# A low cost method to detect polluted surface water outfalls and misconnected drainage.

David Chandler and David N Lerner  
Civil & Structural Engineering, University of Sheffield

**Abstract:** Sewer misconnections lead to discharge of wastewater direct to rivers and streams. They are difficult to detect due to their intermittent discharges and the wide range of compounds which can be discharged. Optical brighteners are strong indicators of the presence of sewer misconnection discharge in surface water sewers, representative of many components of misconnections, and easily identified. The authors have developed and tested a promising method to identify optical brighteners in sewer systems using inexpensive passive samplers and a simple analysis method. The method is used to identify large areas of four sewer systems which are polluted with misconnection discharge. Limited validation shows that the method successfully indicated diffuse pollution in the surface water sewer system.

## 1 Introduction

Polluted surface water outfalls (PSWOs) can be major sources of faecal indicator organisms (O'Keefe et al., 2005), nutrients, and toxic compounds (Environment Agency, 2007; UKWIR, 2012), which can significantly impact receiving waters. Sewer misconnections are the connection of grey or foul water drains to surface water sewers, leading to direct discharge of untreated wastewater to rivers and streams. They are a key contributor of pollution to PSWOs, and can discharge a wide range of pollutants (UKWIR, 2012; Ellis, 2013). Misconnections discharge intermittently and therefore pose problems for monitoring, as impacts may only be observed during discharge.

Monitoring PSWO effluents generally takes the form of either spot sampling, taking an instant sample at a point which can be stored for later analysis, or continuous monitoring, placing a sampler or sensor in situ which will collect samples over time. Passive sampling allows integrated sampling for indicators over time without producing individual data points. Due to the intermittent nature of misconnection discharges, continuous monitoring or passive sampling are the most promising methods to identify these discharges, as spot sampling will only identify effluent if it is present at the time of sampling.

Commonly monitored components include nutrients, sewer solids, bacterial growth, biochemical oxygen demand (BOD), ammonia, phosphorus and pH, among others (Environment Agency and Water UK, 2014). These components are present in a wide range of discharges, and so the value of them for specifically identifying and tracing misconnection discharges is limited. Though misconnections discharge a wide variety of pollutants which could be used as indicators, such as triclosan or tryptophan, these are not expected to be present in many discharges, and can be expensive to monitor, therefore limiting their functionality as indicators.

Optical brighteners (OBs) are a promising indicator of misconnection effluent in surface water sewers, as they are found in many components of effluents, including discharge from washing machines, sinks, and toilets. This paper presents the first UK trial of an inexpensive, simple, passive sampler for OBs in surface water sewers.

## 50 2 Current and developing practice

51

52 Aesthetic indicators such as turbidity, sewage fungus, and solids are common results of  
53 polluted discharge, which are easily identified and develop quickly following exposure to  
54 polluted discharge (Hickey, 1988; Pitt et al., 2004). These are either observed on natural  
55 substrates, or can be sampled in sewers using caging to trap solids (Environment Agency and  
56 Water UK, 2014). However visual indicators are not always present in misconnection  
57 discharge, and are not uniquely a result of misconnection discharges, they can be present as  
58 a result of other inputs to sewer systems, and therefore do not definitively indicate the  
59 presence of misconnections on a sewer system.

60

61 Distributed temperature sensing uses fibre optic cables, temporarily inserted into sewer  
62 systems, to detect changes in temperature of water entering sewer systems (de Haan et al.,  
63 2011). This can be very time-efficient, but is also expensive at around €10-12 (Approximately  
64 £8-9) per meter of sewer tested including analysis costs (Schilperoort et al., 2013). This also  
65 requires considerable technical knowledge to operate the temperature sensor (Hoes et al.,  
66 2009). While this method is rarely used at present, if costs can be reduced it may become  
67 more widely accessible.

68

69 Passive water chemistry samplers can be used in rivers to observe changes in concentrations  
70 of chemicals over time periods from days to months (Namiesnik et al., 2005; Vrana et al.,  
71 2005; Zhang and Davison, 2000). These are inexpensive, do not require external power, and  
72 do not require regular maintenance (Zabiegala et al., 2010), however they have not been  
73 tested for monitoring misconnection effluents, and may only be sufficiently sensitive to  
74 identify large, or constant, discharges.

