What is already known about the topic?

- Good partnerships between patients and health professionals may improve patients' self-management ability and treatment effectiveness for chronic pain. The mechanisms for this improvement, however, are poorly understood.
- Health professionals rely almost exclusively on taught physical exercise to help patients manage their chronic back pain.

What this paper adds?

- A good partnership between patients and health professionals has a direct positive impact on patients' self-management ability and an indirect positive impact on quality of life, where self-management is the mediator.
- Good self-management ability has a one-way positive effect on patients' quality of life.
- Both patients and health professional should be aware that not only is pain self-management support useful, but also good partnerships during the care process is a necessary component to improve quality of life for patients with chronic back pain.
Abstract

Background: Self-management may be a lifelong task for patients with chronic back pain. Research suggests that chronic pain self-management programmes have beneficial effects on patients’ health outcome. Contemporary pain management theories and models also suggest that a good patient-professional partnership enhances patients’ ability to self-manage their condition.

Objectives: 1) To investigate whether there is a reciprocal relationship between self-management of chronic back pain and health-related quality of life (HRQoL); 2) to examine the impact of a good patient-professional partnership on HRQoL, either directly, or indirectly via change in the ability to self-manage pain.

Design and setting: This quasi-experimental study was designed to take place during routine service appointments and conducted in a community-based pain management service in the United Kingdom. A patient-professional partnership was established in which patients were actively involved in setting up goals and developing individualised care plans. Through this, health professionals undertook patients’ health needs assessment, collaborated with patients to identify specific problems, provided written materials and delivered individualised exercise based on patients’ life situation. Patients were recruited following initial consultation and followed up three months later.

Participants: A total of 147 patients (65% female) with a mean age of 48 years (SD: 14 years) were enrolled in the study. Of these, 103 subjects completed the study. Patients were included if they were aged 18 and over, suffered from chronic back pain, had opted in to the clinic and had sufficient ability to read and understand English. Patients were excluded if they opted out this service after the initial assessment, suffered from malignant pain or required acute medical interventions for their pain relief.
Methods: Self-reported measures of HRQoL, patient-professional partnerships and self-management ability were collected at baseline and three months later. Pathways proposed were depicted using structural equation modelling.

Results: There was no association between patients' self-management ability and HRQoL at baseline. However, a positive direct effect was detected at three months (-0.38, \( p<0.01 \)). A patient-professional partnership was not found to be beneficial for patients' HRQoL through a direct pathway, but via an indirect pathway where self-management was a mediator (-19.09, \( p<0.01 \)).

Conclusions: This study suggests that the increase in patients' self-management ability may lead to improvement in HRQoL after pain management support provided in a partnership with health professionals. A good patient-professional partnership appears to be beneficial as an augmentation to self-management practice for patients with chronic back pain.
Introduction

Chronic back pain is a common health problem throughout the world and the leading cause of activity limitation and work absence (Freburger et al., 2009, Vos et al., 2013). People with chronic back pain often experience considerable discomfort, and their family and social relationships are interrupted (Hunfeld et al., 2001). However, patients often struggle to receive adequate management for their condition, or even a diagnosis (Baker et al., 2010). Due to the high prevalence, associated deleterious impact and the lack of any guaranteed cure, self-management has become a commonly accepted addition to medical interventions in the treatment of chronic back pain (Blyth et al., 2005, Dixon et al., 2007, Lorig and Holman, 1993, Moore et al., 2000, Von Korff et al., 1998).

