ABSTRACT: We report on a strategy for using SABRE (signal amplification by reversible exchange) for polarizing $^1$H and $^{13}$C nuclei of weakly-interacting ligands which possess biologically-relevant and non-aromatic motifs. We first demonstrate this via the polarization of acetonitrile, using Ir(IMes)(COD)Cl as the catalyst precursor, and confirm that the route to hyperpolarization transfer is via the J-coupling network. We extend this work to the polarization of protonitrile, benzylnitrite, benzonitrile and trans-3-hexenodinitrile in order to assess its generality. In the $^1$H NMR spectrum, the signal for acetonitrile is enhanced 8-fold over its thermal counterpart when [Ir($H_2$(IMes)(MeCN))]$^+$ is the catalyst. Upon addition of pyridine or $d_5$-pyridine, the active catalyst changes to [Ir($H_2$(IMes)(py)(MeCN))]$^+$ and the resulting acetonitrile $^1$H signal enhancement increases to 20- and 60-fold, respectively. In $^{13}$C NMR studies, polarization transfers optimally to the quaternary $^{13}$C nucleus of MeCN whilst the methyl $^{13}$C is hardly polarized. Transfer to $^{13}$C is shown to occur firstly via the $^1$H-$^1$H coupling between the hydrides and the methyl protons, and then via either the $^3$J or $^2$J-couplings to the respective $^1$Cs, of which the $^2$J route is more efficient. These experimental results are rationalized through a theoretical treatment which shows excellent agreement with experiment. In the case of MeCN, longitudinal two-spin orders between pairs of $^1$H nuclei in the three-spin methyl group are created. Two-spin order states, between the $^1$H and $^{13}$C nuclei, are also created and their existence is confirmed for MeCN in both the $^1$H and $^{13}$C NMR spectra using the Only Parahydrogen Spectroscopy protocol.

Keywords: Parahydrogen, Polarization, NMR, Nitriles

NMR is used extensively in molecular structure determination as well as in the elucidation of chemical reaction mechanisms. Its ubiquity as a method of choice in both areas is achieved in spite of the fact that NMR suffers from inherent low sensitivity due to the very small population differences that exist between probed nuclear spin states even when using the most expensive state-of-the-art NMR spectrometers. However, hyperpolarization techniques, such as DNP (dynamic nuclear polarization) and PHIP (parahydrogen-induced polarization), have been used with great success to overcome this sensitivity issue and are now being used more widely in mainstream NMR and MRI. Both DNP and PHIP use different approaches to redistribute the polarization of propionitrile, benzylnitrile, benzonitrile and trans-3-hexenodinitrile into target molecules through its participation as a reactant in a hydrogenation reaction. Para-$H_2$, although existing in a nuclear singlet state which renders it invisible to NMR, can be made visible by breaking its symmetry in the context of a chemical reaction.

Early investigations utilizing PHIP relied on the use of an inorganic catalyst to introduce the molecule into an unsaturated target such as an alkyne, thereby breaking its symmetry. In these types of reactions, the products are created with non-Boltzmann nuclear spin distributions and substantial signal enhancements are obtained when they are probed by NMR. Investigations employing this approach have been used to identify the involvement of molecules in catalytic reaction mechanisms that would otherwise have been NMR invisible. This approach has proved to be extremely effective but, as the target is chemically changed by the hydrogenation process, the reliance of PHIP on the existence of an unsaturated analogue to the target molecule has obvious consequences if the intention is to use PHIP as a means to hyperpolarize an agent for measurement in an MRI context. This shortcoming has been addressed in a refinement of the method which employs catalytic transfer of polarization rather than chemical by circumventing the hydrogenation step of PHIP. The approach is known as SABRE (signal amplification by reversible exchange) and it achieves hyperpolarization of a substrate by transferring polarization into the target molecule through the establishment of a J-coupled network during its temporary contact with a metal center that simultaneously binds with molecular para-$H_2$. The result is a technique which offers a quick and relatively simple route to hyperpolarize a wide range of molecules capable of interacting with a metal center. It has proved to work in conjunction with several NMR methods that enable analyte characterization and is also capable of facilitating the detection of molecules that are present in very low concentrations. The employment of a catalyst in SABRE is unusual in that its role is to transfer magnetism rather than to provide a lower energy chemical pathway. We and others have developed a range of catalysts for this purpose that include the highly-active species [Ir($H_2$(IMes)(py))Cl] (IMes = 1,3-bis(2,4,6-trimethylphenyl)imidazol-2-ylidene). This complex is formed from the air-stable precursor Ir(IMes)(COD)Cl, 1, (COD = cyclooctadiene) upon reaction with $H_2$ and pyridine. When undertaken in low field, continuously-polarized materials have been produced because SABRE is a reversible process that proceeds without chemical change of the analyte molecule.

