ABSTRACT

Objectives: Licensing of, and coverage decisions on new therapies should rely on evidence from patient-relevant endpoints such as overall survival (OS). Nevertheless, evidence from surrogate endpoints may also be useful, as it may not only expedite the regulatory approval of new therapies but also inform coverage decisions. It is therefore essential that candidate surrogate endpoints be properly validated. However, there is no consensus on statistical methods for such validation and on how the evidence thus derived should be applied by policy-makers.

Methods: We review current statistical approaches to surrogate-endpoint validation based on meta-analysis in various advanced-tumour settings. We assessed the suitability of two surrogates (progression-free survival (PFS) and time-to-progression (TTP)) using three current validation frameworks: Elston and Taylor’s framework, the German Institute of Quality and Efficiency in Health Care’s (IQWiG) framework and the Biomarker-Surrogacy Evaluation Schema (BSES3).

Results: A wide variety of statistical methods have been used to assess surrogacy. The strength of the association between the two surrogates and OS was generally low. The level of evidence (observation-level vs. treatment-level) available varied considerably by cancer type, by evaluation tools and was not always consistent even within one specific cancer type.

Conclusions: Not in all solid tumours the treatment-level association between PFS or TTP and OS has been investigated. According to IQWiG’s framework, only PFS achieved acceptable evidence of surrogacy in metastatic colorectal and ovarian cancer treated with cytotoxic agents. Our study emphasises the challenges of surrogate-endpoint validation and the importance of building consensus on the development of evaluation frameworks.
BACKGROUND

Surrogate endpoints are intended to substitute for final patient-relevant endpoints that directly measure how patients feel, function or survive in clinical trials. Evidence from surrogate endpoints may not only expedite the regulatory approval of new health technologies but also inform coverage and reimbursement decisions. In the United Kingdom, a number of recommendations of the National Institute for Health and Care Excellence (NICE) have been based on cost-effectiveness analyses entirely based on treatment effects derived from clinical trials assessing surrogate endpoints. Moreover, this type of evidence may still be relied upon even when patient-relevant endpoints are available, for example in clinical trials that have terminated prematurely or for which data on the final endpoint are not fully mature. Nevertheless, relying on evidence from surrogate endpoints poses a serious challenge for decision makers, as several failures of candidate surrogate endpoints have been reported over the last decades; such failures have arisen not only from discrepancies in the magnitude of treatment effects between surrogate and final endpoints, but also in their directions. Hence, in order for policy makers to use a surrogate endpoint with confidence, there must be a process of ‘surrogate validation’.

The statistical validation of surrogate endpoints has been a major focus of research activity over the last two decades, but no consensus exists with respect to the standards needed to identify valid surrogates. Nevertheless, two key tenets dominate current views on the issue, namely the ‘correlation’ and the ‘meta-analytic’ approaches. According to these two tenets, the core goal of surrogate validation is to demonstrate a correlation between the surrogate and the final endpoint in the context of a clinical trial as well as between treatment effects on the surrogate and on the final endpoint within the context of a meta-analysis of randomised controlled trials (RCTs). The uptake of surrogate validation methods in technology assessment and coverage decisions is limited, a potential explanation being the lack of harmonisation of statistical techniques that should be used. Moreover, while decision tools have been proposed to assist policy makers in judging the strength of such
validation evidence for a candidate surrogate, there has been little or no empirical testing of these decision tools to date.\textsuperscript{2,7,12}

Cancer trials are one of the areas in which surrogate endpoints have become most common.\textsuperscript{13-16} Progression-free survival (PFS), measured as the time from randomisation to either documented tumour progression or death, is often used as primary endpoint in RCTs as a surrogate for overall survival (OS).\textsuperscript{17} Tumour progression includes radiographic evidence\textsuperscript{18-20} and, in some instances, non-radiographic criteria such as ‘symptomatic progression’ or ‘clinical deterioration’ determined by a clear, unequivocal worsening of the symptoms and signs of disease that are not evident on radiographic assessment.\textsuperscript{21} Some trials use time-to-progression (TTP) rather than PFS, the difference being that in TTP, patients are censored at the time of death with no prior documentation of disease progression. Other surrogate endpoints have been adopted in oncology, the most common being tumour response rate. However, TTP and PFS are more often used in phase III clinical trials\textsuperscript{17} and cost-effectiveness analyses of treatments for metastatic solid tumours,\textsuperscript{22} whilst tumour response rate better served for this purpose in hematologic malignancies.\textsuperscript{16,23}

In this paper, we review current statistical methods of surrogate-endpoint validation that use a meta-analytic framework. In addition, we assess the strength of evidence for PFS and TTP as surrogates for OS and test the application of current surrogate validation decision tools to the evidence base in a number of advanced solid tumours.

