Abstract

Clustering algorithms are a useful tool to explore data structures and have been employed in many disciplines. The focus of this paper is the partitioning clustering problem with a special interest in two recent approaches: kernel and spectral methods. The aim of this paper is to present a survey of kernel and spectral clustering methods, two approaches able to produce nonlinear separating hypersurfaces between clusters. The presented kernel clustering methods are the kernel version of many classical clustering algorithms, e.g., K-means, SOM and Neural Gas. Spectral clustering arise from concepts in spectral graph theory and the clustering problem is configured as a graph cut problem where an appropriate objective function has to be optimized. An explicit proof of the fact that these two paradigms have the same objective is reported since it has been proven that these two seemingly different approaches have the same mathematical foundation. Besides, fuzzy kernel clustering methods are presented as extensions of kernel K-means clustering algorithm.

Key words: partitional clustering, Mercer kernels, kernel clustering, kernel fuzzy clustering, spectral clustering

1 Introduction

Unsupervised data analysis using clustering algorithms provides a useful tool to explore data structures. Clustering methods [39,87] have been addressed in many contexts and disciplines such as data mining, document retrieval, image segmentation and pattern classification. The aim of clustering methods is to group patterns on the basis of a similarity (or dissimilarity) criteria where groups (or clusters) are set of similar patterns. Crucial aspects in clustering are pattern representation and the similarity measure. Each pattern is usually represented by a set of features of the system under study. It is very important to notice that a good choice of representation of patterns can lead to improvements in clustering performance. Whether it is possible to choose an appropriate set of features depends on the system under study. Once a representation is fixed it is possible to choose an appropriate similarity measure among patterns. The most popular dissimilarity measure for metric representations is the distance, for instance the Euclidean one [25].

Clustering techniques can be roughly divided into two categories:

- *hierarchical*;
- *partitioning*.

Hierarchical clustering techniques [39,74,83] are able to find structures which can be further divided in substructures and so on recursively. The result is a hierarchical structure of groups known as *dendrogram*.

Partitioning clustering methods try to obtain a single partition of data without any other sub-partition like hierarchical algorithms do and are often based on the optimization of an appropriate objective function. The result is the creation of separations hypersurfaces among clusters. For instance we can consider two nonlinear clusters as in figure 1. Standard partitioning methods (e.g., K-Means, Fuzzy c-Means, SOM and Neural Gas) using two centroids are not able to separate in the desired way the two rings. The use of many centroids could solve this problem providing a complex description of a simple data set. For this reason several modifications and new approaches have been introduced to cope with this problem.

Among the large amount of modifications we can mention the Fuzzy c-Varieties [8], but the main drawback is that some a priori information on the shape of clusters must be included. Recently, some clustering methods that produce nonlinear separating hypersurfaces among clusters have been proposed. These algorithms can be divided in two big families: kernel and spectral clustering methods.

Regarding kernel clustering methods, several clustering methods have been
modified incorporating kernels (e.g., K-Means, Fuzzy c-Means, SOM and Neural Gas). The use of kernels allows to map implicitly data into an high dimensional space called feature space; computing a linear partitioning in this feature space results in a nonlinear partitioning in the input space.

Spectral clustering methods arise from concepts in spectral graph theory. The basic idea is to construct a weighted graph from the initial data set where each node represents a pattern and each weighted edge simply takes into account the similarity between two patterns. In this framework the clustering problem can be seen as a graph cut problem, which can be tackled by means of the spectral graph theory. The core of this theory is the eigenvalue decomposition of the Laplacian matrix of the weighted graph obtained from data. In fact, there is a close relationship between the second smallest eigenvalue of the Laplacian and the graph cut [16,26].

The aim of this paper is to present a survey of kernel and spectral clustering methods. Moreover, an explicit proof of the fact that these two approaches have the same mathematical foundation is reported. In particular it has been shown by Dhillon et al. that Kernel K-Means and spectral clustering with the ratio association as the objective function are perfectly equivalent [20,21,23]. The core of both approaches lies in their ability to construct an adjacency structure between data avoiding to deal with a prefixed shape of clusters. These approaches have a slight similarity with hierarchical methods in the use of an adjacency structure with the main difference in the philosophy of the grouping procedure.

A comparison of some spectral clustering methods has been recently proposed in [79], while there are some theoretical results on the capabilities and convergence properties of spectral methods for clustering [40,80,81,90]. Recently kernel methods have been applied to Fuzzy c-Varieties also [50] with the aim of finding varieties in feature space and there are some interesting clustering
methods using kernels such as [33] and [34].

Since the choice of the kernel and of the similarity measure is crucial in these methods, many techniques have been proposed in order to learn automatically the shape of kernels from data as in [4,18,27,56].

Regarding the applications, most of these algorithms (e.g., [12,18,50]) have been applied to standard benchmarks such as Ionosphere [73], Breast Cancer [85] and Iris [28] \(^1\). Kernel Fuzzy c-Means proposed in [14,93,94] has been applied in image segmentation problems while in [32] it has been applied in handwritten digits recognition. There are applications of kernel clustering methods in face recognition using kernel SOM [76], in speech recognition [69] and in prediction of crop yield from climate and plantation data [3]. Spectral methods have been applied in clustering of artificial data [60,63], in image segmentation [56,72,75], in bioinformatics [19], and in co-clustering problems of words and documents [22] and genes and conditions [42]. A semi-supervised spectral approach to bioinformatics and handwritten character recognition have been proposed in [48]. The protein sequence clustering problem has been faced using spectral techniques in [61] and kernel methods in [84].

In the next section we briefly introduce the concepts of linear partitioning methods by recalling some basic crisp and fuzzy algorithms. Then the paper is organized as follows: section 3 shows the kernelized version of the algorithms presented in section 2, in section 4 we discuss spectral clustering, while in section 5 we report the equivalence between spectral and kernel clustering methods. In the last section conclusions are drawn.

2 Partitioning Methods

In this section we briefly recall some basic facts about partitioning clustering methods and we will report the clustering methods for which a kernel version has been proposed. Let \( X = \{x_1, \ldots , x_n\} \) be a data set composed by \( n \) patterns for which every \( x_i \in \mathbb{R}^d \). The codebook (or set of centroids) \( V \) is defined as the set \( V = \{v_1, \ldots , v_c\} \), typically with \( c \ll n \). Each element \( v_i \in \mathbb{R}^d \) is called codevector (or centroid or prototype) \(^2\).

The Voronoi region \( R_i \) of the codevector \( v_i \) is the set of vectors in \( \mathbb{R}^d \) for which

\(^1\) These data sets can be found at: ftp://ftp.ics.uci.edu/pub/machine-learning-databases/

\(^2\) Among many terms to denote such objects, we will use codevectors as in vector quantization theory.
\( \mathbf{v}_i \) is the nearest vector:

\[
R_i = \left\{ \mathbf{z} \in \mathbb{R}^d \mid i = \arg \min_j \| \mathbf{z} - \mathbf{v}_j \|^2 \right\}.
\] (1)

It is possible to prove that each Voronoi region is convex [51] and the boundaries of the regions are linear segments.

The definition of the \textit{Voronoi set} \( \pi_i \) of the codevector \( \mathbf{v}_i \) is straightforward. It is the subset of \( X \) for which the codevector \( \mathbf{v}_i \) is the nearest vector:

\[
\pi_i = \left\{ \mathbf{x} \in X \mid i = \arg \min_j \| \mathbf{x} - \mathbf{v}_j \|^2 \right\},
\] (2)

that is, the set of vectors belonging to \( R_i \). A partition on \( \mathbb{R}^d \) induced by all Voronoi regions is called \textit{Voronoi tessellation} or \textit{Dirichlet tessellation}.

Figure 2. An example of Voronoi tessellation where each black point is a codevector.

