35 Abstract:

Nearly half of Greenland's mass loss occurs through iceberg calving, but the physical 36 37 mechanisms operating during calving are poorly known and *in situ* observations are sparse. We show that calving at Greenland's Helheim Glacier causes a minutes-long reversal of the glacier's 38 horizontal flow and a downward deflection of its terminus. The reverse motion results from the 39 40 horizontal force caused by iceberg capsize and acceleration away from the glacier front. The downward motion results from a hydrodynamic pressure drop behind the capsizing berg, which 41 also causes an upward force on the solid Earth. These forces are the source of glacial 42 earthquakes, globally detectable seismic events whose proper interpretation will allow remote 43 sensing of calving processes occurring at an increasing number of outlet glaciers in Greenland 44 and Antarctica. 45

46 Main Text:

47 One third to one half of Greenland's total mass loss occurs through iceberg calving at the margins of tidewater-terminating glaciers (1, 2). Recent, rapid changes in glacier dynamics are 48 associated with increased calving rates (3-5) and increased rates of glacial earthquakes (6). At 49 large glaciers with near-grounded termini, calving typically occurs when buoyancy forces cause 50 icebergs the full thickness of the glacier to capsize against the calving front (6-9). This type of 51 calving is associated with glacial earthquakes (6, 7, 10), long-period seismic emissions of 52 magnitude ~5 that are observed globally (11). The earthquakes have expanded northward and 53 increased seven-fold in number during the last two decades (6, 12, 13), tracking changes in 54 glacier dynamics, the retreat of glacier fronts, and increased mass loss (6, 14). Buoyancy-driven 55 56 calving represents an increasingly important source of dynamic mass loss (6-8) as glacier fronts throughout Greenland have retreated to positions near their grounding lines (15). However, due 57

to the difficulty of instrumenting the immediate near-terminus region of these highly active
glaciers, few direct observations of the calving process are available, limiting development of the
deterministic calving models required for improved understanding of controls on dynamic icemass loss. Detailed knowledge of the glacial-earthquake source would allow quantification of
calving processes at a large class of Greenland glaciers as well as in several regions of Antarctica
(*13*).

Agreement on the source mechanism of glacial earthquakes is limited. Analysis of long-64 period seismic data shows that a sub-horizontal force acts approximately perpendicular to the 65 glacier calving front during the earthquakes (6, 13). The observed seismic signal is generated 66 over a period of one minute or more (6, 11, 16), much longer than the source duration for 67 tectonic earthquakes of similar size (17). Some authors favor a model in which momentum 68 transfer produces a force acting in the upglacier and then downglacier directions as a newly 69 calved iceberg overturns, accelerates away from the calving front and subsequently decelerates 70 71 (6, 10, 13). Others suggest that the seismic signal arises from the iceberg scraping along the 72 calving front or fjord bottom (7) or colliding with the glacier terminus (18). Hydrodynamic 73 interactions with fjord water may be important (19) but are little explored. Analytical investigations admit more than one possible mechanism for the earthquakes (20), and no 74 75 persuasive explanation has been presented for the vertical component of the earthquake force. Here, we combine geodetic, seismic and laboratory data to identify the forces acting during 76 calving at large glaciers and document the source of the associated seismic signals. 77

We recorded geodetic data at the calving margin of Helheim Glacier (Fig. 1) (9), a major outlet of the Greenland Ice Sheet, during 55 days in July-September 2013. A wireless network of on-ice GPS sensors (*21*) captured glacier motion with cm-level accuracy at positions very close

to the calving front at a high temporal sampling rate (22). Hourly images from two cameras 81 located ~4 km down-fjord from and looking at the calving front were used in stereo 82 83 configuration to obtain the 3D geometry of the calving front and calved icebergs (8, 22). Data from the global seismographic network were analysed for the same time period to identify glacial 84 earthquakes (13, 23) and obtain source parameters (11) including the orientation of the force 85 active during the earthquake, the earthquake centroid-single-force (CSF) amplitude, and the 86 earthquake centroid time, t_c (centroid of the temporal force history) (22). 87 The glacier retreated ~ 1.5 km in a series of calving events during the observing period. 88 We identified ten large calving events from the camera images. All coincided with glacial 89 90 earthquakes; in two cases, two earthquakes occurred between subsequent images. During the 91 earthquakes, the region near the calving front shows a dramatic reversal of flow, moving upglacier for several minutes while simultaneously moving downward (Fig. 2, Fig. S1). The 92 horizontal and vertical motion then rebound rapidly. 93

94 Observations from a glacial earthquake occurring on Day of Year (DOY) 206 at 03:13:47 are shown in Figs. 2A and 2C. Analysis of camera images indicates ice loss of $0.461 \pm 0.009 \text{ km}^2$ 95 (Fig. 1) at a location of ice thickness 0.79 km, yielding an iceberg volume of 0.36 km^2 with 96 aspect ratio 0.23. The earthquake had CSF amplitude 0.24×10^{14} kg-m, with the force oriented 97 64°W (Fig. 1) and 9° above the horizontal. GPS sensor 1 (Fig. 1) showed a pre-earthquake flow 98 speed of 29 m/day. Immediately prior to the earthquake centroid time, the sensor reversed its 99 100 direction and moved upglacier at ~40 m/day (displacement 9 cm) and downward (displacement 10 cm). The reversed motion was sustained for ~200 seconds and was followed by a downglacier 101 102 rebound at ~190 m/day (displacement 20 cm) and upward movement (16 cm) for ~90 seconds. Similar temporally coincident signals are seen on nearby sensors 6 and 15 (Fig. 1, Fig. S1). 103

Figures 2B and 2D show glacier deflection for a calving event on DOY 212 (Fig. 1). We observe similar responses for all glacial-earthquake / calving events during which GPS sensors recording data of adequate quality were located within 500 m of the calved block (a total of 9 glacial earthquakes and 8 image pairs). These events occurred on DOY 205, 206 (three events), 207, 211, 212, and 226 and are observed on multiple GPS sensors (further examples in Fig. S1).

