and J.R. conducted hydrocasts and water column analyses. C.T.S.L., K.L., Y.M. and M.R. operated the OFOS and analyzed the video material. T.P., P.G. and J.R. provided the gas analyses. All authors contributed to the development of the paper.

**Figure captions**

**Fig. 1** a) Plate tectonic overview with the South Georgia microplate (SG) located at the eastern part of the North Scotia Ridge. SAM: South American Plate, SCO: Scotia Plate, SAN: Sandwich Plate, ANT:
Antarctic Plate (modified after Cunningham et al.\textsuperscript{20}). b) Map of the main tectonic structures of the South Georgia crustal block (after MacDonald et al.\textsuperscript{67}). The shelf morphology is characterized by at least ten cross-shelf troughs sourcing at the fjords of the island (yellow areas; Graham et al.\textsuperscript{26}).

**Fig. 2**  
a) Echogram recorded with the single beam echosounder (SBES) illustrating a flare composed of numerous oblique high-backscatter traces representing uprising gas bubbles. The footprint of the SBES at a water depth of \(~380\) mbsl corresponds to \(~30\) m to the width of the flare signal at the sea floor (white line). b) SBES echogram combing the water column data and the subbottom information (using 18 and 3.5 kHz frequencies, respectively). Gas emission sites are characterized by acoustic blanking in the subsurface (gas chimneys) and emissions of free gas in the water column causing hydroacoustic flares. For locations see Figs. 3a and b.

**Fig. 3**  
a) Map showing the shelf bathymetry with its characteristic cross-shelf troughs in combination with the ship track (black line) and flare positions (red dots) detected during R/V Polarstern cruise ANT-XXIX/4. Cross-shelf Troughs 1-7 at the northern shelf have been crossed in order to detect free gas in the subbottom and water column. Additionally, two fjords were investigated: the Possession Bay, where Trough 4 is sourced, and the Cumberland Bay, which is directly connected to Trough 5. b) Detailed map of the Cumberland Bay with the processed bathymetric data acquired during cruise ANT-XXIX/4. More than 75 flares were detected during the surveys within the fjord system.

**Fig. 4**  
Three profiles recorded with SBES combining subbottom (3.5 kHz) and water column (18 kHz) information. Flares are repainted in red. For locations see Figs. 3a and b. a) Profile 1 shows an echogram crossing the cross-shelf Trough 4. Several flares were detected, but the majority showed a discontinuous pattern most probably caused by pulsing gas bubble emissions. b) Profile 2 shows an echogram at cross-shelf Trough 6. In contrast to the shallow banks lacking visible sediment strata in the subbottom, the troughs are characterized by sediment accumulation. c) Profile 3 shows an echogram recorded during entering of the Cumberland Bay and crossing the ‘Cumberland Bay flare’.
Several acoustic chimneys characterized by vertical blanking zones illustrate up-rising free gas in the subbottom (red outlines with arrows) and additionally, three flares prove the emission of gas bubbles into the water column.

**Fig. 5**  a) Bathymetric map from ship-based swath echosounder recordings with the dive track of the Ocean Floor Observation System (OFOS; station PS81/285-1) passing two areas, where hydroacoustic investigations indicated gas bubble emissions from the sea floor (light red circles). Rising gas bubbles were recognized in both areas and whitish patches on the sea floor additionally proved the position of the seep sites (white dots).

**Fig. 6**  a) Sea floor picture taken at the Cumberland Bay Flare with the high-resolution video camera mounted on the frame of the Ocean Floor Observation System (OFOS) and showing an elongated mounded structure at the sea floor characterized by whitish color, probably representing microbial mats. b) Sea floor image taken at the northwestern flare area demonstrates the occurrence and intercalation of white colored and additionally dark grey colored patches. For locations see Figs. 3b and 5.

**Fig. 8**  Water column profile illustrating selected data recorded during three CTD casts acquired. Stations CTD-1 (colored dashed lines) and CTD-2 (colored solid lines) were located within the Cumberland Bay and CTD-3 (black lines) seaward the fjord mouth (see Fig. 3b). Elevated methane concentrations were measured in particular in the lowermost ~100 m at the two Cumberland Bay stations taken close to hydroacoustically detected flares. Bottom waters at that depth were characterized by low temperatures, beam transmissions and dissolved oxygen concentrations.

**Supplementary Fig. S3**  Temperature-Salinity diagram of the data from the three CTD stations during ANT-XXIX/4. T-S condition in surface waters at stations CTD-1 and CTD-2 located in the Cumberland Bay clearly differed from those at station CTD-3 positioned seaward (for locations see Fig. 3b).