#### 2.1 Batch K-Means

A simple algorithm able to construct a Voronoi tessellation of the input space was proposed in 1957 by Lloyd [52] and it is known as \textit{batch K-Means}. Starting from the finite data set \( X \) this algorithm moves iteratively the \( k \) codevectors to the arithmetic mean of their Voronoi sets \( \{ \pi_i \}_{i=1,...,k} \). Theoretically speaking, a necessary condition for a codebook \( V \) to minimize the \textit{Empirical Quantization Error}:

\[
E(X) = \frac{1}{2n} \sum_{i=1}^{k} \sum_{\mathbf{x} \in \pi_i} \| \mathbf{x} - \mathbf{v}_i \|^2,
\] (3)
is that each codevector $v_i$ fulfills the centroid condition [29]. In the case of a finite data set $X$ and with Euclidean distance, the centroid condition reduces to:

$$v_i = \frac{1}{|\pi_i|} \sum_{x \in \pi_i} x. \tag{4}$$

Batch K-Means is formed by the following steps:

1. choose the number $k$ of clusters;
2. initialize the codebook $V$ with vectors randomly picked from $X$;
3. compute the Voronoi set $\pi_i$ associated to the codevector $v_i$;
4. move each codevector to the mean of its Voronoi set using Eq. 4;
5. return to step 3 if any codevector has changed otherwise return the codebook.

At the end of the algorithm a codebook is found and a Voronoi tessellation of the input space is provided. It is guaranteed that after each iteration the quantization error does not increase. Batch K-Means can be viewed as an Expectation-Maximization [9] algorithm, ensuring the convergence after a finite number of steps.

This approach presents many disadvantages [25]. Local minima of $E(X)$ make the method dependent on initialization, and the average is sensitive to outliers. Moreover, the number of clusters to find must be provided, and this can be done only using some a priori information or additional validity criterion. Finally, K-Means can deal only with clusters with spherically symmetrical point distribution, since Euclidean distances of patterns from centroids are computed leading to a spherical invariance. Different distances lead to different invariance properties as in the case of Mahalanobis distance which produces invariance on ellipsoids [25].

The term batch means that at each step the algorithm takes into account the whole data set to update the codevectors. When the cardinality $n$ of the data set $X$ is very high (e.g., several hundreds of thousands) the batch procedure is computationally expensive. For this reason an on-line update has been introduced leading to the on-line K-Means algorithm [51,54]. At each step, this method simply randomly picks an input pattern and updates its nearest codevector, ensuring that the scheduling of the updating coefficient is adequate to allow convergence and consistency.
A Self Organizing Map (SOM) [43] also known as Self Organizing Feature Map (SOFM) represents data by means of codevectors organized on a grid with fixed topology. Codevectors move to adapt to the input distribution, but adaptation is propagated along the grid also to neighboring codevectors, according to a given propagation or neighborhood function. This effectively constrains the evolution of codevectors. Grid topologies may differ, but in this paper we consider a two-dimensional, square-mesh topology [44,45]. The distance on the grid is used to determine how strongly a codevector is adapted when the unit $a_{ij}$ is the winner. The metric used on a rectangular grid is the Manhattan distance, for which the distance between two elements $r = (r_1, r_2)$ and $s = (s_1, s_2)$ is:

$$d_{rs} = |r_1 - s_1| + |r_2 - s_2|.$$  \hspace{1cm} (5)

The SOM algorithm is the following:

1. Initialize the codebook $V$ randomly picking from $X$
2. Initialize the set $C$ of connections to form the rectangular grid of dimension $n_1 \times n_2$
3. Initialize $t = 0$
4. Randomly pick an input $x$ from $X$
5. Determine the winner

$$s(x) = \arg \min_{v_j \in V} \| x - v_j \|$$ \hspace{1cm} (6)

6. Adapt each codevector:

$$\Delta v_j = \epsilon(t)h(d_{rs})(x - v_j)$$ \hspace{1cm} (7)

where $h$ is a decreasing function of $d$ as for instance:

$$h(d_{rs}) = \exp \left( -\frac{d_{rs}^2}{2\sigma^2(t)} \right).$$ \hspace{1cm} (8)

7. Increment $t$
8. if $t < t_{\text{max}}$ go to step 4

$\sigma(t)$ and $\epsilon(t)$ are decreasing functions of $t$, for example [64]:

$$\sigma(t) = \sigma_1 \left( \frac{\sigma_f}{\sigma_i} \right)^{t/t_{\text{max}}}, \quad \epsilon(t) = \epsilon_1 \left( \frac{\epsilon_f}{\epsilon_i} \right)^{t/t_{\text{max}}},$$ \hspace{1cm} (9)
where $\sigma_i$, $\sigma_f$ and $\epsilon_i$, $\epsilon_f$ are the initial and final values for the functions $\sigma(t)$ and $\epsilon(t)$.

A final note on the use of SOM for clustering. The method was originally devised as a tool for embedding multidimensional data into typically two dimensional spaces, for data visualization. Since then, it has also been frequently used as a clustering method, which was originally not considered appropriate because of the constraints imposed by the topology. However, the topology itself serves an important purpose, namely, that of limiting the flexibility of the mapping in the first training cycles, and gradually increasing it (while decreasing the magnitude of updates to ensure convergence) as more cycles were performed. The strategy is similar to that of other algorithms, including these described in the following, in the capacity control of the method which has the effect of avoiding local minima. This accounts for the fast convergence often reported in experimental works.

2.3 Neural Gas

Another technique that tries to minimize the distortion error is the neural gas algorithm [55], based on a soft adaptation rule. This technique resembles the SOM in the sense that not only the winner codevector is adapted. It is different in that codevectors are not constrained to be on a grid, and the adaptation of the codevectors near the winner is controlled by a criterion based on distance ranks. Each time a pattern $x$ is presented, all the codevectors $v_j$ are ranked according to their distance to $x$ (the closest obtains the lowest rank). Denoting with $\rho_j$ the rank of the distance between $x$ and the codevector $v_j$, the update rule is:

$$\Delta v_j = \epsilon(t) h_\lambda(\rho_j)(x - v_j)$$

with $\epsilon(t) \in [0, 1]$ gradually lowered as $t$ increases and $h_\lambda(\rho_j)$ a function decreasing with $\rho_j$ with a characteristic decay $\lambda$; usually $h_\lambda(\rho_j) = \exp(-\rho_j/\lambda)$.

The Neural Gas algorithm is the following:

1. Initialize the codebook $V$ randomly picking from $X$
2. Initialize the time parameter $t = 0$
3. Randomly pick an input $x$ from $X$
4. Order all elements $v_j$ of $V$ according to their distance to $x$, obtaining the $\rho_j$
5. Adapt the codevectors according to Eq. 10
6. Increase the time parameter $t = t + 1$
7. if $t < t_{max}$ go to step 3.
Bezdek [8] introduced the concept of hard and fuzzy partition in order to extend the notion of membership of pattern to clusters. The motivation of this extension is related to the fact that a pattern often cannot be thought of as belonging to a single cluster only. In many cases, a description in which the membership of a pattern is shared among clusters is necessary.

**Definition 2.1** Let \( A_{cn} \) denote the vector space of \( c \times n \) real matrices over \( \mathbb{R} \). Considering \( X, A_{cn} \) and \( c \in \mathbb{N} \) such that \( 2 \leq c < n \), the Fuzzy \( c \)-partition space for \( X \) is the set:

\[
M_f = \left\{ U \in A_{cn} \mid u_{ih} \in [0, 1] \forall i, h; \sum_{i=1}^{c} u_{ih} = 1 \forall h ; 0 < \sum_{h=1}^{n} u_{ih} < n \forall i \right\}. \tag{11}
\]

The matrix \( U \) is the so called *membership matrix* since each element \( u_{ih} \) is the fuzzy membership of the \( h \)-th pattern to the \( i \)-th cluster. The definition of \( M_f \) simply tells that the sum of the memberships of a pattern to all clusters is one (probabilistic constraint) and that a cluster cannot be empty or contain all patterns. This definition generalizes the notion of hard \( c \)-partitions in [8].

