Biological hydrogels have been increasingly sought after as wound dressings or scaffolds for regenerative medicine, owing to their inherent biofunctionality in biological environments. Especially in moist wound healing, the ideal material should absorb large amounts of wound exudate while remaining mechanically competent in situ. Despite their large hydration, however, current biological hydrogels still leave much to be desired in terms of mechanical properties in physiological conditions. To address this challenge, a multi-scale approach is presented for the synthetic design of cyto-compatible collagen hydrogels with tunable mechanical properties (from the nano- up to the macro-scale), uniquely high swelling ratios and retained (more than 70%) triple helical features. Type I collagen was covalently functionalized with three different monomers, i.e. 4-vinylbenzyl chloride, glycidyl methacrylate and methacrylic anhydride, respectively. Backbone rigidity, hydrogen-bonding capability and degree of functionalization (F: 16 ± 12–91 ± 7 mol%) of introduced moieties governed the structure-property relationships in resulting collagen networks, so that the swelling ratio (SR: 707 ± 51–1996 ± 182 wt%), bulk compressive modulus (Ec: 3 0 ± 7–168 ± 40 kPa) and atomic force microscopy elastic modulus (EAFM: 16 ± 2–387 ± 66 kPa) were readily adjusted. Because of their remarkably high swelling and mechanical properties, these tunable collagen hydrogels may be further exploited for the design of advanced dressings for chronic wound care.

1. Introduction

Hydrogels are three-dimensional networks based on hydrophilic homo-polymers, co-polymers or macromers, which are cross-linked to form insoluble polymer matrices [1,2]. Following the large amount of water absorbed by the dry polymer network in physiological aqueous conditions, the resulting gels are typically soft and compliant. This behaviour results from the thermodynamic compatibility of the dry polymer with water, the presence of junction knots, as well as the low glass transition temperature (Tg) of the polymer network in hydrated conditions. In view of these features, the potential application of hydrogels in healthcare was first realized in the early 1960s, with the development of poly(2-hydroxyethyl methacrylate) gels as a contact lens material [3]. Subsequently, hydrogels have been designed based on other synthetic polymers, such as poly(ethylene glycol) [4] and poly (vinyl alcohol) [5], for various biomedical applications, including controlled drug delivery [6], wound care [7] and diabetes treatments [8]. Most recently, the design of multi-functional hydrogels based on naturally occurring biomacromolecules has received a great deal of

attention due to the fact that these systems can mimic the extracellular matrix (ECM) of biological tissues [9,10], thereby enabling selective drug sequestration [11] and extended engraftment of transplanted cells [12].

Collagen is the main protein of the human body, ruling structure, function and shape of biological tissues. Also in the light of their unique molecular organization, collagen hydrogels have been widely applied for the design of vascular grafts [13], biomimetic scaffolds for regenerative medicine [14] and non-woven architectures for wound healing [15]. Especially in moist wound healing [16,17], collagen hydrogels have been receiving a great deal of attention, since they can absorb large amounts of water following swelling, while being enzymatically degraded by matrix metalloproteinases (MMPs) present at the wound site. Both functionalities are key to the design of advanced wound dressings, aiming (i) to maintain defined wound temperature and metabolic rate [18] and (ii) to control MMP levels (probably responsible for delayed healing) at the wound site [19]. Following equilibration with medium, however, collagen hydrogels often exhibit limited mechanical properties and processability [20], potentially resulting in damage of the material upon handling. As a result, non-controllable macroscopic properties are observed, whereby a trade-off between the degree of swelling and mechanical properties critically impairs the successful translation of such materials into the clinic [21], especially in chronic wound care [22].

In its monomeric form, the collagen molecule is based on three left-handed polyproline chains, each one containing the repeating unit Gly-X-Y, where X and Y are predominantly proline (Pro) and hydroxyproline (Hyp), respectively [23]. The three chains are staggered to one another by one amino acid residue and are twisted together to form a right-handed triple helix (300 nm in length, 1.5 nm in diameter) [24]. In vivo, triple helices can aggregate in a periodic staggered array to form collagen fibrils, fibres and fascicles, which are stabilized via covalent cross-links. Despite the prevalence of such a hierarchical self-assembled structure in vivo, collagen extracted from biological tissues is mechanically unstable in aqueous environments, owing to the fact that its organization and chemical composition can only partially be reproduced in vitro [25]. Fibrillogenesis can be induced by exposing triple helical collagen to physiological conditions; however, native hydrogen and covalent bonds are partially broken following collagen isolation ex-vivo, so that collagen hierarchical organization and resulting mechanical properties are affected. Cross-linking methods based on either covalent [26–28] or physical [29–31] linkages, gelling strategies employing, for example, fibrillated protein backbones [32], as well as scaffold fabrication techniques [33] can be applied to collagen to enhance mechanical behaviour. Such methods offer elegant but still limited solutions to the stabilization of biomimetic collagen structures.