In this study, we illustrate how it is possible to use SABRE to hyperpolarize a series of weakly-coordinating ligands including acetonitrile, the aromatic ligands, benzylcyanide and benzonitrile, as well as aliphatic ligands trans-3-hexenodinitrile and propionitrile. This work is extended to include, all of these ligands which correspond to motifs that can be found in a range of biologically-relevant materials, such as Anastrazole and key industrial reagents such as TCNE (tetracyanoethylene).
Furthermore, nitriles are very important industrially as solvents (e.g. acetonitrile and benzonitrile), in hydrocyanation reactions (exemplified in the DuPont process for the formation of adiponitrile)\(^6\) and in C–C bond activation.\(^{41, 42}\) We link our experimental observations together with theoretical modeling to provide further insight into the array of magnetic states created by the SABRE process.\(^{27}\) Many of these states are absent during thermal equilibrium NMR experiments that rely solely on simple interactions of nuclei with the applied magnetic field. The importance of such non-equilibrium states is reflected in modern multiple-pulse 1-D and 2-D methods.\(^{53, 44}\) Levitt, Bodenhausen and Warren’s uses of thermally-equilibrated magnetization in the creation of longer-lived pseudo singlet states\(^{45, 47}\) illustrate further how non-equilibrium states are being accessed and utilized. Consistent with these other methods, the use of para-H\(_2\), which itself exists as a long-lived singlet state, in polarization transfer experiments opens up further opportunities for creation and use of non-equilibrium states.\(^{13, 17}\)

The investigations we describe here employ the four isotopomers of acetonitrile that are listed in Scheme 1. These smaller-sized spin systems offer a significant advantage over those used earlier for SABRE, in so far as they offer the possibility to match more closely the experimental and theoretical models. This situation is not simply, if at all realistically, achievable with more complex spin topologies. For example, even if all of the relevant chemical shift and J-coupling parameters were known, full theoretical treatment of a model containing all of the 17\(^{1}\)H–spins associated with the pyridine and hydride ligands of [Ir(H\(_2\))(IMes)(MeCN)(py)]Cl under the strong coupling Hamiltonian is required. This is beyond the capabilities of normal desktop computation. Indeed, the challenges of fitting experimental and theoretical measurements to the SABRE effect have been commented upon,\(^{48}\) and others have recently described how careful consideration of the role of the catalyst is paramount.\(^{33, 49, 50}\) We also show here that high levels of hyperpolarization in the associated \(^{1}\)H and \(^{13}\)C nuclei of these cyano-containing derivatives can also be produced in order to illustrate the technique’s potential as a characterization aid and a possible route to chemical agents that are highly visible to MRI.

**Results and Discussion**

In this work, a \(d_1\)-MeOH solution of A and 1 was first exposed to 3 bar para-H\(_2\), to form [Ir(H\(_2\))(IMes)(MeCN)(py)]Cl, 2. When this reaction was completed in a magnetic field (referred to as the polarization transfer field or PTF) of 65 G, the resulting \(^{1}\)H NMR signal for free acetonitrile was observed three seconds later with an intensity 8-fold larger than its normal, fully-relaxed level. This is due to SABRE and clearly confirms that 1 is able to catalyze the transfer of the spin order of para-H\(_2\) into A. However, when the same sample was reexamined five minutes later, after the introduction of fresh para-H\(_2\), the enhancement seen for the protons of A had fallen to 3-fold. Whilst in both these measurements 2 was seen, it is clearly not itself an efficient SABRE catalyst for A. The fact that stronger SABRE enhancement was seen during the conversion of 1 into 2, and hence before the reaction reached completion, reveals that the introduction of para-H\(_2\) into 2 could be limiting. Hence we added phenylacetylene to the \(d_1\)-MeOH solution to see if it would increase the hyperpolarization level of A. This approach has been used successfully in related studies to increase the detectability of metal dihydride complexes by forcing H\(_2\) exchange.\(^{52}\) However, this treatment proved unsuccessful here, although weak PHIP was observed in the alkene proton resonances of the product styrene which reflects the relatively poor hydrogenation activity of 2 (see SI).

In the light of this result, a small amount of pyridine was introduced as a co-substrate into the reaction system such that the acetonitrile to pyridine ratio was 20:3. Now the methyl protons signal of A, seen in emission, was 9-fold enhanced and remained observable at this intensity for over an hour when the polarization transfer process was repeated. These investigations also revealed that 2 is converted into cis-cis-[Ir(H\(_2\))(IMes)(MeCN)(py)]Cl, 3. This reactivity matched that predicted by density function theory (DFT) calculations which revealed 3 to be more thermodynamically stable than 2 (see SI). It also predicted that cis-cis-[Ir(H\(_2\))(IMes)(MeCN)(py)]Cl is stable, although 3 is lower in energy. We conclude based on these observations, and our DFT data, that 3 is more efficient at hyperpolarizing A than 2.

The three \(^{1}\)H signals for free pyridine were also observed in this NMR spectrum in emission, with a collective 20-fold enhancement. Furthermore, the proton signals for equatorially-bound pyridine of 3 were also enhanced. In contrast, the protons of the axially-bound pyridine ligand of 3 failed to show any observable hyperpolarization. This tells us that the transfer of polarization in the plane \(trans\) to hydride is more efficient than that in the plane at right angles to it.