The self-management of a chronic condition refers to ‘an ability to manage the symptoms, treatment, physical and psychosocial consequences and lifestyle changes inherent in living with a chronic condition individually’ (Barlow et al., 2002, p. 178). Many self-management programmes have been developed worldwide to support patients with chronic conditions (Barlow et al., 2000, Lorig et al., 2001). These are believed to be beneficial for patients to manage their symptoms and improve their quality of life. Patients involved showed a decrease in depression and fatigue, a high degree of self-efficacy, greater relaxation skills and exercise activities and cognitive symptom management (Barlow et al., 2002, Barlow et al., 2000, Bourbeau and Van Der Palen, 2009, Effing et al., 2012, Gurden et al., 2012, Lennon et al., 2013, Lorig, 2003, Lorig, 1993, Lorig et al., 1998, Lorig and Holman, 1993, Smith-Turchyn et al., 2015). As a strategy to foster the implementation of self-management, a practice guideline has been developed in the United Kingdom (UK), recommending that patients’ attributes, needs and preferences should be taken into account when provided with treatment and care by health professionals (Savigny et al., 2009). In addition, self-management practice guidelines in Canada recommend that health professionals should
conduct a broad patient assessment to identify potential factors related to patients' health status (Registered Nurses' Association of Ontario, 2010).

A good partnership between patients and health professionals appears to have a positive impact on the self-management of chronic pain (Dwarswaard et al., 2015, Fu et al., 2015, Lukewich et al., 2015, McQueen, 2001, Wasson et al., 2006). While health professionals are expert in providing health services to support patients, the pain itself and its impact can only be experienced by patients (Coulter and Ellins, 2007, May, 2010). A recent systematic review suggests that patients do not self-manage their chronic conditions, and they expect health professionals to fulfil a comprehensive role (Dwarswaard et al., 2015). A partnership in healthcare refers to collaborative care in which patients are actively involved with health professionals in developing treatment or care plans (Coulter et al., 2013, Enehaug, 2000). Health professionals are identified as the primary facilitator of self-management in primary care settings (Lukewich et al., 2015). Contemporary chronic pain management theories and models also suggest that a good patient-professional partnership enhances patients' ability to self-manage their condition (Bodenheimer et al., 2002, Cooper et al., 2008, Coulter and Collins, 2011, Street et al., 2009, Wagner et al., 2005). However, evidence for the relationship between patient-professional partnerships and self-management remains underspecified as do the practices, mechanisms and resources through which patient-professional partnerships may work in developing self-management ability and improving health outcomes.

Street et al. (2009) presented a theoretical idea on how patient-professional partnerships may contribute to patients' health outcomes, via both a direct and indirect effect (see Fig. 1). In the direct effect, patient-professional partnerships could be therapeutic when health professionals validate patients' perspectives and develop individualised care plans that may improve patients' physical symptoms and psychological well-being. In the indirect effect, partnerships act as a stimulus for shaping patients' beliefs about and attitudes to self-management, and integrating patients and professionals' complementary knowledge and
skills. In this paper, we provide empirical illustrations for two research questions. Firstly, we investigated whether there was a reciprocal relationship between self-management of chronic back pain and HRQoL. Secondly, we examined whether a good patient-professional partnership leads to better HRQoL in both a direct pathway and indirect pathway where self-management is considered as the mediator.

**Fig. 1 Causal paths depicting the relationships between patient-professional partnerships, self-management, and health outcome**

**Methods**

**Design and procedures**

This quasi-experimental study was designed to take place during routine service appointments and not as a stand-alone research study. It was conducted in the community-based pain management service in the UK, where the self-management of chronic back pain was supported by a range of health professionals (physiotherapists, nurses and health care trainer) to improve patients’ self-management ability and quality of life. A patient-professional partnership was generally established in this service by health professionals providing individualised care and working together with the patient. Patients were actively involved with health professionals in setting up realistic goals and developing individualised treatment
and care plans. Through this, health professionals undertook patients’ health needs assessment, collaborated with patients to identify specific problems that they desired to be addressed, set up achievable goals, provided written materials, delivered information and individualised exercise based on patients’ life situation. The patients practised self-management skills and provided feedback on their progress to health professionals during the individual consultations. The face-to-face consultation sessions also offered patients flexible appointment options to bring along their family members and last approximately 60 minutes. This service did not provide any medical interventional treatment such as injection therapy.

On average, new patients referred to the clinic are discharged after two to four months according to their self-management ability. In order to observe the development of self-management of chronic back pain, participants were recruited straight after their initial consultation in which they started to receive self-management support (baseline), and then followed for three months (follow-up). After patients had completed their first appointment and agreed to participate in this study, they were invited by YF or KM into a private room in the clinic for baseline data collection. Once patients had signed the consent forms, self-reported questionnaires were given by YF to be completed by the patients without assistance. Three months later, the same set of questionnaires was collected by YF from the same patients when they returned back to the service for further consultation.