In order to address these challenges, rational approaches to hydrogel design should be developed, whereby systematic investigations of the hydrated mechanical properties should be carried out at all levels of hierarchical organization. Here, the interaction between building blocks, the effect of each building block and contributions of different phases (e.g. protein backbone, cross-linker, swelling medium) to the overall mechanical performance should be explored [34]. At the fibrillar level, however, nanoscale imaging [35] and micro-mechanical measurements on collagen materials have only recently become possible. Grant et al. [36] carried out atomic force microscopy (AFM) tapping mode and force volume measurements on reconstituted type I collagen fibrils. Resulting fibrils revealed the characteristic periodic banding (67 nm) pattern in either air or sodium phosphate buffer, while a three order magnitude decrease in elastic modulus ($E_{\text{AFM}}: 1.85 \pm 0.49 \text{ GPa} \rightarrow 1.18 \pm 0.14 \text{ MPa}$) was observed in the hydrated sample as compared with the dry-state elastic modulus [37]. Obtained nanoindentation values were comparable to the tensile ones measured via a microelectromechanical system [38], while the remarkable decrease in hydrated micromechanical properties, probably ascribed to the formation of hydrogen bonds within collagen molecules, was macroscopically associated with a two-fold swelling of the collagen fibril. Aiming to develop novel architectures for tissue engineering scaffolds, Carlisle et al. [39] probed fibre micromechanical properties in electrospun type I collagen. The resulting elastic modulus proved to be in the same range as that of reconstituted collagen fibrils ($E_{\text{AFM}}: 2.8 \pm 0.4 \text{ GPa}$); however, measurements were only carried out in the dry state, so that the effects of electrospinning and electrospinning solvent on collagen conformation and wet-state stability were not addressed. In an effort to study the effect of intermolecular covalent cross-links, Svensson et al. [40] successfully measured significantly enhanced mechanical properties ($E_{\text{AFM}}: 2.2 \pm 0.9 \text{ GPa} \rightarrow 3.5 \pm 0.4 \text{ GPa}$) in hydrated collagen fibrils with increased levels of tendon cross-link maturity, while no effect of environmental salts was detected [41].

Going towards higher levels of tissue hierarchy, the mechanical properties of collagen fibrils and tendons were also compared, whereby different values of elastic modulus ($E_{\text{tendon}}: 2.0 \pm 0.5 \text{ GPa}; E_{\text{tendon}}: 2.8 \pm 0.3 \text{ GPa}$) were observed [42]. Ultimately, AFM was applied on carbodiimide cross-linked type I collagen gels in order to probe the effect of cross-linking on fibrillar organization [43]. Here, tensile properties were significantly improved, although fibril formation proved to be suppressed when cross-linking was carried out simultaneously with collagen fibrillogenesis. From all the aforementioned examples, it appears rather clear that, while recent developments on AFM and mechanical testing enabled successful mechanical and structural characterization, collagen-based hydrogels with defined relationships between the molecular, microscopic and macroscopic scale are still only partially accomplished. This is, on the one hand, due to the technical limitations related to the resolution of highly swollen networks via AFM and, on the other hand, due to the fact that chemo-selective and tunable functionalization of collagen is still very challenging.

The aim of this work was to study the structure–property–function relationships in photo-activated collagen hydrogels to investigate their potential applicability in chronic wound care. By covalently functionalizing type I collagen with photo-active compounds of varied molecular weight, backbone rigidity and hydrophilicity [44], i.e. 4-vinylbenzyl chloride (4VBC), glycidyl methacrylate (GMA) and methacrylic anhydride (MA), hydrogels were successfully accomplished following collagen precursor photo-activation. By controlling the network molecular architecture, the swelling and mechanical properties from the nano- up to the macro-scale were expected to be adjusted. We selected photo-activated cross-linking for the design of collagen hydrogels since this strategy has been successfully applied to the formation of synthetic polymer systems whose biocompatibility, tunability and control of material properties have been widely reported [1–8,45]. Compared with other synthetic strategies, photo-activated cross-linking provides rapid reaction rates...
2. Material and methods

2.1. Materials

GMA, 4VBC, MA and 2,4,6-trinitrobenzenesulfonic acid (TNBS) were purchased from Sigma-Aldrich. Rat tails were supplied by the School of Dentistry, University of Leeds (UK). All the other chemicals were purchased from Sigma-Aldrich. Type I collagen was isolated in-house via acidic treatment of rat tail tendons [44].

2.2. Functionalization of collagen

Type I collagen (0.25 wt%, 100 g solution) was stirred in 10 mM hydrochloric acid solution at room temperature until a clear solution was obtained. Solution pH was neutralized to pH 7.4 and either GMA, 4VBC or MA was added to the reaction mixture with a 10–50 molar excess with respect to collagen lysines (e.g. 50 mmol monomer per mmol of collagen lysine) depending on the specific sample formulation. An equimolar amount of tri-ethylamine (with respect to the amount of monomer previously added) and 1 wt% of Tween-20 (with respect to the initial solution volume) were added. After 24 h reaction, the mixture was precipitated in 10–15 volume excess of pure ethanol and stirred for 2 days. Ethanol-precipitated functionalized collagen was recovered by centrifugation and air-dried.

2.3. Photo-activation and network formation

GMA- and MA-functionalized collagens (0.8 wt%) were stirred in 1 wt% I2959–phosphate-buffered saline (PBS) solution. The resulting solutions were poured onto Petri dishes and incubated in a vacuum desiccator to remove air bubbles; this was followed by UV irradiation (Spectrolite, 346 nm, 9 mW cm−2) for 30 min on each dish side. Networks based on 4VBC-functionalized collagen were prepared following the same protocol, except that gel samples were glued using a blue-light-activated adhesive to allow clearing of sample edges. Networks were prepared in a vacuum desiccator to remove air bubbles; this was followed by UV irradiation (Spectrolite, 346 nm, 9 mW cm−2) for 30 min on each dish side. Networks based on 4VBC-functionalized collagen were prepared following the same protocol, except that gel samples were glued using a blue-light-activated adhesive to allow clearing of sample edges.