**METHODS**

**Study identification and selection**

Meta-analyses of RCTs quantifying the statistical association between PFS or TTP and OS in advanced solid tumours were sought. Conventional literature searches of electronic bibliographic databases returned a large number (>3,000) of references, and attempts to make the search more specific resulted in the exclusion of many of the papers already known to the authors. Therefore we used a ‘citation pearl-growing’ approach to study identification,\textsuperscript{24} with backward and forward citation searching from an initial list of six papers
known to the authors. The citation searches were conducted using Medline and the Science Citation Index in March 2012, and forward citation searching up until December 2012. Two reviewers independently screened titles and abstracts. We excluded conference abstracts, letters to the editor, papers reporting results from single trials, meta-analyses reporting treatment effects on PFS or TTP and OS without assessing an association between them, and descriptive reviews. Meta-analyses that focused on oncology treatments with curative intent were also excluded, as PFS and TTP are not relevant endpoints in this case.

Data extraction and analysis

Three levels of data were extracted from included meta-analyses using standardised pro-formas: information on the general characteristics of each meta-analysis (authors and date of publication, criteria for inclusion of studies, number and nature of studies included, number of patients included, and type of tumour and interventions considered); details of the statistical methods reported to assess the association between surrogate and final endpoints, the results of these analyses, and each study authors' conclusions based on the results; and details of the literature search performed to identify included studies. Data were extracted by a single reviewer and checked by a second. Finally, we sought to analyse the suitability of PFS and TTP as surrogates for OS using established surrogate validation frameworks. Three surrogate validation frameworks identified by a recent review of surrogate-endpoint methods were applied to each meta-analysis; they are outlined briefly below. To ensure consistency, they were applied to each meta-analysis by a single reviewer and checked by a second reviewer, and discrepancies resolved with involvement of a third reviewer.

Elston and Taylor's framework

In 1999, Bucher and colleagues proposed a set of validity criteria to inform the use of an article measuring the effect of an intervention on surrogate endpoints in clinical practice.
These criteria were adapted by Elston and Taylor\textsuperscript{2} into a three-level evidence hierarchy:

Level 1, evidence demonstrating that treatment effects on the surrogate (i.e., the change on the surrogate endpoint of treatment vs. control arm) correspond to treatment effects on the final patient-relevant endpoint (from RCTs); Level 2, evidence demonstrating a consistent association between surrogate outcome and final patient-relevant outcome (from at least epidemiological/observational studies); Level 3, evidence of biological plausibility of a relationship between surrogate and final patient-relevant outcomes (from pathophysiologic studies and/or understanding of the disease process).

German Institute of Quality and Efficiency in Health Care (IQWiG) framework

In 2011, the Institute of Quality and Efficiency in Health Care (IQWiG), an independent health technology assessment (HTA) agency that assesses the benefits and harms of drug and non-drug technologies on behalf of the German Federal Joint Committee and the Federal Ministry of Health, published a framework for the validation of surrogate endpoints in oncology.\textsuperscript{12} The IQWiG framework proposes that two levels of consideration are required in order to judge the suitability of a surrogate endpoint in the assessment of cancer therapy: the reliability of the evidence and the strength of evidence for surrogate validation. Reliability is measured as high, limited, moderate, or low on the basis of the following aspects: (1) application of a recognized approach described in the specialized statistical literature, (2) conduct of analyses to test the robustness and generalizability of results, (3) systematic compilation of data, (4) sufficient restriction of indications or degrees of disease severity and of interventions, and (5) clear definitions of the endpoints investigated. The strength-of-evidence criterion considers the degree of correlation of effects on the surrogate and the patient-relevant endpoint according to predefined thresholds (i.e., high correlation, when the lower limit of the 95% confidence interval for $R \geq 0.85$; low correlation, when the upper limit of the 95% confidence interval for $R \leq 0.7$; and medium correlation otherwise). Depending on the categorization produced by an algorithm that takes into account both levels of consideration, a conclusion about the validity of the surrogate endpoint is drawn and
expressed as proof, indication, hint or no proof of an effect on the patient-relevant endpoints as derived from an observed effect on the surrogate endpoint. While the IQWiG framework provides a list of elements that contribute to ‘reliability’, we needed to introduce a system of scoring that enabled us to categorise this dimension in a reproducible manner (e.g., a ‘high’ score required all contributing elements to be met).