Participants

The sample size was calculated with respect to the standardized difference of 0.30 with a 90% power level (Cohen, 1988). A total of 147 patients were recruited to participate in this study using a consecutive sampling strategy. Patients were included if they were aged 18 and over, suffered from chronic back pain, had opted in to the clinic and were able to read and understand English sufficiently to understand patients’ information sheets, consent forms and study questionnaires. Patients were excluded if they opted out this service after
the initial assessment, suffered from malignant pain or required acute medical interventions for their pain relief.

Measure of HRQoL

The primary outcome was HRQoL measured by the DoloTest, which is a validated, generic, pain-related quality of life questionnaire routinely used in clinical settings in Denmark and UK (Kristiansen et al., 2012, Kristiansen et al., 2010). This measurement consists of eight domains: ‘pain’, ‘problems with light physical activities’, ‘problems with more strenuous physical activities’, ‘problems doing job’, ‘reduced energy and strength’, ‘low spirit’, ‘reduced social life’ and ‘problems sleeping’. Each domain is scored on a 100mm visual analogue scale. DoloTest Score is the sum of the measurement on each DoloTest domain in millimeters and ranges from 0 to 800. A lower score reflects a more favorable health outcome. It is well-validated and demonstrates a satisfactory level of internal consistency, with coefficients of Cronbach’s alpha being 0.615 to 0.715 (Kristiansen et al., 2010). DoloTest was chosen as it was routinely used in the clinic; it was decided to continue using it as an outcome measure of HRQoL. Inclusion of another questionnaire for the same purpose would have imposed an unnecessary burden on patients, and also would have disturbed routine practice.

Measure of patients’ perceived self-management ability

Patients’ self-management ability for chronic back pain was evaluated using the Partners in Health (PIH) scale, a 12-item self-administered tool for patients to assess their self-management knowledge, attitude, behaviors and impacts of their chronic condition. The PIH scale is primarily designed to measure generic self-management for chronic conditions, which provides a simple tool for health professionals (general practitioners, nurses and allied health professionals) to assess self-management at a given point of time and maximise their patients’ self-management capacity over time (Battersby et al., 2003). Peñarrieta-de Córdova et al. (2014) showed that the scale has internal reliability and face validity. Patients
make a rating for each item on a nine-point (0-8) Likert scale, with 0 being the worst and 8 being the best response. A total score is computed for a possible total of 96 points. A higher score represents better self-management practice. The PIH scale has been shown to have high internal consistency (Cronbach’s alpha=0.82) (Petkov et al., 2010).

**Measure of patients’ perceived patient-professional partnerships**

The Patient Partnership in Care questionnaire (PPiC) was specifically designed to measure the core elements of health professionals to work in partnership with patients with chronic conditions to support self-management (Powell et al., 2009). It was also applied in the NHS Adult Cancer Survivorship Programme (Davies and Batehup, 2010). This generic questionnaire for patients consists of two subscales – partnership and confidence: 11 items using a five-point ‘poor’ to ‘excellent’ ordinal scale to measure the partnership and five items on a rating scale of 0 to 10 to measure the confidence. We did not include the confidence subscale in our analysis to avoid a potential multicollinearity problem, with partnership being correlated with confidence at 0.68 reported in previous research (Powell et al., 2009). We used component factor analysis (CFA) to assess the measurement properties of patient perceived partnership latent variable using the 11 partnership items, which all load significantly and strongly on a single partnership dimension at the 0.01 level. Fig. 2 shows that the standardised loading ranges from 0.52 to 0.81. The subscale of these 11 partnership items also has good internal consistency (Cronbach’s alpha=0.937) in this study. Although the chi-square with 34 degrees of freedom is significant ($\chi^2(34) = 61.61, p < 0.01$), the measures of fit are reasonably good with $\text{RMSEA} = 0.08$ and $\text{CFI} = 0.97$.