![Diagram](image)

Scheme 2: Reaction pathways to form 2 and 3 from 1 (Cl\(^{-}\) and the reaction product cyclooctane omitted for clarity). 3 yielded \(^{1}\)H NMR signals for its two magnetically-inequivalent hydride ligands at \(\delta = 20.56\) and \(\delta = 22.12\) where the former is \(trans\) to acetonitrile and the latter \(trans\) to pyridine (see SI). Both these hydride signals show PHIP in these measurements and when EXSY methods are used to examine 3, pyridine and A ligand exchange processes were readily observed. The experimentally-determined rate constant for pyridine loss from 3 proved to be 1.72 and 0.33 s\(^{-1}\) for the equatorial and axial ligands, respectively, at 298 K. In contrast, the experimentally-determined rate constant for the loss of A was 10.42 s\(^{-1}\) and, therefore, six times larger than that of equatorially-bound pyridine. The experimentally-determined rate constant for hydride interchange in 3 proved to be 5.80 s\(^{-1}\). No evidence of hydride exchange into H\(_2\) was apparent in these measurements, even though PHIP is visible in the hydride signals of 3. The mechanisms of ligand loss in related systems have recently been reported.\(^{51}\) The lifetime of 3 under these SABRE conditions was 0.096 s. Consequently, if polarization transfer into A and pyridine were to be equally efficient, then the hyperpolarization of A should dominate given its more rapid dissociation. Experimentally the reverse is true thus polarization transfer into pyridine must be far more efficient than into acetonitrile.

In the corresponding \(^{1}\)H–\(^{1}\)H COSY spectrum of 3, the hydride ligands showed evidence for spin-spin coupling to their respective \(trans\)-pyridine and \(trans\)-A ligands. These data concur with our suggestion that 3 hyperpolarizes A and pyridine by SABRE through its J-coupling network.\(^{52}\) However, polarization transfer in 3 is complicated by the fact that its hydride ligands are both magnetically- and chemically-distinct from one another. This
means that SABRE transfer in 3 could proceed not just in the equatorial plane but also into the axial ligands as they also see different hydride couplings. However, the slower exchange of the axial ligand allows us to critically demonstrate that it does not receive any direct polarization transfer. The small cis-hydride coupling, therefore, precludes the observation of polarization transfer into this ligand (confirmed experimentally as noted above). In stark contrast, for 2, transfer proceeds only into the ligands in the equatorial plane which are trans to hydride.

Nonetheless, while 3 achieves the 9-fold signal enhancement of A (in a PTF of 65 G), it can be readily optimized further. In order to do so, these measurements were conducted using a mixing chamber and flow probe apparatus\textsuperscript{30, 49} and the results are illustrated in Fig. 1(a). It is important to note that zero PTFs are not achieved from those actually observed for ease of viewing. Whilst the field-coil in the mixing chamber on a 0 G setting delivers a zero field, the resultant field experienced by the sample is better approximated by the Earth’s field. Therefore, an experimental setting of zero should be regarded as 0.5 G. This field value was used in producing the theoretically derived spectra which we compare to our experimental spectra.

Experimentally, an emission signal is seen for the CH\textsubscript{3} proton signal of A at all of the probed PTF values, with the maximum signal intensity, corresponding to a 20-fold signal enhancement, being seen at 80 G. Note the convention which we use here: the hyperpolarized signals appear in emission in contrast to the thermal signals which appear in absorption. Therefore, the enhancement in the above case is 20-fold with a sign change which technically could be stated as a -20-fold enhancement. This may appear somewhat contradictory to some readers and so we have stated enhancements as positive amounts throughout. Likewise, in some of the spectra presented, we have inverted the signal phases from those actually observed for ease of viewing.

Whilst \textlessthan;10% pyridine polarization\textsuperscript{30} has previously been reported, a 20-fold signal enhancement still far exceeds the signal gain achieved using a cryoprobe.\textsuperscript{53, 54} Here our aim was to explore the SABRE effect using nitrile-containing substrates. We did not seek to produce an optimized catalytic system, although we aimed to develop a strategy to aid in this development.

In order to gain insight into the characteristics of hyperpolarization transfer via SABRE, theoretical calculations were performed using the approach reported previously,\textsuperscript{23} the results of which are shown in Fig. 1(b). These calculations explore the evolutions of the resulting spin systems through a spin density operator treatment under the strong coupling Hamiltonian and were performed using Mathematica.\textsuperscript{35} The theoretical predictions accord well with the observations made in the experiment.

![Figure 1: (a) Plot of the \textsuperscript{1}H NMR signal intensity seen for free CH\textsubscript{3}CN as a function of the PTF (indicated); data produced by a CD\textsubscript{3}OD solution containing I (10 mg), CH\textsubscript{3}CN (0.1 M) and pyridine (0.02 M). (b) Matching theoretical plot of the predicted \textsuperscript{1}H NMR signals. The phase of the detected signals has been inverted for ease of viewing. The level of hyperpolarization observed for the methyl protons of acetonitrile can be further increased when the H-pyridine used as a co-substrate is replaced by d\textsubscript{5}-pyridine. This is a consequence of the fact that polarization is not transferred effectively into the \textsuperscript{2}H-nuclei of the deuterated ligands because of the greatly-reduced hydride-\textsuperscript{2}H J-couplings compared to the hydride-\textsuperscript{2}H J-couplings and their frequency difference. Instead it is transferred into the polarization transfer receptors of 3 that remain, the three protons of A and potentially those in the IMes ligand. In this case a 60-fold increase in signal strength for A was observed when the PTF was 80 G rather than the 20-fold enhancement described earlier. Therefore, there is a net 3-fold increase in acetonitrile signal polarization upon changing from H-pyridine to d\textsubscript{5}-pyridine.