2.4. Chemical and structural characterization

The degree of collagen functionalization (F) was determined by TNBS colorimetric assay [48], according to the following equations:

\[
\text{mol(Lys)} = \frac{2 \times \text{Abs(346 nm)} \times 0.02}{1.46 \times 10^4 \times b \times x}
\]

and

\[
F = 1 - \frac{\text{mol(Lys)}_{\text{Collagen}}}{\text{mol(Lys)}_{\text{Collagen}}}
\]

where Abs(346 nm) is the absorbance value at 346 nm, 0.02 is the volume of sample solution (in litres), 1.46 × 10^4 is the molar absorption coefficient for 2,4,6-trinitrophenyl lysine (in M\(^{-1}\) cm\(^{-1}\)), b is the cell path length (1 cm) and x is the sample weight. Here mol(Lys)\(_{\text{Collagen}}\) and mol(Lys)\(_{\text{Funct.Collagen}}\) represent the total molar content of free amino groups in native and functionalized collagen, respectively. The nomenclature (Lys) is hereby used to recognize that lysines make the highest contribution to the molar content of collagen free amino groups, although contributions from hydroxylysines and amino termini are also taken into account.

Besides TNBS, collagen functionalization was also investigated by \(^1\)H-NMR spectroscopy (Bruker Avance spectrophotometer, 500 MHz) by dissolving 5–10 mg of dry samples in 1 ml deuterium oxide. Attenuated total reflectance Fourier-transform infrared (ATR FT-IR) was carried out on dry samples using a Perkin-Elmer Spectrum BX spotlight spectrophotometer with diamond ATR attachment. Scans were conducted from 4000 to 600 cm\(^{-1}\) with 64 repetitions averaged for each spectrum.

Circular dichroism (CD) spectra of functionalized samples were acquired with a Chirascan CD spectrometer (Applied Photophysics Ltd) using 0.2 mg ml\(^{-1}\) solutions in 10 mM HCl. Sample solutions were collected in quartz cells of 1.0 mm path length, whereby CD spectra were obtained with 4.3 nm band width and 20 nm min\(^{-1}\) scanning speed. A spectrum of the 10 mM HCl control solution was subtracted from each sample spectrum. Wide angle X-ray scattering (WAXS) measurements were carried out on dry samples with a Bruker D8 Discover (40 kV, 30 mA, X-ray wavelength: λ = 0.154 nm). The detector was set at a distance of 150 mm covering 2θ from 5° to 40°. The collimator was 2.0 mm and the exposure time was 10 s per frame. Collected curves were subtracted from the background (no sample loaded) and fitted with polynomial functions (R\(^2\) > 0.95).

2.5. Scanning electron microscopy

Fully hydrated hydrogels were investigated via a cool stage SEM (JEOL SM-35) in order to explore the inner morphology of collagen hydrogels. Samples were mounted onto 10 mm stubs fitting a cool stage set at 10°C inside the specimen chamber of a Hitachi S-3400N VP-SEM. A drop of distilled water was placed around the sample, whereas the chamber pressure and stage temperature were correlative decreased to 70 Pa and −20°C, respectively, enabling the use of water vapour as imaging gas. SEM images were captured via backscattered electron detection at 10 kV and 12–13 mm working distance.

2.6. Swelling tests

A total of 2–5 mg of dry sample was placed in 1 ml of either distilled water or PBS under mild shaking. Upon equilibrium with water, the SR was calculated according to the following equation:

\[
SR(\%) = \frac{W_s - W_d}{W_d} \times 100,
\]

where \(W_s\) and \(W_d\) are the swollen and dry sample masses, respectively. Swollen samples were paper blotted prior to measurement of \(W_s\).

2.7. Compression tests

Water-equilibrated hydrogel discs (Ø: 0.8 cm) were compressed at room temperature with a compression rate of 3 mm min\(^{-1}\) (Instron ElectroPuls E3000). A 250 N load cell was operated up to sample break. Four replicates were employed for each composition and the results expressed as the mean ± s.d.

2.8. Atomic force microscopy indentation and scanning

Gel samples were glued using a blue-light-activated adhesive to a standard microscope slide and placed on the sample stage of an MFP-3D AFM (Asylum Research, Santa Barbara, CA, USA) before placing approximately 100 μl of ultrapure water (18.4 MΩ-cm) on the gel surface. AFM imaging was carried out with either tapping or contact mode using a V-shaped silicon nitride cantilever (Hydra6V series; AppNano, Santa Clara, CA, USA) with a spring constant of approximately 0.3 N m\(^{-1}\) and a tip radius of 15 nm, which was independently confirmed.
using a standard calibration grid. Following laser alignment, calibration of the detector sensitivity and the cantilever spring constant ($k \sim 0.32 \text{ N m}^{-1}$) using the thermal method was made [49]. Roughness values ($R_k, R_a$) were computationally calculated using the MFP-3D software from Asylum. These involve the summation and average ($R_a$) and square root of height squared ($R_k$) for all height data above/below a statistically determined centre line.