![Fig. 2 Component Factor Analysis for patients’ perceived patient-professional partnership](image)
Demographic and clinical characteristics

Demographic data were retrieved from the patients’ electronic medical records. Research evidence suggests that increased age (Kawi, 2014), poor health status (Kawi, 2014) and mental health problems (Bair et al., 2009, Hadjistavropoulos and Shymkiw, 2007) may impede the development of patients’ self-management ability. We controlled for seven sociodemographic characteristics (age, gender, marital status, ethnicity, religion, highest level of education, and employment status) in our analyses. These factors are often associated with basic variation in health (Chandola, 2000, Rose and Pevalin, 2000). We also used self-reported duration of their pain problem (Breivik et al., 2006, LeFort et al., 1998) to account for medical treatment histories. Given the fact that patients may experience benefit as a result of taking medication rather than the practice of self-management strategies, medication usage specifically related to pain relief was adopted to control for a potential confounder. We also included self-reported mental health problems in general, which are believed to be associated with decline in HRQoL especially in patients with chronic back pain (Bair et al., 2009, Hadjistavropoulos and Shymkiw, 2007, Schmidt et al., 2012).

Statistical analyses

We performed a causal path analysis to simultaneously depict relationships between partnership, self-management ability, and HRQoL. The autoregressions of the variables, self-management ability and HRQoL, on each other over time allow controlling for
covariance stability. These autoregression coefficients are determined by intra-individual stability (Hertzog and Nesselroade, 1987). A simultaneous equation model that allows for reciprocal effects and autoregressive effects between health-related quality of life \((HRQoL)\) and self-management ability \((SelfMGT)\) at baseline and follow-up may be written as

\[
HRQoL_{t_F} = \alpha^{HRQoL} + \gamma_1 HRQoL_{t_B} + \beta_1 Prtn_{t_F} + \beta_2 SelfMGT_{t_F} + \xi_1 X_t + \epsilon^{HRQoL}
\]  
(1)

\[
SelfMGT_{t_F} = \alpha^{SelfMGT} + \gamma_2 SelfMGT_{t_B} + \beta_2 Prtn_{t_F} + \beta_3 HRQoL_{t_F} + \xi_2 X_t + \epsilon^{SelfMGT}
\]  
(2)

Where \(B\) and \(F\) represent baseline and follow-up respectively; \(t\) represents an individual; \(\alpha\) is a time-invariant intercept; \(\xi\) is row vectors of coefficients of \(X_t\) which is a vector of control variables that vary over individuals (e.g. gender). The term \(\epsilon\) is random disturbance that is assumed to be independent and normally distributed with means of zero and constant variance. We also assumed that \(X_t\) is strictly exogenous, meaning that it is independent of \(\epsilon\).

\(\gamma_1\) and \(\gamma_2\) describe the autoregressive effects, or the effects of self-management ability and HRQoL at baseline on themselves measured at follow-up, respectively. A small or zero autoregressive coefficient means that there has been a substantial reshuffling of the individuals’ standings on the construct over time. In contrast, a sizable autoregressive coefficient means that individuals’ relative standings on the construct have changed very little over time. \(\beta_1\) presents the effect of partnership on the follow-up HRQoL adjusted for the
effect of follow-up self-management ability, and baseline HRQoL. $\beta_2$ presents the effect of partnership on the follow-up self-management ability adjusted for baseline self-management ability and baseline HRQoL. $\beta_1$ and $\beta_2$ present the effects of individuals' self-management ability on their HRQoL and the effect of HRQoL on their self-management ability, respectively. The mediated effect of partnership on HRQoL is $\beta_2 \beta_1$.