The mathematical tool used in all these methods for working out the solution procedure is the Lagrange multipliers technique. In particular a minimization of the intraclusters distance functional with a probabilistic constraint on the memberships of a pattern to all clusters has to be achieved. Since all the functionals involved in these methods depend on both memberships and codevectors, the optimization is iterative and follows the so called *Picard iterations method* [8] where each iteration is composed of two steps. In the first step a subset of variables (memberships) is kept fixed and the optimization is performed with respect to the remaining variables (codevectors) while in the second one the role of the fixed and moving variables is swapped. The optimization algorithm stops when variables change less than a fixed threshold.

### 2.4.1 Fuzzy \( c \)-Means

The Fuzzy \( c \)-Means algorithm [8] identifies clusters as fuzzy sets. It minimizes the functional:

\[
J(U, V) = \sum_{h=1}^{n} \sum_{i=1}^{c} (u_{ih})^m \| x_h - v_i \|^2 \tag{12}
\]
with respect to the membership matrix $U$ and the codebook $V$ with the probabilistic constraints:

$$\sum_{i=1}^{c} u_{ih} = 1, \quad \forall i = 1, \ldots, n.$$  \hfill (13)

The parameter $m$ controls the fuzziness of the memberships and usually it is set to two; for high values of $m$ the algorithm tends to set all the memberships equals while for $m$ tending to one we obtain the K-Means algorithm where the memberships are crisp. The minimization of Eq. 12 is done introducing a Lagrangian function for each pattern for which the constraint is in Eq. 13.

$$L_h = \sum_{i=1}^{c} (u_{ih})^m \| x_h - v_i \|^2 + \alpha_h \left( \sum_{i=1}^{c} u_{ih} - 1 \right).$$ \hfill (14)

Then the derivatives of the sum of the Lagrangian are computed with respect to the $u_{ih}$ and $v_i$ and are set to zero. This yields the iteration scheme of these equations:

$$u_{ih}^{-1} = \sum_{j=1}^{c} \left( \frac{\| x_h - v_i \|}{\| x_h - v_j \|} \right)^{2-m},$$ \hfill (15)

$$v_i = \frac{\sum_{h=1}^{n} (u_{ih})^m x_h}{\sum_{h=1}^{n} (u_{ih})^m}.$$ \hfill (16)

At each iteration it is possible to evaluate the amount of change of the memberships and codevectors and the algorithm can be stopped when these quantities reach a predefined threshold. At the end a soft partitioning of the input space is obtained.

2.5 Possibilistic clustering methods

As a further modification of the K-Means algorithm, the possibilistic approach [46,47] relaxes the probabilistic constraint on the membership of a pattern to all clusters. In this way a pattern can have a low membership to all clusters in the case of outliers, whereas for instance, in the situation of overlapped clusters, it can have high membership to more than one cluster. In this framework the membership represents a degree of typicality not depending on the membership values of the same pattern to other clusters. Again the optimization procedure is the Picard iteration method, since the functional depends both on memberships and codevectors.
2.5.1 Possibilistic \(c\)-Means

There are two formulations of the Possibilistic \(c\)-Means, that we will call PCM-I [46] and PCM-II [47]. The first one aims to minimize the following functional with respect to the membership matrix \(U\) and the codebook \(V = \{v_1, \ldots, v_c\}\):

\[
J(U, V) = \sum_{h=1}^{n} \sum_{i=1}^{c} (u_{ih})^m \|x_h - v_i\|^2 + \sum_{i=1}^{c} \eta_i \sum_{h=1}^{n} (1 - u_{ih})^m ,
\]

while the second one addresses the functional:

\[
J(U, V) = \sum_{h=1}^{n} \sum_{i=1}^{c} u_{ih} \|x_h - v_i\|^2 + \sum_{i=1}^{c} \eta_i \sum_{h=1}^{n} (u_{ih} \ln(u_{ih}) - u_{ih}) .
\]

The minimization of Eq. 17 and Eq. 18 with respect to the \(u_{ih}\) leads respectively to the following equations:

\[
u_{ih} = \left[1 + \left(\frac{\|x_h - v_i\|^2}{\eta_i} \right)^{\frac{1}{m-1}}\right]^{-1},
\]

\[
u_{ih} = \exp\left(-\frac{\|x_h - v_i\|^2}{\eta_i}\right).
\]

The constraint on the memberships \(u_{ih} \in [0, 1]\) is automatically satisfied given the form assumed by Eq. 19 and Eq. 20. The updates of the centroids for PCM-I and PCM-II are respectively:

\[
v_i = \frac{\sum_{h=1}^{n} (u_{ih})^m x_h}{\sum_{h=1}^{n} (u_{ih})^m},
\]

\[
v_i = \frac{\sum_{h=1}^{n} u_{ih} x_h}{\sum_{h=1}^{n} u_{ih}}.
\]

The parameter \(\eta_i\) regulates the trade-off between the two terms in Eq. 17 and Eq. 18 and it is related to the width of the clusters. The authors suggest to estimate \(\eta_i\) for PCM-I using this formula:

\[
\eta_i = \frac{\sum_{h=1}^{n} (u_{ih})^m \|x_h - v_i\|^2}{\sum_{h=1}^{n} (u_{ih})^m}
\]

which is a weighted mean of the intracluster distance of the \(i\)-th cluster and the constant \(\gamma\) is typically set at one. The parameter \(\eta_i\) can be estimated with scale estimation techniques as developed in the robust clustering literature.
for M-estimators [35, 59]. The value of $\eta_i$ can be updated at each step of the algorithm or can be fixed for all iterations. The former approach can lead to instabilities since the derivation of the equations has been obtained considering $\eta_i$ fixed. In the latter case a good estimation of $\eta_i$ can be done only starting from an approximate solution. For this reason often the Possibilistic $c$-Means is run as a refining step of a Fuzzy $c$-Means.

3 Kernel Clustering Methods

In machine learning, the use of the kernel functions [57] has been introduced by Aizerman et al. [1] in 1964. In 1995 Cortes and Vapnik introduced Support Vector Machines (SVMs) [17] which perform better than other classification algorithms in several problems. The success of SVM has brought to extend the use of kernels to other learning algorithms (e.g., Kernel PCA [70]). The choice of the kernel is crucial to incorporate a priori knowledge on the application, for which it is possible to design ad hoc kernels.

3.1 Mercer kernels

We recall the definition of Mercer kernels [2, 68], considering, for the sake of simplicity, vectors in $\mathbb{R}^d$ instead of $\mathbb{C}^d$.