Force volume measurements were made in organized arrays (50 × 50) of indentations at a piezo velocity of 2 µm s⁻¹. The elastic modulus was estimated using a linear elastic Hertzian-centre line.

$$F = \frac{2}{\pi} \left( \frac{E}{1 - \nu^2} \right) \delta^2 \tan \alpha,$$

where $\nu$ is Poisson’s ratio and is assigned a value of 0.5 (i.e. incompressible), $\delta$ is the indentation depth and $\alpha$ is the half cone angle of the probe (36°).

2.9. Cell viability

L929 cells were incubated in a 5-chloromethylfluorescein diacetate solution (CellTrackerGreen CMFDA, Invitrogen) for 45 min. The applied working solution was replaced with serum-free medium and cells incubated for 45 min intervals twice. Labelled cells were seeded onto ethanol-treated hydrogel discs (Ø: 8 mm; h: 3 mm; 10³ cells sample⁻¹) for 48 h followed by optical observation via fluorescent microscopy. Other than that, an extract cytotoxicity assay was also conducted (EN DIN ISO standard 10993–5) in order to further investigate the material compatibility with L929 cells. A total of 0.1 mg of ethanol-treated hydrogel was incubated in 1 ml cell culture medium (Dulbecco’s modified Eagle medium; DMEM) at 37°C. After 72 h incubation, the sample extract was recovered and applied to 80% confluent L929 mouse fibroblasts cultured on a polystyrene 96-well plate. Dimethyl sulfoxide was used as the negative control, while DMEM was applied as the positive control. Cell morphology was investigated using a transmitted light microscope in phase contrast mode.

3. Results and discussion

Sample nomenclature is as follows: functionalized collagen precursors are identified as ‘CRT-XXYY’, where ‘CRT’ indicates type I collagen isolated in-house from rat tails; ‘XX’ identifies the monomer reacted with CRT (either 4VBC, GMA or MA); ‘YY’ describes the monomer/lysine molar ratio used in the functionalization reaction. Collagen hydrogels are identified as ‘CRT-XXYY’, where ‘CRT’, ‘XX’ and ‘YY’ have the same meanings as previously mentioned, while ‘a’ indicates that the sample results from the photo-activation of a collagen precursor.

3.1. Synthesis of functionalized collagen precursors and networks

In-house isolated type I collagen was functionalized with varied vinyl moieties in order to obtain covalent hydrogel networks following photo-activation of resulting precursors (figure 1a). Collagen functionalization can occur via nucleophilic reaction of free amino groups, e.g. the ones found in lysine (Lys), hydroxylsine and arginine as well as collagen amino termini. At the same time, arginine is unlikely to react in these conditions, owing to the high pH ($K_a$ approx. 12.5) and the resonance stabilization of the protonated guanidium group.

4VBC and GMA were selected as rigid, aromatic monomer and flexible, aliphatic monomer, respectively, while MA was chosen as short, methacryl compound. $^1$H-NMR (electronic supplementary material, figure S1) and TNBS colorimetric assay (figure 1d) confirmed the covalent functionalization in all three collagen products; the presence of the characteristic geminal proton peaks of MA (5.3 and 5.6 ppm) [50,51] were clearly identified in the $^1$H-NMR spectrum of sample CRT-MA25, in line with spectral information obtained via ATR-FTIR (electronic supplementary material, figure S2). A tunable number of lysine amino groups was covalently functionalized, based on the monomer type and the molar excess of monomer with respect to the collagen lysine content (R, figure 1d) in the reacting mixture. These results probably reflect the different reactivity and solubility of selected monomers in water, so that the degree of collagen functionalization (F) was successfully adjusted in the range of $16 \pm 12–91 \pm 7$ mol%.

Further to the chemical yield, the impact of functionalization on collagen triple helix organization was also addressed, since this is an important molecular feature influencing collagen stability, mechanical properties and biofunctionality [52–54]. Far-UV CD spectra of functionalized collagens displayed a positive peak at 221 nm, associated with collagen triple helices, and a negative peak at 198 nm, describing polyproline chains, as in the case of native collagen spectrum (figure 1b). Importantly, the magnitude ratios of the positive to negative peak (RPN) in functionalized collagen spectra (figure 1d) were found to be comparable (RPN: 0.092–0.127) to the value of native collagen (RPN: 0.117) [55,56], indicating that the triple helix architecture could be preserved in photo-active collagen products depending on the type and extent of collagen functionalization. Interestingly, sample CRT-4VBC25 revealed lower RPN and slightly higher F values than sample CRT-4VBC10 (figure 1d). Normalization of corresponding RPN values with respect to the RPN value of native collagen resulted in triple helix contents of 79% and 98% in samples CRT-4VBC25 and CRT-4VBC10, respectively. This observation may therefore suggest that the additional functionalization of collagen with bulky 4VBC aromatic moieties is likely to result in a detectable reduction of collagen triple helices, due to the inability of 4VBC moieties to mediate hydrogen bonds (as crucial bonds to triple helix stability) [57]. Other than CD, corresponding collagen networks were also analysed via WAXS in order to explore the organization of functionalized collagen in the cross-linked state. Obtained WAXS spectra displayed characteristic peaks related to the collagen intermolecular lateral packing ($d \sim 1.1 \text{ nm}, 2\theta \sim 8$°), isotropic amorphous region ($d \sim 0.5 \text{ nm}, 2\theta \sim 20$°) and axial polyproline periodicity ($d \sim 0.29 \text{ nm}, 2\theta \sim 31$°), as observed in the spectrum of native collagen (figure 1c). The integration ratio between the peak related to collagen intermolecular lateral packing (describing the presence of collagen triple helices) and the overall WAXS spectrum was determined in order to quantify the triple helix content in functionalized collagen networks. Normalization of resulting integration ratios with respect to the integration ratio in native collagen indicated that at least 73% of native triple helix content was successfully preserved, confirming previous CD results. In contrast to that, a gelatin control was also analysed during the measurements, whereby only 2% of collagen-like triple helices was detected, in agreement
with previous WAXS quantifications in gelatin samples [58]. These CD and WAXS results therefore provided supporting evidence that obtained functionalized and photo-activated collagen systems displayed only slightly altered triple helical organization with respect to the case of native rat tail type I collagen, despite the fact that covalent functionalization of collagen lysines could be accomplished with varied monomers and tunable degrees of functionalization.