In order to test more comprehensively the potential role of the IMes ligand in the polarization transfer process, the analogous complex with a deuterated IMes ligand was prepared. Samples consisting of either I or Ir(IMes-d\textsubscript{5}CN)(COD)(Cl)\textsuperscript{11} in the presence of 20 equivalents of pyridine and 4 equivalents of A were then compared and found to give almost identical enhancements for A after being shaken in each of a PTF of 0.5 or 80 G. A series of EXSY measurements on cis-cis-[Ir(H\textsubscript{2})(IMes-d\textsubscript{5}CN)(PCy\textsubscript{3})(py)]\textsuperscript{1+} revealed that pyridine and A loss occurred on the same timescale to those observed for I, within the limits of experimental uncertainty. Furthermore, vibrational analysis of the CO stretch in the two related Ir(CO)\textsubscript{2}(NHC)(Cl) complexes revealed a 4 cm\textsuperscript{-1} difference in their frequencies and thus is indicative that both the protoi and deuterio NHCs have comparable electron-donating abilities (confirmed further by DFT calculations - see SI). The IMes ligand in these complexes, therefore, plays a minimal role as an acceptor of polarization, and deuteration of the co-ligand pyridine clearly provides for the best route to increase SABRE efficiency.

We note, however, that upon the addition of 1.1 equivalents of PC\textsubscript{3}Y (Cy = cyclohexyl) to these samples, a significant difference is observed. The PC\textsubscript{3}Y ligand binds by displacing the axial pyridine and forms [Ir(IMes)(MeCN)(PC\textsubscript{3}Y)(H\textsubscript{2}CN)]\textsuperscript{14} (4). Thus the PC\textsubscript{3}Y ligand in 4 is placed trans to the IMes ligand and cis to both the hydride ligands. I now proved to be 100% more effective at polarizing A than 4-d\textsubscript{5}Y. In contrast, when the 4-d\textsubscript{5}Y derivative was examined identical polarization levels resulted. Hence when PC\textsubscript{3}Y is located in the axial position different SABRE behavior is seen and now deuteration of the axial ligand acts to improve efficiency. These observations confirm that polarization transfer into the axial groups leads to a reduction in SABRE activity with some catalysts.\textsuperscript{51}

As indicated earlier in this paper, our theoretical calculations, in which we assumed a single MeCN ligand coming into contact with the metal center of the catalyst, reproduced the experimental behavior well for both the \textsuperscript{1}H-spectra. These calculations show that the key spin-system parameters in 3 are the 2-bond hydride-hydride coupling, the 5-bond trans hydride-A coupling, and the lifetime of the H-Ir-NCMe interaction. These were determined experimentally; the splitting \textsuperscript{2}J\textsubscript{HH} was measured at \textapprox;7.6 Hz, the trans \textsuperscript{2}J\textsubscript{HH} at 2.1 Hz, and the lifetime of 3 at 0.096 s. The lifetime was obtained from the rate of exchange of A with the metal center of J determined under saturation kinetics as necessary for a dissociative process. Close agreement between the theoretical and experimental spectrum resulted when the \textsuperscript{1}J\textsubscript{HH} value was set to \textapprox;6.7 Hz, \textsuperscript{2}J\textsubscript{HH} to \textsim;2.1 Hz, and the complex lifetime set to 0.096 s (see SI for further details of the parameters used in the theoretical calculations). Furthermore, the sign of \textsuperscript{2}J\textsubscript{HH} controls the sign of the coefficient defining the observed hyperpolarization amplitude, and hence the phase of the signal, which in this case are both negative.

The \textsuperscript{1}H NMR signals that were detected in these measurements were encoded using a \textpi/2 pulse. The observed peaks reflect the
measurement of longitudinal magnetization as would be created in a normal NMR measurement, albeit with much higher absolute amplitude. Additionally, the formation of three two-spin order terms, such as $2I_1zI_2z$, and the three-spin order term, $4I_1zI_2zI_3z$, are predicted according to our theoretical modelling to be formed under SABRE in A. However, such two- and three-spin order terms are not visible after a $\pi/2$ measurement pulse (or indeed any pulse angle) because the spins are completely magnetically equivalent. Normally, when at least one nucleus is magnetically inequivalent, OPSY can be employed to view and differentiate these terms (see SI for description). In the case of A this should not be possible because of the magnetic equivalence of the methyl protons. However, a small residual signal was observed for A in the $^1$H double-quantum filtered OPSY spectrum. Similar signals were also observed for B and C where their magnitude relative to the hydride peak at $\delta = -22.12$ was 0.05–0.1%, whereas it was 6% for A. Given the fact that we are dealing with the creation of hyperpolarized states low levels of residual magnetization might be expected.