**Definition 3.1** Let $X = \{x_1, \ldots, x_n\}$ be a nonempty set where $x_i \in \mathbb{R}^d$. A function $K : X \times X \to \mathbb{R}$ is called a positive definite kernel (or Mercer kernel) if and only if $K$ is symmetric (i.e. $K(x_i, x_j) = K(x_j, x_i)$) and the following equation holds:

$$
\sum_{i=1}^{n} \sum_{j=1}^{n} c_i c_j K(x_i, x_j) \geq 0 \quad \forall n \geq 2 ,
$$

(24)

where $c_r \in \mathbb{R} \forall r = 1, \ldots, n$

Each Mercer kernel can be expressed as follows:

$$
K(x_i, x_j) = \Phi(x_i) \cdot \Phi(x_j) ,
$$

(25)

where $\Phi : X \to \mathcal{F}$ performs a mapping from the input space $X$ to a high dimensional feature space $\mathcal{F}$. One of the most relevant aspects in applications is that it is possible to compute Euclidean distances in $\mathcal{F}$ without knowing explicitly $\Phi$. This can be done using the so called distance kernel trick [58, 70]:
\[ \|\Phi(x_i) - \Phi(x_j)\|^2 = (\Phi(x_i) - \Phi(x_j)) \cdot (\Phi(x_i) - \Phi(x_j)) \\
= \Phi(x_i) \cdot \Phi(x_i) + \Phi(x_j) \cdot \Phi(x_j) - 2\Phi(x_i) \cdot \Phi(x_j) \\
= K(x_i, x_i) + K(x_j, x_j) - 2K(x_i, x_j) \quad (26) \]

in which the computation of distances of vectors in feature space is just a function of the input vectors. In fact, every algorithm in which input vectors appear only in dot products with other input vectors can be kernelized [71]. In order to simplify the notation we introduce the so called Gram matrix \( K \) where each element \( k_{ij} \) is the scalar product \( \Phi(x_i) \cdot \Phi(x_j) \). Thus, Eq. 26 can be rewritten as:

\[ \|\Phi(x_i) - \Phi(x_j)\|^2 = k_{ii} + k_{jj} - 2k_{ij} . \quad (27) \]

Examples of Mercer kernels are the following [78]:

- linear:
  \[ K^{(l)}(x_i, x_j) = x_i \cdot x_j \quad (28) \]

- polynomial of degree \( p \):
  \[ K^{(p)}(x_i, x_j) = (1 + x_i \cdot x_j)^p \quad p \in \mathbb{N} \quad (29) \]

- Gaussian:
  \[ K^{(g)}(x_i, x_j) = \exp \left( -\frac{\|x_i - x_j\|^2}{2\sigma^2} \right) \quad \sigma \in \mathbb{R} \quad (30) \]

It is important to stress that the use of the linear kernel in Eq. 26 simply leads to the computation of the Euclidean norm in the input space. Indeed:

\[ \|x_i - x_j\|^2 = x_i \cdot x_i + x_j \cdot x_j - 2x_i \cdot x_j \\
= K^{(l)}(x_i, x_i) + K^{(l)}(x_j, x_j) - 2K^{(l)}(x_i, x_j) \\
= \|\Phi(x_i) - \Phi(x_j)\|^2 , \quad (31) \]

shows that choosing the kernel \( K^{(l)} \) implies \( \Phi = I \) (where \( I \) is the identity function). Following this consideration we can think that kernels can offer a more general way to represent the elements of a set \( X \) and possibly, for some of these representations, the clusters can be easily identified.

In literature there are some applications of kernels in clustering. These methods can be broadly divided in three categories, which are based respectively on:

- kernelization of the metric [86,92,93];
• clustering in feature space [32,38,53,62,91];
• description via support vectors [12,37].

Methods based on kernelization of the metric look for centroids in input space and the distances between patterns and centroids is computed by means of kernels:

$$\|\Phi(x_h) - \Phi(v_i)\|^2 = K(x_h, x_h) + K(v_i, v_i) - 2K(x_h, v_i).$$

Clustering in feature space is made by mapping each pattern using the function $\Phi$ and then computing centroids in feature space. Calling $v_\Phi^i$ the centroids in feature space, we will see in the next sections that it is possible to compute the distances $\|\Phi(x_h) - v_\Phi^i\|^2$ by means of the kernel trick.

The description via support vectors makes use of One Class SVM to find a minimum enclosing sphere in feature space able to enclose almost all data in feature space excluding outliers. The computed hypersphere corresponds to nonlinear surfaces in input space enclosing groups of patterns. The Support Vector Clustering algorithm allows to assign labels to patterns in input space enclosed by the same surface. In the next subsections we will outline these three approaches.

### 3.2 Kernel K-Means

Given the data set $X$, we map our data in some feature space $\mathcal{F}$, by means of a nonlinear map $\Phi$ and we consider $k$ centers in feature space ($v_\Phi^i \in \mathcal{F}$ with $i = 1, \ldots, k$) [30,70]. We call the set $V^\Phi = (v_\Phi^1, \ldots, v_\Phi^k)$ Feature Space Codebook since in our representation the centers in the feature space play the same role of the codevectors in the input space. In analogy with the codevectors in the input space, we define for each center $v_\Phi^i$ its Voronoi Region and Voronoi Set in feature space. The Voronoi Region in feature space ($R_\Phi^i$) of the center $v_\Phi^i$ is the set of all vectors $x$ in $X$ such that $v_\Phi^i$ is the closest vector

$$R_\Phi^i = \left\{ x_\Phi \in \mathcal{F} \bigg| i = \arg\min_j \|x_\Phi - v_\Phi^j\| \right\}.\quad (33)$$

The Voronoi Set in Feature Space $\pi_\Phi^i$ of the center $v_\Phi^i$ is the set of all vectors $x$ in $X$ such that $v_\Phi^i$ is the closest vector to their images $\Phi(x)$ in the feature space:

$$\pi_\Phi^i = \left\{ x \in X \bigg| i = \arg\min_j \|\Phi(x) - v_\Phi^j\| \right\}.\quad (34)$$
The set of the Voronoi Regions in feature space define a Voronoi Tessellation of the Feature Space. The Kernel K-Means algorithm has the following steps:

1. Project the data set $X$ into a feature space $\mathcal{F}$, by means of a nonlinear mapping $\Phi$.
2. Initialize the codebook $V^\Phi = (v^\Phi_1, \ldots, v^\Phi_k)$ with $v^\Phi_i \in \mathcal{F}$
3. Compute for each center $v^\Phi_i$ the set $\pi^\Phi_i$
4. Update the codevectors $v^\Phi_i$ in $\mathcal{F}$
   \[
   v^\Phi_i = \frac{1}{|\pi^\Phi_i|} \sum_{x \in \pi^\Phi_i} \Phi(x) \tag{35}
   \]
5. Go to step 3 until any $v^\Phi_i$ changes
6. Return the feature space codebook.

This algorithm minimizes the quantization error in feature space.

Since we do not know explicitly $\Phi$ it is not possible to compute directly Eq. 35. Nevertheless, it is always possible to compute distances between patterns and codevectors by using the kernel trick, allowing to obtain the Voronoi sets in feature space $\pi^\Phi_i$. Indeed, writing each centroid in feature space as a combination of data vectors in feature space we have:

\[
   v^\Phi_j = \sum_{h=1}^{n} \gamma_{jh} \Phi(x_h), \tag{36}
\]

where $\gamma_{jh}$ is one if $x_h \in \pi^\Phi_j$ and zero otherwise. Now the quantity:

\[
   \|\Phi(x_i) - v^\Phi_j\|^2 = \left\|\Phi(x_i) - \sum_{h=1}^{n} \gamma_{jh} \Phi(x_h)\right\|^2 \tag{37}
\]

can be expanded by using the scalar product and the kernel trick in Eq. 26:

\[
   \left\|\Phi(x_i) - \sum_{h=1}^{n} \gamma_{jh} \Phi(x_h)\right\|^2 = k_{ii} - 2 \sum_{h} \gamma_{jh} k_{ih} + \sum_{r} \sum_{s} \gamma_{jr} \gamma_{js} k_{rs}. \tag{38}
\]

This allows to compute the closest feature space codevector for each pattern and to update the coefficients $\gamma_{jh}$. It is possible to repeat these two operations until any $\gamma_{jh}$ changes to obtain a Voronoi tessellation of the feature space.