3.2. Morphology, swelling and compression properties

Following investigation of the molecular architecture in functionalized precursors and networks, attention moved to the characterization of photo-activated collagen hydrogels. Functionalized collagen solutions proved to promptly result in a gel following UV irradiation. Formed hydrogels displayed a micro-porous architecture as revealed by SEM (figure 2a). The presence of micro-pores (P: 35 ± 7 μm) is appealing for wound dressing applications, since the wound exudate is expected to diffuse through the pores, resulting in increased permeation and exudate absorbency [59]. Likewise, the presence of micro-pores would also be advantageous for cell culture applications, since pores are expected to facilitate proliferation of cells and diffusion of nutrients within the materials [21].

Besides optical and SEM observations, the macroscopic mechanical properties of formed hydrogels were also addressed. As observed in figure 2c, the SR was determined; all hydrogel systems displayed very high SR values (SR > 700 wt%), with 4VBC-based hydrogels swelling more (1600 ± 224–1996 ± 182 wt%) than GMA- (851 ± 52–1363 ± 70 wt%) and MA-based (707 ± 51–1087 ± 96 wt%) hydrogels. Examples, SR was not found to change significantly when collagen networks CRT-MA10 were equilibrated in PBS instead of water (SR: 1190 ± 34 wt%; figure 2c); this suggests that the presence of a covalent network makes the collagen hydrogel insensitive to changes in solution pH and ionic strength, in agreement with previous results on reconstituted collagen fibrils [37, 41]. The molar excess of monomer/Lys employed to accomplish functionalized collagen precursors was found to rule the swelling behaviour of hydrogels CRT-(G)MA*, while the SR of samples CRT-4VBC* did not show significant variations. Figure 1d previously proved that variations in monomer/Lys...
molar excess during the functionalization reaction resulted in adjusted degrees of functionalization in precursors CRT-(G)MA, while a nearly constant $F$ was determined in 4VBC-based products, regardless of the reaction conditions. Observed trends in swelling behaviour therefore reflected the extent of lysine derivatization imparted with collagen functionalization, so that an inverse relationship between $F$ (in the collagen precursors) and $SR$ (in the resulting hydrogels) was found. Such inverse $F$–$SR$ relationships demonstrated that the functionalization step was key to the formation of collagen networks, whereby an increased content of attached vinyl moieties in collagen precursors effectively led to the formation of hydrogels with an increased degree of cross-linking and decreased $SR$.

Despite the high $SR$ values observed, resulting materials were still highly stable in an aqueous environment, with significantly higher compression modulus ($E_c$: $150 \pm 54–168 \pm 40$ kPa) and smaller compression at break ($\varepsilon_b$: $35 \pm 2–41 \pm 6\%$) observed in 4VBC-based, with respect to GMA-based, systems ($E_c$: $30 \pm 7–50 \pm 18$ kPa; $\varepsilon_b$: $53 \pm 13–73 \pm 3\%$), while hydrogels CRT-MA$^*$ displayed intermediate compressive moduli ($E_c$: $129 \pm 45–134 \pm 62$ kPa) (figure 2d,e). Remarkably, the results showed a direct $SR-E_c$ relationship in hydrogels CRT-4VBC$^*$, which is rather unexpected given that mechanical properties are supposed to decrease in hydrogels with increased $SR$ and decreased degree of functionalization/cross-linking [39], as found in hydrogels CRT-(G)MA$^*$. While the higher $SR$ values could be explained in samples CRT-4VBC$^*$ in light of their lower degree of functionalization in comparison with methacrylated hydrogel networks, the compression properties were also increased in aromatic collagen systems. These observations speak against classical rubber elasticity theories describing synthetic polymer networks [1–5]; we hypothesized that the molecular organization and secondary interactions make additional contributions to the mechanical properties of aromatic collagen systems. We have previously demonstrated that the triple helix conformation can be preserved in functionalized collagen depending on the type and extent of functionalization (figure 1c) [44]. In the case of networks CRT-4VBC, the inter-strand physical cross-links between the C=O and N–H groups in the triple helical structure could no longer be mediated following incorporation of the aromatic backbone [20,44,57], as suggested by RPN values deriving from corresponding CD spectra (figure 1b,d). Consequently, the resulting free-standing collagen chains were likely to form new hydrogen bonds with water, thereby explaining the increased $SR$ measured in samples CRT-4VBC$^*$ (figure 1d). At the same time, the incorporation of the stiff, aromatic 4VBC segment was supposed to play a major role in the compression behaviour of corresponding hydrogels. Aromatic moieties can mediate additional $\pi-\pi$ stacking interactions [60,61], so that additional and reversible junction knots could be established during material compression, owing to the vicinity of network chains. The presence of these additional junction knots together with considerations on the molecular stiffness of the introduced aromatic backbone was likely to count for the significant increase in compressive modulus and decrease in strain at break in comparison with hydrogels...
based on non-aromatic cross-linking segments. Consequently, the molecular architecture of the collagen networks was found to significantly affect both compression and swelling properties, suggesting that material properties could be adjusted in order to meet specific clinical requirements.