As well as the $^1$H homonuclear longitudinal two-spin order terms, corresponding polarized coupled states between protons and the $^{13}$C nuclei are also predicted to be produced simultaneously via SABRE. This provides a route of polarization transfer to $^{13}$C. Indeed, it has been reported that $^{13}$C nuclei can be successfully polarized using SABRE when a $^{13}$C NMR measurement was made on a sample of A, $d_7$-pyridine and 3 under 3 bar para-H$_2$, at the same concentrations as those listed in Fig. 1 and following evolution at a PTF of 0.5 G, a hyperpolarized signal for the quaternary $^{13}$C in natural abundance of free A at 116.7 ppm was observed with a S/N ratio of 11 in a single scan measurement. This appeared as an antiphase quartet with relative intensities $1:1:1:1$ and a splitting of 9.2 Hz. It is important to note that no signal was observed for the methyl $^{13}$C resonance in this measurement (see SI).

In order to probe polarization transfer to $^{13}$C more effectively, the $^{13}$C labeled materials B and C shown in Scheme 1 were employed together with 1 and $d_7$-pyridine. Firstly, for B, where the $^{13}$C label is located at the methyl site, its $^1$H signal was observed to hyperpolarize and yielded a 14-fold enhancement following polarization transfer in an optimal PTF of 80 G. The drop in $^1$H hyperpolarization level, relative to that seen for A, can be associated with the extra $^{13}$C nuclear spin, in 100% abundance, which causes a significant increase in the number of available magnetic states that can be populated (many of which are not directly observable).

Transfer of hyperpolarization to the methyl $^{13}$C nucleus, albeit very weak, was also observed (see Fig. 2(a)). This signal appeared as a 1:1:3:0.3 multiplet with a 136 Hz splitting, simulated theoretically in Fig. 2(b), instead of the expected 1:3:3:1 profile. The difference in intensity between the hyperpolarized and the thermal NMR spectra was actually very slight. The calculated relative contributions to the spectrum of the thermal and polarized components are 3:1. When we monitored the $^{13}$C spectra as a function of PTF we saw no change in the efficiency of polarization transfer even when the PTF of our apparatus was set to 0.5 G, in order to minimize the $^1$H-$^{13}$C Zeeman frequency difference. As noted in the SI, this equipment setting does not achieve a resultant zero field and the actual field produced by the apparatus was insufficiently low to produce an effectively enhanced signal. We note, however, that the methyl $^{13}$C resonance can also be observed as a weakly-hyperpolarized signal under INEPT transfer from the CH$_3$ protons. Our theoretical calculations agreed with this low level of polarization transfer and showed that a PTF of 5 mG would be required to effect efficient polarization transfer into the methyl $^{13}$C nucleus.

![Figure 2: $^{13}$C NMR spectra of the methyl $^{13}$C of B obtained after hyperpolarization in a PTF of 5 G obtained using 8 scans (a) and theoretically calculated (b).](image)
In contrast, when $\text{C}$ is studied, its quaternary $^{13}\text{C}$ signal at $\delta$ 116.7 and 140 G. However, the theoretical model of these data only

becomes strongly hyperpolarized at a PTF of 0.5 G yielding a signal for a 0.1 M sample in a single shot experiment with a S/N value of 105 as shown in Fig. 3(a). We obtained excellent agreement between the experimental and theoretical spectra of free $\text{C}$ recorded and calculated following evolution in a PTF of 0.5 G as seen in Fig. 3(b). Fig. 3(c) shows, the corresponding PTF plot which reveals enhancement maxima at 0.5 G and 100 G are observed. The bound quaternary $^{13}\text{C}$ signal for equatorial $\text{C}$ of 3 is also readily observed experimentally at $\delta$ 117.8. Again no significant hyperpolarization of the methyl $^{13}\text{C}$ signal was detected (Fig. 3(a)). In the corresponding $^1\text{H}$ NMR spectrum, the free methyl group signal enhancement for $\text{C}$ was 12-fold at the optimum PTF of 90 G. Over the PTF range of 0 – 140 G, these signals generally appear as antiphase doublets. They are observed with unequal line amplitudes resulting from varying contributions of the theoretically-predicted longitudinal magnetization and longitudinal two-spin order terms. Analysis of the experimental spectra revealed that the longitudinal two-spin order terms were the dominant terms at all fields except 90 and 140 G.

Figure 3 (a): Single scan $^{13}\text{C}$ NMR spectrum of free $\text{C}$ ($\delta$ 116.7, 15.5 $\mu$L) in the presence of 1 (10 mg) and $d_5$-pyridine (3.75 $\mu$L). Hyperpolarization transfer was completed in a PTF of 0.5 G. The inset trace shows the corresponding methyl $^{13}\text{C}$-region, magnified 128 times relative to the main trace. The antiphase multiplet at 117.8 ppm is due to the quaternary $^{13}\text{C}$ signal of bound $\text{C}$ in 3; (b): Experimental (upper) and theoretically calculated (lower) $^{13}\text{C}$ NMR spectra of the quaternary signal of $\text{C}$ after hyperpolarization in a PTF of 0.5 G; (c) $^{13}\text{C}$ field plot of $\text{C}$ after hyperpolarization transfer using 1 over the PTF range of 0.5 to 140 G at intervals of 20 G collected experimentally (left) and theoretically calculated (right).