An on-line version of the kernel K-Means algorithm can be found in [70]. A further version of K-Means in feature space has been proposed by Girolami [30]. In his formulation the number of clusters is denoted by $c$ and a fuzzy membership matrix $U$ is introduced. Each element $u_{ih}$ denotes the fuzzy membership
of the point $x_h$ to the Voronoi set $\pi_i^\Phi$. This algorithm tries to minimize the following functional with respect to $U$:

$$J^\Phi(U, V^\Phi) = \sum_{h=1}^{n} \sum_{i=1}^{c} u_{ih} \left\| \Phi(x_h) - v_i^\Phi \right\|^2 .$$

(39)

The minimization technique used by Girolami is Deterministic Annealing [65] which is a stochastic method for optimization. A parameter controls the fuzziness of the membership during the optimization and can be thought proportional to the temperature of a physical system. This parameter is gradually lowered during the annealing and at the end of the procedure the memberships have become crisp; therefore a tessellation of the feature space is found. This linear partitioning in $\mathcal{F}$, back to the input space, forms a nonlinear partitioning of the input space.

### 3.3 Kernel SOM

The kernel version of the SOM algorithm [38,53] is based on the distance kernel trick. The method tries to adapt the grid of codevectors $v_j^\Phi$ in feature space. In kernel SOM we start writing each codevector as a combination of points in feature space:

$$v_j^\Phi = \sum_{h=1}^{n} \gamma_{jh} \Phi(x_h) ,$$

(40)

where the coefficients $\gamma_{ih}$ are initialized once the grid is created. Computing the winner by writing Eq. 6 in feature space leads to:

$$s(\Phi(x_i)) = \arg \min_{v_j^\Phi \in V} \left\| \Phi(x_i) - v_j^\Phi \right\| ,$$

(41)

that can be written, using the kernel trick:

$$s(\Phi(x_i)) = \arg \min_{v_j^\Phi \in V} \left( k_{ii} - 2 \sum_h \gamma_{jh} k_{ih} \sum_r \sum_s \gamma_{jr} \gamma_{js} k_{rs} \right) .$$

(42)

To update the codevectors we rewrite Eq. 7:

$$v_j^{\Phi'} = v_j^\Phi + \epsilon(t) h(d_{rs}) \left( \Phi(x) - v_j^\Phi \right) .$$

(43)
Using Eq. 40:

\[
\sum_{h=1}^{n} \gamma'_{jh} \Phi(x_h) = \sum_{h=1}^{n} \gamma_{jh} \Phi(x_h) + \epsilon(t) h(d_{rs}) \left( \Phi(x) - \sum_{h=1}^{n} \gamma_{jh} \Phi(x_h) \right). \tag{44}
\]

Thus the rule for the update of \(\gamma_{jh}\) is:

\[
\gamma'_{jh} = \begin{cases} 
(1 - \epsilon(t) h(d_{rs})) \gamma_{jh} & \text{if } i \neq j \\
(1 - \epsilon(t) h(d_{rs})) \gamma_{jh} + \epsilon(t) h(d_{rs}) & \text{otherwise}
\end{cases} \tag{45}
\]

### 3.4 Kernel Neural Gas

The Neural Gas algorithm provides a soft update rule for the codevectors in input space. The kernel version of neural gas [62] applies the soft rule for the update to the codevectors in feature space. Rewriting Eq. 10 in feature space for the update of the codevectors we have:

\[
\Delta \mathbf{v}_j^\Phi = \epsilon h_{\lambda}(\rho_j) \left( \Phi(x) - \mathbf{v}_j^\Phi \right). \tag{46}
\]

Here \(\rho_j\) is the rank of the distance \(\|\Phi(x) - \mathbf{v}_j^\Phi\|\). Again it is possible to write \(\mathbf{v}_j^\Phi\) as a linear combination of \(\Phi(x_i)\) as in Eq. 40, allowing to compute such distances by means of the kernel trick. As in the kernel SOM technique, the updating rule for the centroids becomes an updating rule for the coefficients of such combination.

### 3.5 One Class SVM

This approach provides a support vector description in feature space [36,37,77]. The idea is to use kernels to project data into a feature space and then to find the sphere enclosing almost all data, namely not including outliers. Formally a radius \(R\) and the center \(\mathbf{v}\) of the smallest enclosing sphere in feature space are defined. The constraint is thus:

\[
\|\Phi(x_j) - \mathbf{v}\|^2 \leq R^2 + \xi_j \quad \forall j, \tag{47}
\]

where the non negative slack variables \(\xi_j\) have been added. The Lagrangian for this problem is defined [11]:

\[
L = R^2 - \sum_j (R^2 + \xi_j - \|\Phi(x_j) - \mathbf{v}\|^2) \beta_j - \sum_j \xi_j \mu_j + C \sum \xi_j \tag{48}
\]
where \( \beta_j \geq 0 \) and \( \mu_j \geq 0 \) are Lagrange multipliers, \( C \) is a constant and \( C \sum_j \xi_j \) is a penalty term. Computing the partial derivative of \( L \) with respect to \( R \), \( v \) and \( \xi_j \) and setting them to zero leads to the following equations:

\[
\sum_j \beta_j = 1, \quad v = \sum_j \beta_j \Phi(x_j), \quad \beta_j = C - \mu_j. \tag{49}
\]

The Karush-Kuhn-Tucker (KKT) complementary conditions [11] result in:

\[
\xi_j \mu_j = 0, \quad (R^2 + \xi_j - \|\Phi(x_j) - v\|^2)\beta_j = 0. \tag{50}
\]

Following simple considerations regarding all these conditions it is possible to see that:

- when \( \xi_j > 0 \), the image of \( x_j \) lies outside the hypersphere. These points are called *bounded support vectors*;
- when \( \xi_j = 0 \) and \( 0 < \beta_j < C \), the image of \( x_j \) lies on the surface of the hypersphere. These points are called *support vectors*.

Moreover, it is possible to write the Wolfe dual form [36], whose optimization leads to this quadratic programming problem with respect to the \( \beta_j \):

\[
J_W = \sum_j k_{jj} \beta_j - \sum_i \sum_j k_{ij} \beta_i \beta_j \tag{51}
\]

The distance from the image of a point \( x_j \) and the center \( v \) of the enclosing sphere can be computed as follows:

\[
d_j = \|\Phi(x_j) - v\|^2 = k_{jj} - 2 \sum_r \beta_r k_{jr} + \sum_r \sum_s \beta_r \beta_s k_{rs}. \tag{52}
\]

In Fig. 3 it is possible to see the ability of this algorithm to find the smallest enclosing sphere without outliers.

### 3.5.1 Support Vector Clustering

Once boundaries in input space are found, a labeling procedure is necessary in order to complete clustering. In [37] the cluster assignment procedure follows a simple geometric idea. Any path connecting a pair of points belonging to different clusters must exit from the enclosing sphere in feature space. Denoting with \( Y \) the image in feature space of one of such paths and with \( y \) the elements of \( Y \), it will result that \( R(y) > R \) for some \( y \). Thus it is possible to
Figure 3. One class SVM applied to two data sets with outliers. The gray line shows the projection in input space of the smallest enclosing sphere in feature space. In (a) a linear kernel and in (b) a Gaussian kernel have been used.

Clustering is simply the connected components of the graph with the adjacency matrix just defined. In the implementation in [36] the check is made sampling the line segment $Y$ in 20 equidistant points. There are some modifications on this labeling algorithm (e.g., [49,88]) that improve performances. An improved version of SVC algorithm with application in handwritten digits recognition can be found in [15].