The exceptionally high SR values and compressive moduli of the presented collagen hydrogels make these systems particularly attractive for wound dressing applications, since both properties are crucial but challenging material requirements for successful moist wound healing [40]. An ideal wound dressing should display swelling and mechanical properties adjusted for each type of wound [17,62]. Alginate non-woven fabrics have been proposed as wound or burn dressings, whereby a water absorbency (related to contributions of both bound and unbound water) greater than 25 g of deionized water per gram of fabric was observed [63].

In order to further investigate the relevance of the presented collagen hydrogels in wound care, benchmarking experiments were carried out against a carboxymethylated cellulose-based non-woven dressing (Aquacel), as optimal fibrous material for the management of exudative wounds [62,64]; remarkably, higher values of SR and E, were observed in collagen hydrogels CRT-4VBC with respect to the non-woven material (SR: 1759 ± 107; E: 34 ± 18 kPa). Together with the observed viability of 5-chloromethylfluorescein-stained L929 fibroblasts following cell culture on collagen hydrogels (electronic supplementary material, figure S3 (left)) as well as the spread-like cell morphology of L929 cells following cell culture with material extract (electronic supplementary material, figure S3 (right)), the above-mentioned observations provide supporting evidence of the potential applicability of these hydrogels as a material building block for the design of advanced wound dressings. In light of these results, current investigations are focusing on the design of collagen non-wovens based on functionalized collagen precursors.

### 3.3. Atomic force microscopy study

When designing biomaterials, such as wound dressings or tissue scaffolds, it is important that the mechanical properties match the requirements of the intended application. Four distinct contributions were expected to rule the overall mechanical properties in collagen hydrogels: (i) internal microstructure, (ii) molecular architecture of the covalent network, (iii) molecular organization of the protein building block, and (iv) inherent mechanical properties of the hydrogel phase. In this study, we have so far investigated points (i) (figure 2a,b) and (ii) (figure 1b,d), while point (iii) was partially addressed for the triple helical structural ordering at short length scales using CD and WAXS on collagen precursors and networks following functionalization with MA (figure 1c) as well as GMA and 4VBC [44]. In order to fully address points (iii) and (iv) and gain an overall understanding of the governing structure–property relationships, we envisioned a sample preparation method to probe hydrogel micro-mechanical properties via AFM, whereby the presence of any long-range fibrillar structural ordering was also elucidated. AFM on such highly swollen materials is very challenging, considering (i) the material softness, imposing the demand for relatively low load resolution testing; (ii) the large amount of water bound to the material, limiting reliable material fixation on a substrate; and (iii) the material heterogeneity resulting from the inner micro-pores and large surface roughness, potentially leading to resolution artefacts. In order to address these challenges, water-equilibrated networks were fixed on microscope glass slides via application of a photo-curable adhesive, so that AFM mechanical and structural analyses could be performed (figure 3c–c). Distinct force-indentation plots on hydrogel CRT-MA10 were successfully acquired using a conical indenter with force volume mode, describing a local elastic response with no detectable permanent plastic deformation (figure 3, bottom left) similar to the behaviour observed in hydrated collagen fibrils [36,37]. Here, the presence of the covalent network at the molecular level was mostly responsible for the elastic recovery from the nano- to the macro-scale [24], as also supported by the minimal adhesion and small amount of hysteresis (approx. attojoule; electronic supplementary material, figure S4) between the approach and retraction indentation curves.

The elastic modulus was extracted from the force-indentation curves using the Hertzian model, giving confirmation that the ranges of compression properties observed at the macroscopic scale were correlated to those at smaller length scales. Furthermore, AFM indentation carried out in two separate regions resulted in similar distributions of elastic modulus (figure 3, bottom centre). Both results provided evidence that the sample preparation method ensured complete fixation of the hydrogel to the supporting glass substrate, so that meaningful information on the mechanical and surface properties could be obtained.

Following validation of the AFM experimental set-up, each hydrogel system was analysed. Figure 4a displays the results of EAFM in samples CRT-4VBC. Obtained EAFM values were comparable to the elastic moduli determined via bulk compression tests. Additionally, no significant variation of nano- to micro-mechanical properties was measured between samples CRT-4VBC10 and CRT-4VBC25 (EAFM: 237 ± 77 → 374 ± 36 kPa), which was expected because of the comparable bulk compressive modulus (macro-scale), on the one hand, and the nearly constant degree of functionalization in respective collagen precursors (figure 1e), on the other hand. While similar mechanical properties were also found in samples CRT-4VBC50 (figure 4b), a large regional variation of EAFM was observed (EAFM: 100 ± 48 → 387 ± 66 kPa). In principle, these results may derive from the non-homogeneous material surface, i.e. surface roughness, as revealed by the corresponding height and phase images taken in tapping mode under water (figure 4c,d) and respective height profile (figure 4e). The AFM elastic modulus is generally affected by the surface roughness, given that the interaction volume between the tip and the sample changes depending on how many surface protrusions are in contact with the tip [65]. By comparing surface heterogeneities among hydrogels, however, larger roughness values (Rq: 31 nm; Rq: 20 nm; table 1) were determined on hydrogel CRT-4VBC25 with respect to hydrogel CRT-4VBC50 (Rq: 13 nm; Rq: 16 nm; table 1), despite larger EAFM regional variations being observed in the latter compared with the former sample. Furthermore, force mapping indentation depths (h > 100 nm) proved to be much higher than the surface roughness of corresponding hydrogels, suggesting that surface effects played only a minimal role [65].