![Figure 3](image)

In the experimental intensity versus field profile for the quaternary $^{13}\text{C}$ resonance shown in Fig. 3(c), that is detected after a $\pi/2$ pulse, a complex intensity variation with increase in PTF is observed with a reversal of the signals sign being seen between 120 and 140 G. The bound quaternary $^{13}\text{C}$ signal enhancement maxima at 0.5 G and 100 G are observed in Fig. 3(b). Fig. 3(c) shows, the corresponding PTF plot recorded and calculated following evolution in a PTF of 0.5 G.

In contrast, when $\text{C}$ is studied, its quaternary $^{13}\text{C}$ signal at $\delta$ 116.7 and 140 G. However, the theoretical model of these data only

produced the signal reversal in this field range when the rate of loss of $\text{C}$ was set to $55 \text{s}^{-1}$, corresponding to a residence time of the ligand on the catalyst of 0.018 s. The profile is also sensitive to small variations in the hydride-hydride $J_{\text{HH}}$ coupling. When the experimentally-determined rate of exchange of $\text{C}$ (10.42 s$^{-1}$, corresponding to a residence time of 0.096 s) is employed in the calculation, the reversal occurs at around 70 G. We are working to understand this difference.

Our theoretical calculations involving $\text{C}$ confirmed that SABRE creates longitudinal two-spin order terms, $2I_kS_z$ ($k = 1, 2, 3$), where the $I_k$ spins are proton nuclei of the three-spin methyl group and $S$ is the quaternary carbon. The terms resulting from these states after a $\pi/2$ pulse dominate the spectra. No $S_z$ longitudinal magnetization terms are produced with any meaningful amplitude at PTF’s other than pure (theoretical) 0 G. This is because of the large $^1\text{H}$-$^{13}\text{C}$ Zeeman frequency difference at anything other than the most minute PTFs. The initial magnetization created after a $\pi/2$ rf pulse to $^{13}\text{C}$ is $2I_5S_z$, and antiphase with respect to a single $J_{\text{CH}}$ coupling. Further calculation of the evolution of $2I_5S_z$ within a four-spin system under a weak-coupling Hamiltonian during the FID acquisition obtained the following modulations of the real part of the observable terms: 90\degree out-of-phase oscillations with respect to $I_2$ and $I_5$, in-phase oscillation with respect to $I_1$.

Figure 4: $^1\text{H}$ (a) and $^{13}\text{C}$ (b) NMR spectra of a CD$_3$OD solution (0.6 ml) consisting of 1 (2 mg), $\text{C}$ (3.1 $\mu$L) and $d_5$-pyridine (0.75 $\mu$L) obtained using a modified OPSY sequence in which the double quantum coherence originating from the $2I_5S_z$ starting state ($I_k$ are $^1\text{H}$

In the experimental intensity versus field profile for the quaternary $^{13}\text{C}$ resonance shown in Fig. 3(c), that is detected after a $\pi/2$ pulse, a complex intensity variation with increase in PTF is observed with a reversal of the signals sign being seen between 120 and 140 G. However, the theoretical model of these data only

produced the signal reversal in this field range when the rate of loss of $\text{C}$ was set to $55 \text{s}^{-1}$, corresponding to a residence time of the ligand on the catalyst of 0.018 s. The profile is also sensitive to small variations in the hydride-hydride $J_{\text{HH}}$ coupling. When the experimentally-determined rate of exchange of $\text{C}$ (10.42 s$^{-1}$, corresponding to a residence time of 0.096 s) is employed in the calculation, the reversal occurs at around 70 G. We are working to understand this difference.

Our theoretical calculations involving $\text{C}$ confirmed that SABRE creates longitudinal two-spin order terms, $2I_kS_z$ ($k = 1, 2, 3$), where the $I_k$ spins are proton nuclei of the three-spin methyl group and $S$ is the quaternary carbon. The terms resulting from these states after a $\pi/2$ pulse dominate the spectra. No $S_z$ longitudinal magnetization terms are produced with any meaningful amplitude at PTF’s other than pure (theoretical) 0 G. This is because of the large $^1\text{H}$-$^{13}\text{C}$ Zeeman frequency difference at anything other than the most minute PTFs. The initial magnetization created after a $\pi/2$ rf pulse to $^{13}\text{C}$ is $2I_5S_z$, and antiphase with respect to a single $J_{\text{CH}}$ coupling. Further calculation of the evolution of $2I_5S_z$ within a four-spin system under a weak-coupling Hamiltonian during the FID acquisition obtained the following modulations of the real part of the observable terms: 90\degree out-of-phase oscillations with respect to $I_2$ and $I_5$, in-phase oscillation with respect to $I_1$.
and 90° out-of-phase oscillations with respect to the chemical shift of S, all of which are 180° phase shifted from original 2J(S,  S) terms. The couplings between I, J, K, and S are all equal and this result is in a cos(\[\text{Jерт} \times \sin(\text{Jерт}) \times \sin(\text{Oertz})\]) modulation. It is the combination of these effects that produces the unusual [1-1:1:1:1] multiplet seen in these measurements (Fig. 3(a)). Three-spin order terms, 4J(I, J, K) (k = 1; 2, m = 2, k \neq m) and four-spin order terms, 8J(I, J, K, L) (k = 1, l = 2, m = 3), are also produced but with amplitudes an order of magnitude lower than the two-spin order term. These do not appear to contribute significantly to the experimentally-produced quadrature 13C spectra. In addition to their smaller amplitudes, the absence of their contributions could also be attributable to their relatively fast relaxation (T1 \sim 1 \text{s}). In fact, only the quadrature 13C resonance was observed as an enhanced signal at a PTF of 0.5 G and upon proton decoupling the expected singlet appeared with diminished intensity. Refocusing of the antiphase coupling did, however, improve the resulting signal intensity (see SI).