### 3.5.2 Camastra and Verri algorithm

A technique combining K-Means and One Class SVM can be found in [12]. The algorithm uses a K-Means-like strategy, i.e., moves repeatedly all centers $v_i$ in the feature space, computing One Class SVM on their Voronoi sets $\pi_i$, until no center changes anymore. Moreover, in order to introduce robustness against outliers, the authors have proposed to compute One Class SVM on $\pi_i(\rho)$ of each center $v_i$. The set $\pi_i(\rho)$ is defined as

$$\pi_i(\rho) = \{x_j \in \pi_i, \|\Phi(x_j) - v_i\| < \rho\}.$$  

$\pi_i(\rho)$ is the Voronoi set in the feature space of the center $v_i$ without outliers, that is the images of data points whose distance from the center is larger than
The parameter $\rho$ can be set up using model selection techniques [9] (e.g., cross-validation). In summary, the algorithm has the following steps:

1. Project the data set $X$ into a feature space $\mathcal{F}$, by means of a nonlinear mapping $\Phi$.
2. Initialize the codebook $V^\Phi = (v_1^\Phi, \ldots, v_k^\Phi)$ with $v_i^\Phi \in \mathcal{F}$
3. Compute $\pi_i^\Phi(\rho)$ for each center $v_i^\Phi$.
4. Apply One Class SVM to each $\pi_i^\Phi(\rho)$ and assign the center obtained to $v_i^\Phi$.
5. Go to step 2 until any $v_i^\Phi$ changes.
6. Return the feature space codebook.

### 3.6 Kernel fuzzy clustering methods

Here we show some kernelized versions of Fuzzy c-Means algorithms, showing in particular Fuzzy and Possibilistic c-Means. In the first subsection we show the method of the kernelization of the metric while in the second one the Fuzzy c-Means in feature space is shown. The third subsection is devoted to the kernelized version of the Possibilistic c-Means.

#### 3.6.1 Kernel Fuzzy c-Means with kernelization of the metric

The basic idea is to minimize the functional [86,92,93]:

$$
J^\Phi(U,V) = \sum_{h=1}^{n} \sum_{i=1}^{c} (u_{ih})^m \| \Phi(x_h) - \Phi(v_i) \|^2 ,
$$

with the probabilistic constraint over the memberships (Eq. 13). The procedure for the optimization of $J^\Phi(U,V)$ is again the Picard iteration technique. Minimization of the functional in Eq. 55 has been proposed only in the case of a Gaussian kernel $K^{(g)}$. The reason is that the derivative of $J^\Phi(U,V)$ with respect to the $v_i$ using a Gaussian kernel is particularly simple since it allows to use the kernel trick:

$$
\frac{\partial K(x_h,v_i)}{\partial v_i} = \frac{(x_h - v_i)}{\sigma^2} K(x_h,v_i) .
$$

We obtain for the memberships:

$$
u_{ih}^{-1} = \sum_{j=1}^{c} \left( \frac{1 - K(x_h,v_i)}{1 - K(x_h,v_j)} \right) \frac{1}{m-1} ,
$$
and for the codevectors:

\[ v_i = \frac{\sum_{h=1}^{n} (u_{ih})^m K(x_h, v_i) x_h}{\sum_{h=1}^{n} (u_{ih})^m K(x_h, v_i)} \quad (58) \]

3.6.2 Kernel Fuzzy c-Means in feature space

Here we derive the Fuzzy c-Means in feature space, which is a clustering method which allows to find a soft linear partitioning of the feature space. This partitioning, back to the input space, results in a soft nonlinear partitioning of data. The functional to optimize [32,91] with the probabilistic constraint in Eq. 13 is:

\[ J^\Phi(U, V^\Phi) = \sum_{h=1}^{n} \sum_{i=1}^{c} (u_{ih})^m \left\| \Phi(x_h) - \Phi(v_i) \right\|^2 . \quad (59) \]

It is possible to rewrite the norm in Eq. 59 explicitly by using:

\[ v_i^\Phi = \frac{\sum_{h=1}^{n} (u_{ih})^m \Phi(x_h)}{\sum_{h=1}^{n} (u_{ih})^m} = a_i \sum_{h=1}^{n} (u_{ih})^m \Phi(x_h) \quad , \quad (60) \]

which is the kernel version of Eq. 16. For simplicity of notation we used:

\[ a_i^{-1} = \sum_{r=1}^{n} (u_{ir})^m \quad . \quad (61) \]

Now it is possible to write the kernel version of Eq. 15:

\[ u_{ih}^{-1} = \sum_{j=1}^{c} \left[ \frac{k_{hh} - 2a_j \sum_{r=1}^{n} (u_{ir})^m k_{hr} + a_j^2 \sum_{r=1}^{n} \sum_{s=1}^{n} (u_{ir})^m (u_{is})^m k_{rs}}{k_{hh} - 2a_j \sum_{r=1}^{n} (u_{jr})^m k_{hr} + a_j^2 \sum_{r=1}^{n} \sum_{s=1}^{n} (u_{jr})^m (u_{js})^m k_{rs}} \right]^{1 \over m-1} \quad (62) \]

Eq. 62 gives the rule for the update of the membership \( u_{ih} \).

3.6.3 Possibilistic c-Means with the kernelization of the metric

The formulation of the Possibilistic c-Means PCM-I with the kernelization of the metric used in [92] involves the minimization of the following functional:

\[ J^\Phi(U, V) = \sum_{h=1}^{n} \sum_{i=1}^{c} (u_{ih})^m \left\| \Phi(x_h) - \Phi(v_i) \right\|^2 + \sum_{i=1}^{c} \eta_i \sum_{h=1}^{n} (1 - u_{ih})^m \quad (63) \]
Minimization leads to:

\[ u_{ih}^{-1} = 1 + \left( \frac{\|\Phi(x_h) - \Phi(v_i)\|^2}{\eta_i} \right)^{\frac{1}{m-1}}, \]  \hspace{1cm} (64)

that can be rewritten, considering a Gaussian kernel, as:

\[ u_{ih}^{-1} = 1 + 2 \left( \frac{1 - K(x_h, v_i)}{\eta_i} \right)^{\frac{1}{m-1}}. \]  \hspace{1cm} (65)

The update of the codevectors follows:

\[ v_i = \frac{\sum_{h=1}^{n} (u_{ih})^m K(x_h, v_i)x_h}{\sum_{h=1}^{n} (u_{ih})^m K(x_h, v_i)}. \]  \hspace{1cm} (66)

The computation of the \( \eta_i \) is straightforward.

4 Spectral Clustering

Spectral clustering methods [19] have a strong connection with graph theory [16,24]. A comparison of some spectral clustering methods has been recently proposed in [79]. Let \( X = \{x_1, \ldots, x_n\} \) be the set of patterns to cluster. Starting from \( X \), we can build a complete, weighted undirected graph \( G(V, A) \) having a set of nodes \( V = \{v_1, \ldots, v_n\} \) corresponding to the \( n \) patterns and edges defined through the \( n \times n \) adjacency (also affinity) matrix \( A \). The adjacency matrix for a weighted graph is given by the matrix whose element \( a_{ij} \) represents the weight of the edge connecting nodes \( i \) and \( j \). Being an undirected graph, the property \( a_{ij} = a_{ji} \) holds. Adjacency between two patterns can be defined as follows:

\[ a_{ij} = \begin{cases} h(x_i, x_j) & \text{if } i \neq j \\ 0 & \text{otherwise.} \end{cases} \]  \hspace{1cm} (67)

The function \( h \) measures the similarity between patterns and typically a Gaussian function is used:

\[ h(x_i, x_j) = \exp \left( -\frac{d(x_i, x_j)}{2\sigma^2} \right), \]  \hspace{1cm} (68)
where $d$ measures the dissimilarity between patterns and $\sigma$ controls the rapidity of decay of $h$. This particular choice has the property that $A$ has only some terms significantly different from 0, i.e., it is sparse.