It was therefore unlikely that roughness effects could account for the observed variations in mechanical properties. Given that these hydrogels resulted from the formation of a molecular covalent network, small localized variations in the cross-linking density were therefore expected to be mostly responsible for the above observation. Collagen hydrogel
networks were indeed obtained via the photo-activation of functionalized collagen molecules, whereby network molecular defects can occur during the photo-cross-linking reaction. The localized variations in cross-linking density are also in agreement with the fact that such variability in elastic modulus was mainly detected at the nano- to micro-scale rather than at the macro-scale (figure 2d). Overall, these nano-mechanical investigations suggested that changes in the molecular architecture of the collagen networks dictated the overall mechanical behaviour of resulting hydrogels, while surface topography mainly played a contribution at smaller length scales.

Together with force mapping, AFM imaging was carried out in order to explore the protein organization of functionalized triple helical collagen molecules at the hydrogel surface. As depicted in figure 4c,d, no detectable presence of renatured collagen-like fibrils was displayed in samples CRT-4VBC501. This observation was also supported by obtained roughness values, which were much lower than those of fibrillar surfaces in the sclera (Rq: 60–200 nm) [65]. The fact that no fibril could be revealed by the obtained AFM images could be mostly explained by the specific solvent applied for hydrogel preparation; 4VBC-functionalized collagen precursors were dissolved in diluted acidic conditions (10 mM HCl), whereby no fibrillogenesis could occur and only collagen triple helices were expected to be present in the solution [66]. Following hydrogel formation, the resulting triple helices were therefore frozen in a cross-linked state, so that minimal fibrillar renaturation could be induced even at neutral or basic pH, as confirmed via AFM imaging (figure 4c,d).

Further to the investigation on samples CRT-4VBC5, hydrogels CRT-GMA15 and CRT-GMA25 were addressed. Good agreement between E_AF and E values was still observed (figure 5a,c,d), whereby hydrogel formulation seemed to affect the mechanical properties of corresponding hydrogels, in contrast to the case of hydrogels CRT-4VBC5. This latter point could result from the fact that GMA-functionalized collagen precursors displayed a wider variation in the degree of collagen functionalization (F_GMA: 29 ± 8 – 54 ± 4 mol%; figure 1d), unlike the case of hydrogels CRT-4VBC5 (F_4VBC: 16 ± 12 – 34 ± 4 mol%; figure 1d). Other than that, a significant regional variation of E_AF was measured in hydrogel CRT-GMA50 (figure 5e), as already observed in hydrogel CRT-4VBC50. In order to explain these results, surface roughness values (table 1), AFM maps (figure 5c,f) and SEM images (figure 2a,b) were considered. The corresponding surface roughness (Rq: 113 ± 24 nm; Ru: 141 ± 27 nm) was about one order of magnitude higher than that of samples CRT-4VBC50, suggesting that surface effects may be responsible for E_AF variation. As observed previously, the surface roughness gives an indication of the degree of fibrillogenesis in collagen materials [65]. Evidence of fibrillar organization was observed in AFM height maps of these highly hydrated collagen hydrogels (figure 5d,f), in line with the hypothesis that renatured fibrils formed the solid phase of the scaffold (figure 2a,b). These considerations were also supported by the fact that these hydrogels were prepared in PBS (unlike the case of hydrogels CRT-4VBC5), which is a common medium applied to induce fibrillogenesis of collagen triple helices [66]. From these considerations, it was therefore likely that surface roughness effects together with the presence of a heterogeneous microstructure consisting of pores and regenerated collagen fibrils could count for the significant variation in AFM-probed mechanical properties.

Comparing hydrogels CRT-GMA15 and CRT-4VBC25, as based on collagen precursors showing a comparable degree (i.e. F_GMA: 24 ± 19 mol%; F_4VBC: 26 ± 1 mol%; figure 1d), but different type, of functionalization (i.e. GMA- versus 4VBC-based), a decreased elastic modulus was observed in the former system throughout the sample (figure 5b,c,g). Given that the two hydrogels were obtained from precursors with a comparable degree of functionalization (F_GMA = 24 ± 19 mol%; F_4VBC = 26 ± 1 mol%; figure 1d), the most probable explanation for this observation was that the backbone stiffness of cross-linking segments directly affected the mechanical
Figure 4. (a) Variation of $E_{\text{AFM}}$ in hydrogels CRT-4VBC* determined via AFM indentation. Two replicates were used for sample CRT-4VBC10*, while two different regions in the same replica were investigated for the other two sample formulations. (b–d) Exemplary $E_{\text{AFM}}$ map (b, 5 nN indentation force), surface image (c) and phase tapping mode image (d) obtained in hydrogel CRT-4VBC50*. As expected, no collagen fibrils could be observed on the material surface, since these hydrogels were prepared in 10 mM HCl solution, with which no fibrillogenesis can occur. (e) Height profile determined along the cross line section of figure 2c. (Online version in colour.)