The standard homonuclear OP SY57, 58 sequence was modified to create a heteronuclear experiment by the application of simultaneous \(\pi/2\) pulses to the 1H and 13C nuclei in conjunction with coherence selection gradients in the ratio of 64 : 80 for 1H observation and 16 : 80 for 13C. This facilitated the selective detection of the theoretically-predicted 2\(\text{J}_{\text{IS}}\) longitudinal two-spin order term through either its 1I or 1S nuclei. Typical NMR spectra are shown in Figs. 4A and 4B that illustrate these observables.

It should be noted, that the addition of the 13C spin allows the creation of the 4\(\text{J}_{\text{IKS}}\) term which can also be detected using the same heteronuclear OP SY pulse sequence but with a gradient ratio of 45.7 : 80. However, the resulting 1H NMR signal had a very small amplitude (S/N ratio 19) compared with the 1H signal arising from the two-spin order term (S/N ratio 995) as described and shown in Fig. 4(a). This corresponds with the theoretical calculations which show the amplitudes of these terms to be 75x smaller than the two-spin terms.

In the case of D, the absence of any 1H-1H coupling between the substrate and the hydride ligands of 3 results in no visible 1H or 13C-hyperpolarization transfer within the experimental range of PTFs explored here. In this instance, not even the quaternary 13C could be observed after 32 scans with re-polarization between scans. Our theoretical calculations show no polarization transfer and agree completely with this result. This situation does not change with time thereby confirming I is very inefficient at driving H-D exchange in A-D. Deuteration effects have recently been reported to complicate the SABRE process with pyridine.50

Figure 5: 1H NMR spectrum of propionitrile (4.6 \(\mu\l\)), d5-pyridine (0.75 \(\mu\l\)) and I (2 mg) in \(d_2\)-MeOH after being shaken in a PTF of 65 G.

We extended our experimental investigations to longer chains molecules containing cyano groups. In the Supplementary Information, we detail experimental 1H and 13C data that were collected when propionitrile, benzynitrile, benzoniitrile and trans-3-hexeneditrile were examined. We note that for propionitrile, both the CH2 and CH3 protons were enhanced by 10- and 4-fold, respectively, in the 1H NMR spectrum. The spectrum can be simplified by the use of d5-pyridine instead of \(d_2\)-pyridine; the resulting hyperpolarized 1H NMR spectrum is shown in Figure 5. In the 13C NMR spectrum, recorded after exposure to 3 bar \(\text{para-H}_2\) in a PTF of 0.5 G, an antiphase multiplet was detected at \(\delta\ 9.4\) which is indicative of polarization transfer to the methyl 13C nucleus. For benzynitrile, enhancements of 2- and 18-fold were seen for the benzyl and CH\(_2\) proton signals, respectively, after polarization transfer at a PTF of 65 G. Conversely, benzoniitrile displayed no enhancement upon exposure to 3 bar \(\text{para-H}_2\) at a PTF of 65 G. These important observations support the hypothesis that polarization transfer must occur in the first instance via a suitable J\(_{\text{IH}}\) coupling between the hydride and substrate protons. Such a coupling is effectively zero for benzoniitrile due to the remote (six bonds) location of the substrate proton nearest to the hydride nucleus in this molecule. trans-3-hexeneditrile also proved to polarize via SABRE and, interestingly, its alkene functionality proved resistant to hydrogenation. The CH\(_2\) and alkene protons were enhanced by 4- and 10-fold, respectively. In this last case, the preference for either the nitrile or alkene ligating to the metal was probed using DFT. Structures were optimized using the PBE0 functional from Adamo and the basis sets from Aldrich described by the def2-SVP label. These calculations showed that, in terms of enthalpy, the dominant form of interaction with the iridium centre was via the nitrile group of trans-3-hexeneditrile, by 105.9 kJ mol\(^{-1}\) compared to binding through the alkene component, hence reducing the propensity for alkene hydrogenation. It has been noted that in the absence of disopropylmethyamine (DIPeA) Ir/PHOX catalysts are unable to hydrogenate the alkene bond of \(\alpha,\beta\)-unsaturated nitriles due to coordination of two substrate molecules bound through the nitrile group leading to deactivation of the catalyst.55 Even in the presence of DIPeA, 50 – 100 bar of H\(_2\) was required to achieve full conversion. This is despite \(\alpha,\beta\)-unsaturated nitriles being easier to hydrogenate than \(\beta,\gamma\)-unsaturated nitriles due to activation by the nitrile group and increased conjugation.60 It is, therefore, not surprising that trans-3-hexeneditrile, a \(\beta,\gamma\)-unsaturated nitrile, doesn’t hydrogenate under the conditions we employ here.