The earthquake centroid times occur at or near the end of the glacier's rapid rebound phase, such that the upglacier earthquake force aligns in time with the reverse motion of the glacier. The horizontal glacier deflection is consistent with a model in which the reaction force on the glacier due to seaward acceleration of the newly calved iceberg compresses the glacier front elastically. The front then rebounds as the force decreases and reverses polarity during iceberg deceleration. The glacier front thus acts as a spring, compressing and re-extending in phase with the applied force, which is the horizontal component of the seismic source.

116 The downward deflection of the glacier front occurs in a region where vertical motion of the GPS sensors at tidal frequencies shows the glacier is ungrounded and seawater is present 117 beneath it. Iceberg rotation is likely to cause a low-pressure zone in the opening cavity between 118 119 the iceberg and the glacier front. This pressure decrease would lower the load on the bedrock, resulting in an upward force acting on the solid Earth, as observed in our seismic analysis. A 120 pressure decrease near the calving front would apply a net downward force on the glacier 121 terminus, lowering the glacier surface in a manner similar to that occurring twice each day when 122 the ocean tides draw down the water level. At sensors experiencing earthquake deflections, we 123 observe variations in vertical position due to the water tide of ~ 0.1 m per 1 m of tidal variation. 124 125 The calving-related deflection of the glacier surface is ~0.1-0.16 m, suggesting a change in water pressure equivalent to a water-height change of $\sim 1-1.6$ m, or roughly 1-2 x 10⁴ Pa. 126

127	No observations of pressure or water-level variations are available from the region in the
128	fjord immediately in front of the glacier, where thick ice mélange (Fig. 1) prohibits
129	instrumentation. However, results from analog laboratory experiments allow us to evaluate our
130	inferences (22). A model glacier "terminus" was secured at one end of a water-filled tank, and
131	plastic "icebergs" made from low-density polyethylene were placed flush against the terminus
132	and allowed to capsize spontaneously under the influence of gravitational and buoyancy forces
133	(24; Fig. 3). Sensors embedded in the model glacier terminus monitored pressure in the water
134	column and the force exerted on the terminus during iceberg capsize.
135	The measured force on the terminus as the iceberg begins to capsize is oriented in the
136	upglacier direction and slowly increases as the iceberg rotates. As the iceberg nears horizontal,
137	the force decreases rapidly. Pressure at the terminus decreases as the iceberg rotates, increasing
138	again as the iceberg nears horizontal. Once the iceberg loses contact with the terminus, the
139	measured force and pressure begin to oscillate due to induced wave action in the tank.
140	We scaled up the measured forces and pressures to match the dimensions of icebergs
141	calved at Helheim Glacier (Fig. 3). The laboratory data scale by powers of the ratio of the
142	iceberg height in the field to the iceberg height in the laboratory (19,24). The scaled peak force
143	agrees well with typical values inferred from earthquake analysis (~10 ¹¹ N). The scaled peak
144	pressure drop (\sim 5x10 ⁴ Pa) applied over an area corresponding to the iceberg's map-view
145	dimensions yields an upward-directed force consistent with the seismically inferred vertical force
146	component, such that the total force acting on the solid Earth is oriented $\sim 10^{\circ}$ above the
147	horizontal. Computation and inversion of synthetic seismograms from the scaled force and
148	pressure data confirms the consistency of the laboratory model with real-world data.

We use the scaled force and pressure to predict the deformation of the terminus region 149 (22). The total force F_{tot} per unit area A_F acting on the calving region produces a horizontal, 150 linear deflection orthogonal to the calving front $F_{tot}/A_F = E\Delta L/L$, where E is the Young's 151 modulus of glacial ice. The value of L is chosen to provide the best match to the glacier position 152 data. This length-scale likely represents the distance from the terminus to the grounding zone. 153 154 We model the ungrounded section of the glacier as an elastic beam of length L loaded by the vertical force due to the pressure drop. The inferred distances L are a few km, consistent with 155 values estimated from GPS data. 156

Glacier displacements predicted from the scaled laboratory data for iceberg dimensions corresponding to a calving event on DOY 206 (Fig. 1, Fig. 2A) are shown in Fig. 3. Agreement with the observed glacier displacement is very good, particularly during the time over which the force acts in the upglacier direction (until the earthquake centroid time). After this time, the laboratory-derived prediction is dominated by oscillations of the water column in the tank, which does not contain the thick layer of ice mélange present in Helheim Fjord and expected to damp such high-frequency oscillations.

We conclude that as large icebergs rotate and accelerate away from the glacier calving 164 front (Fig. 4), the reaction force, which is the horizontal component of the earthquake force, 165 compresses the glacier front elastically, overcoming normal downglacier flow and temporarily 166 reversing the motion of the glacier. Hydrodynamic interaction of the iceberg with the fjord water 167 rapidly reduces pressure behind the rotating iceberg, resulting in an upward force on the solid 168 Earth that is the vertical force observed in the earthquake. The lowered water pressure draws 169 170 down the ungrounded glacier margin, pulling the glacier surface downward during the earthquake. 171

- 172 Our results document the forces active during an increasingly important class of calving
- events and definitively identify the processes that cause glacial earthquakes. This understanding
- of glacier calving and glacial earthquakes opens the potential for remote, quantitative
- 175 characterisation of iceberg calving and calving rates, as well as improved models for ice-ocean
- 176 interaction.