Table 1. Mean ($R_a$) and root mean square ($R_q$) roughness values obtained in collagen hydrogels via AFM. $R_a$ and $R_q$ were computationally calculated from AFM height data on a $5 \times 5 \mu m$ scan size.

properties of the resulting hydrogels, e.g. the incorporation of 4VBC aromatic moieties imparted superior mechanical properties in corresponding networks with respect to GMA-based systems (as observed via the bulk compression measurements). Other than \( E_{\text{AFM}} \), the fibril-forming properties of functionalized collagen molecules in hydrogels CRT-GMA15* (figure 5f) and CRT-4VBC25* (figure 5h) appeared to be different. Evidence of long-range structural assemblies was found in the former system similarly to the case of CRT-GMA50*, although this was not supported via the roughness data (table 1); other than that, a random organization was apparent in the case of hydrogel CRT-4VBC25* (as already shown in hydrogel CRT-4VBC50*). Given that these hydrogels were prepared in different solutions, these observations provided supporting evidence of the effect the solvent, e.g. with respect to the solution pH, employed during hydrogel preparation can have on the fibrillar renaturation of functionalized collagen precursors.

Following AFM investigation on samples CRT-4VBC* and CRT-GMA*, attention moved to the characterization of hydrogels CRT-MA*, whereby mechanical properties, surface images and \( E_{\text{AFM}} \) maps were measured. The resulting hydrogels displayed an averaged \( E_{\text{AFM}} \) of around 104–130 kPa (figure 6a), which was comparable to the value observed via compression \( (E_c: 129–134\) kPa) and between \( E_{\text{AFM}} \) values of hydrogels CRT-GMA* (figure 5i) and CRT-4VBC* (figure 4i). At the same time, \( E_{\text{AFM}} \) was nearly constant among samples regardless of the hydrogel formulations, which was expected because of the slight variation in the degree of functionalization in corresponding collagen precursors. Comparing the three sets of hydrogel systems, hydrogels CRT-MA* displayed a much higher degree of functionalization than hydrogels CRT-GMA* (figure 1d), which was likely to explain why the elastic modulus in hydrogels CRT-MA* was higher than that in hydrogels CRT-GMA*. Moreover, both GMA and MA are aliphatic molecules, so the backbone rigidity of resulting cross-linking segments was expected to be similar between the two networks.

Following similar reasoning, the molecular stiffness of the introduced cross-linking segments of collagen molecules was likely to explain the lower elastic modulus observed in hydrogels CRT-MA* with respect to hydrogels CRT-4VBC*, given that the 4VBC-based cross-linking segments were previously confirmed to provide a stiffer junction between collagen molecules with respect to the GMA aliphatic segments. Other than the tunability of \( E_{\text{AFM}} \) among hydrogels, \( E_{\text{AFM}} \) values showed a nearly homogeneous regional distribution throughout \( E_{\text{AFM}} \) maps of hydrogels CRT-MA10* (\( E_{\text{AFM}}: 130 \pm 23 \rightarrow 127 \pm 22 \) kPa; figure 3, centre bottom), which was in agreement with the surface roughness values \((R_s: 36 \text{ nm}; \ R_u: 46 \text{ nm})\) table 1) derived from corresponding surface images (figure 6b). The nearly homogeneous regional distribution of mechanical properties could be explained by a uniform cross-linking density in the corresponding collagen network at the molecular level, in light of the almost quantitative functionalization of collagen lysines (\( f_{\text{MA}} > 80 \text{ mol\%})\) in respective collagen precursors. In addition, the relatively low values of surface roughness also suggested a low degree of fibrillogenesis in hydrogel CRT-MA10*, as revealed by the AFM surface image (figure 6b). Fibrillogenesis should be expected in this case, since a 73% triple helix content (with respect to native collagen) was determined in this sample via WAXS (figure 1c). Furthermore, hydrogels CRT-MA* were prepared in PBS, which is a solvent promoting renaturation of collagen triple helices into fibrils. The most probable explanation for the absence of collagen fibrils in AFM images was that the higher functionalization degree of MA-functionalized collagen precursors (compared with, for example, the case of GMA-functionalized ones) was likely to strongly affect the kinetics of native collagen fibrillogenesis. Consequently, a longer incubation time under physiological conditions was likely to be required in order to enable MA-functionalized collagen to reconstitute into fibrils. The influence of the degree of collagen functionalization on the fibril-forming capability of the corresponding collagen precursors will be systematically addressed in a different study.

### 4. Conclusion

Mechanically competent collagen hydrogels were successfully developed from varied photo-active precursors, i.e. CRT-4VBC, CRT-GMA and CRT-MA, and investigated from the molecular up to the macroscopic scale. Photo-active precursors exhibited systematically adjusted degrees of functionalization \((F: 16 \pm 12–91 \pm 7 \text{ mol\%})\) depending on the type and feed ratio of the monomer. Because of the changes at the molecular level, the resulting collagen hydrogels displayed wide tunability in bulk compressive modulus \((E_c: 30 \pm 7–168 \pm 40 \text{ kPa})\), which was confirmed by the AFM elastic modulus \((E_{\text{AFM}}: 16 \pm 2–387 \pm 66 \text{ kPa})\) measured at the nanoscale. The backbone stiffness of vinyl moieties incorporated in the collagen network was the key factor affecting hydrogel mechanical properties, as was the incorporation of 4VBC aromatic moieties.