**Biomarker-Surrogacy Evaluation Schema (BSES3)**

The Biomarker-Surrogacy Evaluation Schema (BSES3)\(^{36}\) is a revised version of a previous scheme (BSES),\(^{38}\) proposed in 2010. The BSES3 validation framework consists of four domains: study design, target endpoint, statistical evaluation, and generalisability. Details of the elements that comprise these domains are shown in the online data supplement (Supplementary Table 1). Each domain is ranked from 0 to 3 and combined to determine an overall score (ranging from 0 to 12). A hierarchical scale of validity is attached to the overall score, with ‘A’ corresponding to highest validity (i.e., overall score 12) and ‘F-’ to lowest. The developers suggest that an overall score of 9 or above, equivalent to a category of ‘A’ or ‘B’, is required to identify a good level of evidence of surrogate validation.

**RESULTS**

**Characteristics of included meta-analyses**

Of the 758 papers identified by citation searching, 31 publications were included. Figure 1 summarises the selection process, whereas Table 1 presents a summary of the characteristics of the included meta-analyses. Details for each meta-analysis are provided in Supplementary Table 2. The majority of them (N=24, 77%) restricted their analyses to a single tumour type, although some reported separate analyses for two,\(^{26,29,39,40}\) or more tumour types.\(^{25,41,42}\) Two meta-analyses\(^{43,44}\) of patients with glioblastoma multiforme were included; the poor median survival and the fact that metastases are seldom found in this disease suggest that PFS and OS would be important endpoints. The most frequent tumour
types examined were colorectal cancer,\textsuperscript{25-29,39-42,45-47} non-small-cell lung cancer (NSCLC),\textsuperscript{25,29,41,48-52} breast cancer,\textsuperscript{25,30,39,41,42,53-55} and ovarian cancer.\textsuperscript{9,26,40-42,56,57}

Eighteen meta-analyses were based on aggregate data, while 13 used individual patient data (IPD). In the aggregate-data meta-analyses, the number of included trials per meta-analysis ranged from 13 to 191 (median, 39) and the number of patients per meta-analysis ranged from approximately 4,300 to 44,000 (median, 15,850). For IPD meta-analyses, these numbers were lower, ranging from two to 27 trials (median, four) and 193 to 3,953 patients (median 1,158). Aggregate-data meta-analyses frequently reported using a systematic literature search to identify included studies (15/18, 84\%) whereas none of the IPD meta-analyses stated so. The criteria used to select included trials varied markedly across meta-analyses. The scope of meta-analyses were determined by type of intervention (e.g., gefitinib or erlotinib monotherapy,\textsuperscript{49}), line of therapy (e.g., first-line\textsuperscript{29,45,46,48,52}), or other trial characteristics (e.g., sample size\textsuperscript{27,45,46}).

**Statistical methods to assess the association between surrogate and final endpoints**

A wide variety of differing methods to examine the association between surrogate and final endpoints were employed across the 31 meta-analyses. Two broad criteria may be used to summarise these statistical methods. The first criterion is the type of meta-analysis, as noted above (meta-analyses using aggregate data and those using IPD). The second criterion is the level of association reported: ten meta-analyses (32\%) reported on the ‘observation-level association’ or Level-2 evidence\textsuperscript{2} or ‘individual-level surrogacy’\textsuperscript{10}, i.e., the association between surrogate and final endpoints regardless of the treatment effect on each of the endpoints; 12 meta-analyses (39\%) reported the ‘treatment-level association’ or Level-1 evidence\textsuperscript{2} or ‘trial-level surrogacy’\textsuperscript{10}, i.e., the association between the treatment effect on the surrogate and the treatment effect on the final endpoint; and nine studies (29\%) reported both levels of association. Combining these two criteria allowed for four core categorizations of the assessment and reporting of the association between PFS/TTP and OS: (1) meta-
analyses that reported an observation-level association based on aggregate data, e.g., single-arm median PFS/TTP vs. median OS; (2) meta-analyses that reported an observation-level association based on IPD, e.g., patients’ TTP vs. survival time; (3) meta-analyses that reported a treatment-level association using aggregate data, e.g., hazard ratio (HR) for PFS/TTP vs. HR for OS; and (4) meta-analyses that reported a treatment-level association using IPD. An overview of the statistical methods used presented according to these four categorisations is provided in a Supplementary technical note, with further details shown in Supplementary Table 2 and Supplementary Table 3.