The degree matrix $D$ is the diagonal matrix whose elements are the degrees of the nodes of $G$.

$$d_{ii} = \sum_{j=1}^{n} a_{ij} .$$  \hfill (69)

In this framework the clustering problem can be seen as a graph cut problem [16] where one wants to separate a set of nodes $S \subset V$ from the complementary set $\bar{S} = V \setminus S$. The graph cut problem can be formulated in several ways depending on the choice of the function to optimize. One of the most popular functions to optimize is the cut [16]:

$$cut(S, \bar{S}) = \sum_{\substack{v_i \in S, v_j \in \bar{S}}} a_{ij} .$$  \hfill (70)

It is easy to verify that the minimization of this objective function favors partitions containing isolated nodes. To achieve a better balance in the cardinality of $S$ and $\bar{S}$ it is suggested to optimize the normalized cut [72]:

$$Ncut(S, \bar{S}) = cut(S, \bar{S}) \left( \frac{1}{assoc(S, V)} + \frac{1}{assoc(S, V)} \right) ,$$  \hfill (71)

where the association $assoc(S, V)$ is also known as the volume of $S$:

$$assoc(S, V) = \sum_{\substack{v_i \in S, v_j \in V}} a_{ij} \equiv vol(S) = \sum_{v_i \in S} d_{ii} .$$  \hfill (72)

There are other definitions of functions to optimize (e.g., the conductance [40], the normalized association [72], ratio cut [21]).

The complexity in optimizing these objective functions is very high (e.g., the optimization of the normalized cut is a NP-hard problem [72,82]) and for this reason it has been proposed to relax it by using spectral concepts of graph analysis. This relaxation can be formulated by introducing the Laplacian matrix [16]:

$$L = D - A ,$$  \hfill (73)

which can be seen as a linear operator on $G$. In addition to this definition of Laplacian there are alternative definitions:
• Normalized Laplacian $L_N = D^{-\frac{1}{2}}LD^{-\frac{1}{2}}$
• Generalized Laplacian $L_G = D^{-1}L$
• Relaxed Laplacian $L_\rho = L - \rho D$

Each definition is justified by special properties desirable in a given context. The spectral decomposition of the Laplacian matrix can give useful information about the properties of the graph. In particular it can be seen that the second smallest eigenvalue of $L$ is related to the graph cut [26] and the corresponding eigenvector can cluster together similar patterns [10,16,72].

Spectral approach to clustering has a strong connection with Laplacian Eigen-maps [5]. The dimensionality reduction problem aims to find a proper low dimensional representation of a data set in a high dimensional space. In [5], each node in the graph, which represents a pattern, is connected just with nodes corresponding to neighboring patterns and the spectral decomposition of the Laplacian of the obtained graph permits to find a low dimensional representation of $X$. The authors point out the close connection with spectral clustering and Local Linear Embedding [67] providing theoretical and experimental validations.

4.1 Shi and Malik algorithm

The algorithm proposed by Shi and Malik. [72] applies the concepts of spectral clustering to image segmentation problems. In this framework each node is a pixel and the definition of adjacency between them is suitable for image segmentation purposes. In particular, if $x_i$ is the position of the $i$-th pixel and $f_i$ a feature vector which takes into account several of its attributes (e.g., intensity, color and texture information), they define the adjacency as:

$$a_{ij} = \exp \left( -\frac{\|f_i - f_j\|^2}{2\sigma^2_1} \right), \begin{cases} \exp \left( -\frac{\|x_i - x_j\|^2}{2\sigma^2_2} \right) & \text{if } \|x_i - x_j\| < R \\ 0 & \text{otherwise.} \end{cases} \quad (74)$$

Here $R$ has an influence on how many neighboring pixels can be connected with a pixel, controlling the sparsity of the adjacency and Laplacian matrices. They provide a proof that the minimization of $Ncut(S, \bar{S})$ can be done solving the eigenvalue problem for the normalized Laplacian $L_N$. In summary, the algorithm is composed of these steps:

1. Construct the graph $G$ starting from the data set $X$ calculating the adjacency between patterns using Eq. 74
2. Compute the degree matrix $D$
3. Construct the matrix $L_N = D^{-\frac{1}{2}}LD^{-\frac{1}{2}}$
(4) Compute the eigenvector $e_2$ associated to the second smallest eigenvalue $\lambda_2$

(5) Use $D^{-\frac{1}{2}}e_2$ to segment $G$

In the ideal case of two non connected subgraphs, $D^{-\frac{1}{2}}e_2$ assumes just two values; this allows to cluster together the components of $D^{-\frac{1}{2}}e_2$ with the same value. In a real case the splitting point must be chosen to cluster the components of $D^{-\frac{1}{2}}e_2$ and the authors suggest to use the median value, zero or the value for which the clustering gives the minimum $Ncut$. The successive partitioning can be made recursively on the obtained sub-graphs or it is possible to use more than one eigenvector. An interesting approach for clustering simultaneously the data set in more than two clusters can be found in [89].

### 4.2 Ng, Jordan and Weiss algorithm

The algorithm that has been proposed by Ng et al. [60] uses the adjacency matrix $A$ as Laplacian. This definition allows to consider the eigenvector associated with the largest eigenvalues as the “good” one for clustering. This has a computational advantage since the principal eigenvectors can be computed for sparse matrices efficiently using the power iteration technique. The idea is the same as in other spectral clustering methods, i.e., one finds a new representation of patterns on the first $k$ eigenvectors of the Laplacian of the graph.

The algorithm is composed of these steps:

1. Compute the affinity matrix $A \in \mathbb{R}^{n \times n}$:
   \[
   a_{ij} = \begin{cases} 
   \exp \left( -\frac{\|x_i - x_j\|^2}{2\sigma^2} \right) & \text{if } i \neq j \\
   0 & \text{otherwise}
   \end{cases} \tag{75}
   \]

2. Construct the matrix $D$.

3. Compute a normalized version of $A$, defining this Laplacian:
   \[
   L = D^{-\frac{1}{2}}A D^{-\frac{1}{2}} \tag{76}
   \]

4. Find the $k$ eigenvectors $\{e_1, \ldots, e_k\}$ of $L$ associated to the largest eigenvalues $\{\lambda_1, \ldots, \lambda_k\}$.

5. Form the matrix $Z$ by stacking the $k$ eigenvectors in columns.

6. Compute the matrix $Y$ by normalizing each of the $Z$’s rows to have unit length:
   \[
   y_{ij} = \frac{z_{ij}}{\sum_{r=1}^{k} z_{ir}} \tag{77}
   \]
In this way all the original points are mapped into a unit hypersphere.

(7) In this new representation of the original $n$ points apply a clustering algorithm that attempts to minimize distortion such as K-means.

As a criterion to choose $\sigma$ they suggest to use the value that guarantees the minimum distortion when the clustering stage is performed on $Y$. They tested this algorithm on artificial data sets showing the capability of the algorithm to separate nonlinear structures. Here we show the steps of the algorithm when applied to the data set in Fig. 1. Once the singular value decomposition of $L$ is computed, we can see the matrices $Z$ and $Y$ in Fig. 4 (here obtained with $\sigma = 0.4$). Once $Y$ is computed, it is easy to cluster the two groups of points obtaining the result shown in Fig. 5.

Figure 4. (a) The matrix $Z$ obtained with the first two eigenvectors of the matrix $L$. (b) The matrix $Y$ obtained by normalizing the rows of $Z$ clustered by K-means algorithm with two centroids.

Figure 5. The result of the Ng and Jordan algorithm on the ring data set.
An interesting view of spectral clustering is provided by Meilă et al. [56] who describe it in the framework of Markov random walks [56] leading to a different interpretation of the graph cut problem. It is known, from the theory of Markov random walks, that if we construct the stochastic matrix $P = D^{-1}A$, each element $p_{ij}$ represents the probability of moving from node $i$ to node $j$. In their work they provide an explicit connection between the spectral decomposition of $L$ and $P$ showing that both have the same solution with eigenvalues of $P$ equal to $1 - \lambda_i$ where $\lambda_i$ are the eigenvalues of $L$. Moreover they propose a method to learn a function of the features able to produce a correct segmentation starting from a segmented image.