75

76 Dye testing involves pouring fluorescent dye into appliances in households, which can then  
77 be detected in the surface water sewer system if the appliance is misconnected (Hoes et al.,  
78 2009; Environment Agency and Water UK, 2014). Dye testing is only used once a region of the  
79 sewer system suffering from misconnections is identified using other methods, as it is a  
80 relatively slow process, visiting individual properties to perform testing. However, this is the  
81 only method at present which unambiguously identifies specific appliances which are  
82 discharging to the surface water system, and therefore is needed in the final stage of  
83 misconnection correction actions.

84

85 Further information on these and other less commonly used methods for tracing and  
86 correcting sewer misconnections in the UK and USA can be found in Environment Agency  
87 and Water UK (2014) and Center for Watershed Protection and Pitt (2004) respectively.

88

## 89 3 Passive sampling for optical brighteners

90

### 91 3.1 Method

92

93 Optical brighteners (OBs) are chemicals which fluoresce under ultraviolet (UV) light and do  
94 not occur naturally in the environment. They have a high affinity for fabrics such as cotton,  
95 and are commonly used in laundry detergents, toilet paper, and cleaning products (Burrell,  
96 2011). These are components which are expected to be present in the majority of  
97 misconnection effluents (UKWIR, 2012). OBs have been used to identify illicit discharge to  
98 surface water sewers (Braun, 2011), usually using a fluorometer to measure the fluorescence  
99 of discharged water. Fluorometers are relatively inexpensive, though they require flow in the  
100 sewer, so will not detect a response if there is no flow or no optical brighteners discharged

101 at the time of sampling. Therefore the ability to identify intermittently discharged  
102 misconnection effluents is limited. To overcome this limitation, an in situ passive method has  
103 been tested and developed to identify misconnection effluents in the field using OB free  
104 tampons as a sorbent to collect OBs.

105  
106 Laboratory testing was performed to determine concentrations of detergent at which  
107 fluorescence would be observed. Twenty five microliters of detergent, the smallest volume  
108 which could accurately be measured, were added to 25 litres of tap water. A tampon was  
109 submerged in the container for 5 seconds. OBs adsorbed to the tampon immediately, and  
110 were still identifiable up to 30 days after initial exposure (figure 1). Modern washing  
111 machines discharge between 29 and 144 litres of water per use, with an average of 77 litres  
112 (Australian government WELS 2014). This equates to roughly 0.65ml of detergent per litre of  
113 discharged water if manufacturers recommendations for the volume of detergent used in an  
114 average laundry load are used. This therefore means that even with a 300 times dilution in  
115 the sewer pipe, which is far beyond anything which could be expected from normal sources,  
116 polluted discharge would still be observable.

117  
118 For sampling OBs in situ, tampons were fixed in surface water sewers, either by tying to a  
119 suitable point in the sewer, or tied to lengths of bamboo cane which could then be wedged in  
120 the sewer so that they lay in the invert of the sewer out of direct sunlight to avoid photo  
121 decay of optical brighteners. If there was flow in the sewer at the time of sampling, the  
122 tampon was briefly exposed to the flow and tested for fluorescence on site using an  
123 inexpensive UV light, if suitable darkness could be achieved to accurately identify  
124 fluorescence. However sufficient darkness could not be achieved in the field during this trial,  
125 so samples were transferred to the lab for testing. If a positive response was not observed  
126 instantly, tampons were left in situ for a three day period, to ensure polluted discharge was  
127 not missed. Three days was empirically found to be the optimum time to leave a sample in  
128 place to avoid fouling, but ensure a good exposure time, with five and seven days exposure  
129 leading to considerable fouling of the samples. When samplers were removed from the  
130 sewers, they were placed in individual zip-lock bags and stored in darkness to avoid  
131 contamination between samples and photodecay of OBs until samples could be exposed to a  
132 UV light to test for fluorescence. The cost of initial purchase of raw materials (UV light,  
133 cotton, apparatus to attach them in place) in this investigation was approximately 20 pence  
134 per sampler.

### 135 136 3.2 Field trial

137  
138 Sampling was performed in 16 surface water sewer outfalls across three catchments in the  
139 Sheffield area in March 2013. Nine of the 16 outfalls were indicated as discharging OBs. Four  
140 sewer systems were further investigated using the method in accessible manholes to trace  
141 OB containing effluent to its source. Samplers were returned to the laboratory and tested  
142 for OBs using an inexpensive 365nm UV light. Where OBs were found below a section of  
143 sewer, but not above it, a misconnection was indicated between the two points, and  
144 therefore an area of the system to be dye tested could be identified (figures 2 and 3).