Assessment of the validity of PFS and TTP as surrogates for OS
The main results of meta-analyses on the potential role of PFS or TTP as surrogates for OS are presented in Tables 2 and 3, respectively. The validity of these candidate surrogates was assessed according to the Elston and Taylor’s, IQWiG, and BSES3 frameworks applied to each meta-analysis, grouped according to the tumour type. An extract of the original authors’ conclusions on the surrogacy of PFS or TTP is also presented for each meta-analysis. The four most frequently evaluated advanced solid tumours were colorectal cancer, NSCLC, breast cancer, and ovarian cancer. While the available evidence consistently shows an association between treatment effects on PFS or TTP and treatment effect on OS (i.e., Level 1 evidence according to Elston and Taylor’s framework) in metastatic colorectal cancer, the validity of these surrogate measures appear relatively low when rated by both the IQWiG and BSES3 frameworks (Tables 2 and 3). However, four studies provide an ‘indication’ of an effect on the final endpoint given the effect observed on PFS, according to the IQWiG framework (Table 2). Nevertheless, as these analyses were limited to trials within a specific treatment setting (i.e., the comparison of fluorouracil (FU) plus leucovorin with either FU alone or with raltitrexed) and did not provide evidence across different risk populations and drug-class mechanisms, they were scored down on the BSES3 framework. For advanced lung cancer, three meta-analyses only reported observation-level
association between PFS and OS in NSCLC; in small-cell lung cancer, Foster et al.\textsuperscript{59} reported high correlation (\(R^2_{\text{trial}} = 0.79\)) between HR observed on PFS and OS (on the log scale), thus providing an ‘indication’ for an effect on OS having observed an effect on PFS according to the IQWiG framework (Table 2). TTP does not appear to be a good surrogate measure in advanced lung cancer according to any of the three frameworks (Table 3). In metastatic breast cancer, despite the moderate to high quality of the meta-analyses assessed\textsuperscript{42,53,55}, PFS is not judged to be a valid surrogate for OS according to the three evaluation frameworks adopted (Table 2). However, Hackshaw and colleagues\textsuperscript{54} reported a medium association between TTP and OS (\(R^2 = 0.56\)) in trials of first-line chemotherapy, which provided a ‘hint’ for an effect on the final endpoint according to the IQWiG framework (Table 3). In metastatic ovarian cancer, three IPD meta-analyses, two related to PFS (Table 2),\textsuperscript{26,40} and one to TTP\textsuperscript{9} (Table 3) show an indication of an effect on OS drawn on the observation of an effect on the two surrogate endpoints, with \(R^2_{\text{trial}}\) ranging from 0.83 to 0.95. Nonetheless, as according to the BSES3 criteria (see Supplementary Table 1) they lack generalisability, these studies were scored down. The remaining six solid tumour types (renal, prostate, brain, gastric, head and neck, and pancreatic) were each assessed in one or two meta-analyses (Tables 2 and 3). Across these indications, the level of evidence was mixed and the strength was poor; moreover, the endpoints were not always clearly specified, therefore all scores for strength of surrogacy relationship were low in both the IQWiG and BSES3 frameworks (in brain and gastric cancer Level 2 was the highest level of evidence according to Elston and Taylor’s framework).

DISCUSSION

We sought to review the current statistical approaches to surrogate endpoint validation in advanced solid tumours, as well as to assess the suitability of PFS and TTP as surrogates for OS using currently available validation frameworks.\textsuperscript{35} Our review included 31 meta-analyses (1,363 RCTs enrolling more than 290,000 patients) and showed that a variety of statistical methods have been used to examine the relationship between PFS or TTP and
OS. In addition, we observed a degree of variation in validity rating when using different validation frameworks across meta-analyses in general and even within a particular tumour type.