An interesting study on spectral clustering has been conducted by Kannan et al. [40]. The authors exploit the objective function with respect to some artificial data sets showing that there is no objective function able to properly cluster every data set. In other words there always exists some data set for which the optimization of a particular objective function has some drawback. For this reason they propose a bi-criteria objective function. These two objectives are respectively based on the conductance and the ratio between the auto-association of a subset of nodes $S$ and its volume. Again the relaxation of this problem is achieved by the decomposition of the Laplacian of the graph associated to the data set.

5 A Unified View of Spectral and Kernel Clustering Methods

Recently a possible connection between unsupervised kernel algorithms and spectral methods has been studied to find whether these two seemingly different approaches can be described under a more general framework. The hint for this unifying theory lies the adjacency structure constructed by both these approaches. In the spectral approach there is an adjacency between patterns which is the analogous of the kernel functions in kernel methods.

A direct connection between Kernel PCA and spectral methods has been shown [6,7]. More recently a unifying view of kernel K-means and spectral clustering methods [20,21,23] has been pointed out. In this section we show explicitly the equivalence between them highlighting that these two approaches have the same foundation and in particular that both can be viewed as a matrix trace maximization problem.
5.1 Kernel clustering methods objective

To show the direct equivalence between kernel and spectral clustering methods we introduce the weighted version of the kernel K-means [23]. We introduce a weight matrix $W$ having weights $w_k$ on the diagonal. Recalling that we denote with $\pi_i$ the $i$-th cluster we have that the functional to minimize is the following:

$$J^\Phi(W, V^\Phi) = \sum_{i=1}^{c} \sum_{x_k \in \pi_i} w_k \|\Phi(x_k) - v_i^\Phi\|^2,$$  \hspace{1cm} (78)

where:

$$v_i^\Phi = \frac{\sum_{x_k \in \pi_i} w_k \Phi(x_k)}{\sum_{x_k \in \pi_i} w_k^2} = \frac{\sum_{x_k \in \pi_i} w_k \Phi(x_k)}{s_i},$$  \hspace{1cm} (79)

where we have introduced:

$$s_i = \sum_{x_k \in \pi_i} w_k.$$  \hspace{1cm} (80)

Now let’s define the matrix $Z$ having:

$$z_{ki} = \begin{cases} s_i^{-1/2} & \text{if } x_k \in \pi_i \\ 0 & \text{otherwise.} \end{cases} \hspace{1cm} (81)$$

Since the columns of $Z$ are mutually orthogonal it is easy to verify that:

$$s_i^{-1} = (Z^T Z)_{ii},$$  \hspace{1cm} (82)

and that only the diagonal elements are not null.

Now we denote with $F$ the matrix whose columns are the $\Phi(x_k)$. It is easy to verify that the matrix $FW$ yields a matrix whose columns are the $w_k \Phi(x_k)$. Moreover the expression $FWZZ^T$ gives a matrix having $n$ columns which are the nearest centroids in feature space of the $\Phi(x_k)$.

Thus, substituting Eq. 79 in Eq. 78 we obtain the following matrix expression for $J^\Phi(W, V^\Phi)$:

$$J^\Phi(W, V^\Phi) = \sum_{k=1}^{n} w_k \left\| F_{-k} - (FWZZ^T)_{-k} \right\|^2.$$  \hspace{1cm} (83)
Here the dot has to be considered as a selection of the \( k \)-th column of the matrices. Introducing the matrix \( Y = W^{1/2}Z \), which is orthonormal \( (Y^TY = I) \), the objective function can be rewritten as:

\[
J^\Phi(W, V^\Phi) = \sum_{k=1}^{n} w_k \left\| F_k - \left( FW^{1/2}YY^TW^{-1/2}\right)_k \right\|^2
= \left\| FW^{1/2} - FW^{1/2}YY^T \right\|_F^2
\tag{84}
\]

where the norm \( \| \cdot \|_F \) is the Frobenius norm [31]. Using the fact that \( \| A \|_F = \text{tr}(AA^T) \) and the properties of the trace, it is possible to see that the minimization of the last equation is equivalent to the maximization of the following [20,21]:

\[
J^\Phi(W, V^\Phi) = \text{tr}(Y^TW^{1/2}F^TFW^{1/2}Y)
\tag{85}
\]

### 5.2 Spectral clustering methods objective

Recalling that the definition of association between two sets of edges \( S \) and \( T \) of a weighted graph is the following:

\[
\text{assoc}(S, T) = \sum_{i \in S, j \in T} a_{ij}
\tag{86}
\]

it is possible to define many objective functions to optimize in order to perform clustering. Here, for the sake of simplicity, we consider just the ratio association problem, where one has to maximize:

\[
J(S_1, \ldots, S_c) = \sum_{i=1}^{c} \frac{\text{assoc}(S_i, S_i)}{|S_i|}
\tag{87}
\]

where \( |S_i| \) is the size of the \( i \)-th partition. Now we introduce the indicator vector \( z_i \) whose \( k \)-th value is zero if \( x_k \notin \pi_i \) and one otherwise. Rewriting the last equation in a matrix form we obtain the following:

\[
J(S_1, \ldots, S_c) = \sum_{i=1}^{c} \frac{z_i^T A z_i}{|z_i|^2}
\tag{88}
\]

Normalizing the \( z_i \) letting:

\[
y_i = \frac{z_i}{(z_i^T z_i)^{1/2}}
\tag{89}
\]
we obtain:

\[ J(S_1, \ldots, S_c) = \sum_{i=1}^c y_i^T A y_i = \text{tr}(Y^T A Y) \] (90)

5.3 A unified view of the two approaches

Comparing Eq. 90 and Eq. 85 it is possible to see the perfect equivalence between kernel K-means and the spectral approach to clustering when one wants to maximize the ratio association. To this end, indeed, it is enough to set the weights in the weighted kernel K-means equal to one obtaining the classical kernel K-means. It is possible to obtain more general results when one wants to optimize other objective functions in the spectral approach, such as the ratio cut [13], the normalized cut and the Kernighan-Lin [41] objective. For instance, in the case of the minimization of the normalized cut which is one of the most used objective functions, the functional to minimize is:

\[ J(S_1, \ldots, S_c) = \text{tr}(Y^T D^{-1/2} A D^{-1/2} Y) \] (91)

Thus the correspondence with the objective in the kernel K-means imposes to choose \( Y = D^{1/2} Z \), \( W = D \) and \( K = D^{-1} A D^{-1} \). It is worth noting that for an arbitrary \( A \) it is not guaranteed that \( D^{-1} A D^{-1} \) is definite positive. In this case the kernel K-means will not necessarily converge. To cope with this problem in [20] the authors propose to enforce positive definiteness by means of a diagonal shift [66]:

\[ K = \sigma D^{-1} + D^{-1} A D^{-1} \] (92)

where \( \sigma \) is a positive coefficient large enough to guarantee the positive definiteness of \( K \). Since the mathematical foundation of these methods is the same, it is possible to choose which algorithm to use for clustering choosing, for instance, the approach with the less computational complexity for the particular application.

6 Conclusions

Clustering is a classical problem in pattern recognition. Recently spectral and kernel methods for clustering have provided new ideas and interpretations to the solution of this problem. In this paper spectral and kernel methods for clustering have been reviewed paying attention to fuzzy kernel methods
for clustering and to the connection between kernel and spectral approaches. Unlike classical partitioning clustering algorithms they are able to produce nonlinear separating hypersurfaces among data since they construct an adjacency structure from data. These methods have been successfully tested on several benchmarks, but we can find few applications to real world problem due to the high computational cost. Therefore an extensive validation on real world applications remains a big challenge for kernel and spectral clustering methods.