145  
146 The method successfully identified areas of the sewer systems in which further investigation  
147 using dye and visual misconnection inspection could be performed. This significantly  
148 reduced the area in which detailed investigation was required, and thus reduced cost of  
149 follow up investigations. Samples corroborated well, with indicated misconnected points  
150 joining up, and correctly connected points joining up. The method showed only one conflict  
151 over four catchments where a sewer was indicated as correctly connected at one point, but  
152 misconnected further up the catchment (figure 3).

153

154 Visual inspection of properties was performed in part of sewer system 3 (figure 3). A sink  
155 and a soil stack were found misconnected in this area. These misconnections were  
156 corrected, though additional sampling could not be performed, to determine whether other  
157 misconnection problems existed in the system after correction, due to budgetary  
158 constraints.

159

### 160 3.3 Practical issues

161

162 When large quantities of suspended solids are present in sewer systems, tampon samplers  
163 can become fouled, and fluorescence masked to the extent that if OBs are present,  
164 fluorescence is not observable. Once significantly fouled, washing the sampler did not  
165 remove enough of these solids to allow analysis to be performed on the sampler. A  
166 shortened period of exposure reduced the risk of this problem, however to ensure the same  
167 exposure period as samplers on other outfalls, samplers were replaced more frequently,  
168 which increased the cost for those points.

169

170 At some sewer outfalls, samplers were vandalised by members of the public. This only  
171 occurred when sampling outfalls, and only at sites which were close to footpaths, even  
172 though they were generally not visible from the footpath. This may be avoided by inserting  
173 the samplers further into the outfall, though in the present study this was not possible  
174 without contravening health and safety requirements.

175

176 There is a risk of misinterpretation of fluorescence due to the presence of oil (Lambert et al.,  
177 2003) or surface discharges of OB containing compounds, such as from car washing with  
178 soaps, though these still indicate an abuse of the system and so are important to identify as  
179 they cause polluted discharge to the receiving water. Oil, which also should not be present in  
180 the surface water sewer system, will leave a coating on the sampler, and therefore should be  
181 easily identified. Surface discharge of OB containing compounds are not expected to be a  
182 frequent occurrence, but may cause confusion where they do occur.

183

184 The major limitation of the method is that some misconnections may not discharge  
185 compounds containing OBs, and therefore will not be detected using the method. Combining  
186 the optical brightener method with other established methods, such as visual inspection  
187 methods, allows an integrated sampling strategy so that a weight of evidence approach can  
188 be taken to identify systems which require further investigation.

189

### 190 3.4 Further development

191

192 This study demonstrated that the method successfully identified misconnection discharge in  
193 surface water sewer systems, however budget limitations prevented full validation of the  
194 sewer systems from being performed. The next development of the method should be to  
195 perform a full validation of the method, including full tampon sampling throughout several  
196 sewer systems, and thorough dye testing to ensure that where misconnections are indicated,  
197 they are found, and where they are not indicated, they are not found. This would give a  
198 better indication of the accuracy of the method and may discover methodological  
199 improvements which may in turn change costs.

200

201 Following thorough method validation, the main improvement which could be made to the  
202 method is to develop a way to protect the sampler from sewer solids. Fouling is a major  
203 problem for the method at present, limiting the time that samplers can be left in situ, yet it is  
204 one of the easiest limitations to overcome. Solving this may require development of a

D.M. Chandler and D.N. Lerner, 2015. A low cost method to detect polluted surface water outfalls and misconnected drainage. *Water and Environment Journal*, **29**, 202-206. doi:10.1111/wej.12112.

205 protective barrier to block solids, or a cleaning process to clean off solids, and leave OBs in  
206 place on the sampler. This would reduce the number of visits required, and therefore reduce  
207 costs of sampling, though it would increase the cost of individual samplers.  
208

## 209 4 Conclusion

210  
211 This paper presents the first UK investigation of an inexpensive and simple passive method to  
212 identify sewer misconnection effluents using cotton samplers onto which optical brighteners  
213 bind. The method successfully identified optical brighteners in surface water sewer systems,  
214 and limited validation showed misconnections were present where they were indicated.  
215 Further development may improve the method and either increase or decrease the current  
216 low costs. This proved a very promising method for identifying sewer misconnections and  
217 other diffuse pollution discharge to surface water sewer systems. Pending further validation,  
218 this is recommended for investigation of sewer misconnections in surface water sewer  
219 systems.  
220

221 Acknowledgements: The authors thank Yorkshire Water and the Environment Agency for  
222 their technical support. Field testing of the method throughout sewer catchments was  
223 performed by technical staff at Yorkshire Water. Funding was provided by Yorkshire Water  
224 and the EPSRC.