The various statistical methods used thus far in surrogacy research can be summarised in two broad categorisations. First, according to whether the assessment of the statistical association is made between the surrogate and final endpoint (observation-level association, which does not take treatment into account and is therefore an assessment of the prognostic role of the candidate surrogate), or between the treatment effects on both surrogate and final endpoints (treatment-level association, which assesses the predictive role of the candidate surrogate by taking treatment into account). Second, according to whether aggregate data or IPD were used. Observation-level association has been reported both using aggregate data and IPD, with different metrics used to quantify the correlation between endpoints (e.g., Spearman’s \( \rho \) for median PFS versus median OS in the former\(^{27,45,46,51,58} \) and \( R^2_{\text{individual}} \) in the latter\(^9 \)). In a number of cancer types, such as metastatic gastric cancer and glioblastoma multiforme, only the observation-level association has been investigated so far. This is acknowledged to be insufficient evidence to establish surrogacy for putative surrogate endpoints.\(^{10} \) For most tumour types, including colorectal cancer, breast cancer, and NSCLC, both observational-level and treatment-level surrogacy has been investigated, with treatment-level surrogacy being assessed using both IPD and aggregate data. Although treatment-level associations were often reported using the common statistic of \( R^2_{\text{trial}} \), this was calculated using different analytic approaches (e.g., meta-regression for aggregate data,\(^{27,29,30,41,42,45,46,55,62} \) and hierarchical regression methods for IPD\(^9,26,28,40,47,53,59 \)).

There is little literature directly comparing statistical validation of surrogates using IPD compared with aggregate level data.\(^{28} \) Buyse and colleagues have proposed IPD meta-analysis and calculation of both the \( R^2_{\text{individual}} \) and \( R^2_{\text{trial}} \) to be the gold standard approach to the statistical surrogate validation.\(^{10} \) However, only 22% of the meta-analyses in this review met this criterion. Such a low proportion is in large part due to the practical challenges of conducting an IPD meta-analysis. Gathering, cleaning and formatting patient data from
across clinical trial centres involves substantial resources, as due to commercial or academic restrictions, IPD for some trials are not immediately available in the public domain. While regulatory agencies can require companies to make such data available, this is often not the case for HTA organizations or agencies with a coverage or reimbursement mandate. Hence, while an IPD meta-analytic approach remains the optimal statistical approach to surrogate validation, it is likely that meta-analyses of treatment-level associations reporting the $R^2_{\text{trial}}$ or equivalent statistics will continue to be undertaken. There is often a lack of appreciation that the use of aggregate data entails a loss of information that may have a profound impact on the analyses performed, and their interpretation. For instance, several meta-analyses included in our review used the ratio of medians as a measure of treatment effects.\textsuperscript{27,32,48,54,55} Such an approach could be seriously misleading if the time to event distributions were not exponential and, even if they were, the medians usually have wide confidence intervals and so their ratio is likely to be extremely unstable.\textsuperscript{63} Few regression analyses make proper allowance for the estimation error,\textsuperscript{9,26,28,40,53} other than through a weighting of the trials by their sample size. Regression analyses that ignore estimation errors are likely to underestimate the true relationship between the treatment effects on the surrogate and the final endpoint. The availability of IPD allows the association between the surrogate and the final endpoints to be modelled, which is theoretically preferable to looking only at the marginal association between the treatment effects on the two endpoints.\textsuperscript{9}

**Limitations of this study**

To the best of our knowledge, this is the first study to empirically test the application of current surrogate validation frameworks across a sample of meta-analyses in a disease area. On the other hand, our study has some limitations. First, as we were unable to use a conventional search strategy, we cannot claim to have identified all relevant meta-analyses. A more exhaustive search might have been feasible if we had narrowed our scope to a single tumour type. However, our aim was to keep the scope of the study broad and to identify a sufficient number of meta-analyses to assess a variety of statistical methods. Our
The list of included meta-analyses appears indeed to be comprehensive when compared with recent reviews in the field. Second, we have not formally appraised the overall quality of each meta-analysis. Given that the focus of the study was not to determine an unbiased estimate of the efficacy or safety of interventions, we believe that this decision was justified. However, to assess potential selection or publication bias, we noted if each included meta-analysis reported undertaking a formal literature search strategy to identify studies. In line with the findings of previous studies, we found that meta-analyses of aggregate data were more likely to undertake a literature search and include more studies than IPD meta-analyses. Third, we have not attempted to replicate any of the analyses presented in the included meta-analyses. This might have been useful, as it would allow us to examine whether all of the assumptions made in the presented analyses are supported by the primary data and whether the conclusions change when all relevant trials are considered in a single analysis and after updating for more recently published trials. Fourth, the application of both the IQWiG and BSES3 evaluation frameworks involved an element of subjective judgement. In order to minimise potential assessment bias, the application of the frameworks undertaken was independently checked by a second reviewer and a third reviewer used to resolve disagreements in judgement of these two reviewers. All of them were HTA analysts with experience in the field of oncology. Finally, although survival is a definitive patient-relevant outcome in the case of most solid tumours, there may be problems with using OS in the context of surrogate validation. Despite its primacy, OS has been claimed to be unsuitable in detecting treatment benefit in settings for which effective therapy is available after trial participation. Because patients in oncology trials are often permitted to cross over from the control arm to the treatment arm or switch to other therapies due to lack of response or symptoms, the attribution of OS gain to initial treatment allocation may be confounded by these subsequent lines of therapy.
Implications for policy and practice