In summary, the small J\(_{\text{IH}}\) couplings that exist between hydride nuclei and the CH\(_2\)/CH\(_3\) protons located directly next to the cyano group in A, propionitrile, benzynitrile and trans-3-hexeneditrile are adequate to propagate polarization transfer. This contrasts to the J\(_{\text{IH}}\) coupling to the ortho proton in benzoniitrile which results in no detectable polarization transfer.

Conclusions

In this paper we have proved that hyperpolarization transfer from the hydride ligands of the polarization transfer catalyst into the weakly coordinating acetonitrile ligand occurs in a homonuclear fashion via their spin-spin coupling network to the methyl protons when the polarization transfer field is \(\geq 0.5\) G. We have also demonstrated that a range of aromatic and non-aromatic nitrile-containing substrates can be polarized via SABRE, provided that there is a suitable homonuclear coupling pathway. This is a departure from the aromatic systems that have been more commonly polarized by SABRE.

Our theoretical calculations details how the transfer of polarization to the quaternary 13C nucleus occurs via the “long-range” coupling to the methyl protons rather than directly from the former \(\text{para-H}_2\) derived hydride nuclei in the catalyst. According to the theoretical study it is the fact that this heteronuclear coupling is of the same order of magnitude as the hydride-hydride coupling that facilitates this process in fields \(\geq 15\) G. In sharp contrast, the “short-range” coupling between the methyl protons and the methyl 13C nucleus which is an order of magnitude larger than the hydride-hydride coupling enables very little hyperpolarization transfer to it. The inefficiency of transfer in this case was predicted in our calculations and observed as a result experimentally.

\[ \text{Figure 5: 1H NMR spectrum of propionitrile (4.6 \mu\l), d5-pyridine (0.75 \mu\l) and I (2 mg) in d2-MeOH after being shaken in a PTF of 65 G.} \]
Theoretically, the population of both homonuclear and heteronuclear two spin order terms within A-C was predicted. A modified OPSY sequence, was used to detect the longitudinal two-spin order existing between $^1$H and $^{13}$C to confirm this experimentally. The complete magnetic equivalence of the methyl protons precludes detection of this homonuclear state. This situation lowers the efficiency of polarization transfer into visible states by a theoretically predicted value of 20% at 70.5 G and increases to a maximum of 33% at 90.5 G.

This series of observations have significant implications on how best to complete any $^{13}$C labeling if SABRE is to be used in vivo. For such nitrile containing systems, placing the label into a site that exhibits a long-range coupling to the SABRE polarized protons is suggested. The theoretical calculations provide excellent agreement with the experimental observations of the $^1$H spectrum and the variations of the spectral amplitudes with PTF. Also the theoretical $^1$C spectrum of the methyl $^{13}$C nucleus and the quaternary $^{13}$C nucleus at low field both provide excellent agreement with experiment. The only departure from this otherwise excellent agreement is the quaternary $^{13}$C PTF profile. Here the inversion of the phase of the spectrum predicted by our models does not occur at the same PTF as the experiment shows, when the experimentally-measured parameters are used in the model. We are continuing our research to improve this fit.

We have further demonstrated that the precise identity of the ligands and their conformation within the complex determines the propagation of polarization to ligands that are cis to the hydride ligands. In the complex [Ir(H)$_2$(IMes)(MeCN)(py)$_2$]$^+$, no detectable polarization is transferred into the IMes ligand. Crucially, the same PTF plot and enhancement levels are observed regardless of whether or not the IMes ligand is deuterated. However, addition of PCy$_3$ to this complex and subsequent elimination of pyridine, forms Ir(IMes)(H)$_2$(MeCN)(Py)(PCy$_3$), 4, in which PCy$_3$ is trans to IMes and cis to the hydrides. The resulting enhancement of the protons in A is half of that for the former complex. In stark contrast, the use of IMes-d$_2$ instead of IMes, resulted in the enhancement level being maintained in the presence of PCy$_3$. It is, therefore, possible to control transfer into the axial site by ligand design.

We believe that these methods illustrate a viable strategy to develop SABRE for weakly-interacting, non-pyridine-based systems. We are currently exploring alternative catalysts to improve further SABRE’s polarization transfer efficiency and signal enhancement levels. Such increases in catalyst efficiency would improve the likelihood that drug molecules possessing weakly interacting groups, such as nitriles, could be polarized by this method. Once successfully hyperpolarized such molecules could potentially feature as contrast agents, or reagents that enable the study of reaction mechanisms and the detection of reaction intermediates. An assessment of the steric bulk and ligand exchange rates will have to be made before the polarization of an unknown nitrile by SABRE can be contemplated.

**SUPPORTING INFORMATION AVAILABLE**

Experimental information including synthesis, methods, NMR characterization for 3, hyperpolarized $^1$H and $^{13}$C spectra for A-C, propionitrile, benzyl nitrite, benzonitrile and trans-3-hexenenitrile, parameters used in theoretical models, DFT calculations and details about the theoretical approach. This information is available free of charge from the Internet at [http://psbs.acs.org](http://psbs.acs.org)