Surrogate validation studies also have important relevance for the assessment of the cost effectiveness of new treatments. Using a reported relationship between OS and the surrogate, decision analysts can estimate the incremental cost per quality-adjusted life-year (QALY) based on the observed treatment effect on the surrogate.

Our study has important implications for the use of surrogate outcomes in HTA and coverage/reimbursement policy decisions. In order to appropriately apply evidence of surrogate validation, policy makers need decision frameworks that help them do so. While the IQWiG and BSES3 frameworks are potentially useful tools for clinicians and health care decision makers, there are problems in their practical application. Both have elements that require subjective judgement. In addition, they require a high level of association to demonstrate surrogacy, i.e., $R^2_{\text{treatment}} \geq 0.60$ or $R^2_{\text{treatment}} \geq 0.85$, raising a query on the origins of such thresholds. With a small number of exceptions, we found the strength of the association between PFS or TTP and OS across meta-analyses to be consistently low (i.e., $R_{\text{treatment}} < 0.7$) across tumour types. Indeed, according to the IQWiG and BSES3 validation frameworks, the evidence available about surrogacy of PFS and TTP in metastatic cancer is still insufficient to guide policy. Moreover, we noted a degree of variation in validity rating of IQWiG and BSES3 frameworks across meta-analyses within a particular tumour type. For example, for PFS in colorectal cancer, four meta-analyses showed an ‘indication’ of an effect on OS given an effect observed on the surrogates, however the highest level of evidence achieved according to BSES3 is C, well below the minimum acceptable level for a good surrogate. We believe that this variation probably reflects differences in the evidence within each meta-analysis due to differences in the precise patient population, definition and assessment of progression, drug therapy and comparator of included trials. Moreover, variation may also be due to differences in the statistical methods applied by each meta-analysis. Finally, the criteria considered by the two evaluation frameworks are different and in some cases opposite; for instance, BSES3 favours generalisability across populations and
drug-class mechanisms while the IQWiG framework gives precedence to restricted indications and therapies. Nonetheless, within each indication, different meta-analyses deal with overlapping evidence, and the underlying redundancy may have accounted for similar conclusions. 

When considering conclusions across indications, our results support the need for a disease-specific approach to the validation of surrogate endpoints, with careful consideration of transferability of results from one disease to the other.

The three evaluation tools used herein were developed through different processes: Elston and Taylor’s framework was based on a guide for clinicians proposed by the Journal of the American Medical Association (JAMA) Evidence-Based Medicine Working Group; the algorithm for surrogate endpoints validation in oncology was developed at IQWiG after a systematic search of the literature by the Agency; whereas the BSES3’s initial version originated from a literature review followed by a stakeholder workshop that evaluated it for applications in rheumatology. We believe that the development of future surrogate validation tools would benefit from formal consensus methods. Further research is needed to examine the application of surrogate validation frameworks in the context of candidate surrogates both in oncology and other disease areas.

In conclusion, we found that the level of evidence available supporting a relationship between PFS or TTP and OS varies considerably by tumour type and is not always consistent even within one specific type. Overall, the strength of the association between PFS or TTP and OS was relatively low and only PFS in advanced colorectal and ovarian cancers treated with cytotoxic agents was found to be a valid surrogate endpoint according to one of the evaluation frameworks used. Our study emphasises the importance of building consensus on appropriate statistical techniques to examine surrogacy and on development of evaluation frameworks, not only in oncology but across all areas of medicine, across jurisdictions and scientific communities.