Structural equation models (SEM) allow for the use of latent variables to correct for measurement error, multivariate outcomes, and the calculation of overall fit statistics for model evaluation (Bovaird, 2007, Curran, 2003, Mehta and Neale, 2005). The two equations are simultaneously estimated on our data by maximum likelihood methods in SEM procedure of Stata13.1 (StataCorp, 2013). Evaluation of model-data fit is based on the most recommended indices, such as the root mean-square error of approximation (RMSEA) and the comparative fit index (CFI). The RMSEA is an absolute misfit index. Values less than 0.08 indicate an adequate fit and values of 0.06 or less indicate a good fit of the model (Hu and Bentler, 1998, Hu and Bentler, 1999). The CFI measures the proportional improvement in fit by comparing a hypothesised model with the null hypothesis model as the baseline model. Values ranged from 0.90 to 1 (perfect fit), indicating a good fit of the model (Hu and Bentler, 1999). Baseline PPIC scores were added to account for any possible imbalance and to improve the precision of the estimates. To account for missing data, the full information maximum likelihood procedure was used.

**Rigour**

This analysis of this study controlled and adjusted history, maturation and multiple treatment interference threats. Meanwhile, the time interval between baseline and follow-up (three months) was relatively short in comparison with the history of patients' back pain, which limited the likelihood of maturation threat. All questionnaires used have demonstrated good
validity and reliability. The same set of questionnaires was administrated by the same people to collect patients’ responses at both baseline and follow-up, helping to minimise the threat to the internal validity of this study.

Results

A total of 103 patients completed this study. The results showed that there was no association between patients’ self-management ability and HRQoL at baseline. However, a positive direct effect was detected at three months (-0.38, p<0.01). A patient-professional partnership was not found to be beneficial for patients’ HRQoL through a direct pathway, but via an indirect pathway where self-management was a mediator (-19.09, p<0.01). These results are presented in detail below.

Demographic and clinical characteristics

The demographic and clinical characteristics of the patients collected at the time of initial consultation were presented in Table 1. The cohort mean age was 48 years (SD: 14 years, range: 19-84 years). There was a majority of women (65.3%), with 59.9% living with a spouse or partner. More than three quarters (79.6%) of the patients were White British, and around half (46.3%) were Christian. The proportion of patients who were unemployed (40.1%) is almost double those who were in full time employment (23.1%). In terms of the educational background, only 8.8% of the patients held a higher degree or equivalent while approximately 30.6% of them held no qualification at all. All participants reported experiencing back pain for at least 12 months with about half of them (45.6%) suffering for more than eight years. Most (87.1%) took medication for pain relief, and only 19 participants (12.9%) did not. A majority (79.6%) had a current mental health condition, with 23.1% reporting anxiety, 5.5% reporting depression, and around half of them (51.0%) reporting both anxiety and depression.

At three months, 103 (70.1%) completed both baseline and follow-up data collection. Twelve (8.2%) patients failed to attend for follow-up as they had had similar previous treatment
experience without improvement, and 32 (21.7%) patients were discharged automatically according to the service attendance policy (patients would be discharged if they did not attend two consecutive appointments without any contact). With respect to demographic characteristics (age, gender, marital status, and highest level of education), as well as the outcome variables (patient-professional partnership, self-management ability, and HRQoL), there was no significant difference detected between patients who participated at both data collection points and those who participated only at baseline. As a result, missing data in our sample were likely to have been missing by chance, and therefore the completed-case analysis was used providing unbiased estimates. Categorical variables were compared by Wilcoxon rank sum test and continuous variables were compared by paired t-test.

</table>

1 **Structural model**

2 The SEM with the partnership latent variable mediated by self-management ability indicates

3 that the estimated model provides an acceptable fit to the data

4 ($\chi^2 = 7.65, df = 1, RMSEA < 0.001, CFI = 1$). Fig. 3 shows the standardised coefficients for

5 hypothesised paths at the 1% significance level. The model accounts for 47% of the

6 variance in HRQoL scores. To avoid clutter, the correlations between all demographic and

7 clinical factors have been omitted from Fig. 3.

8 **Fig. 3 Standardised path coefficients for hypothesised relationships**
As shown in Fig. 3, after adjusting for demographic and clinical factors, the stationary autoregressive effect of self-management ability ($0.54, p < 0.01$) is significant as is the stationary autoregressive effect of HRQoL ($0.53, p < 0.01$). These coefficients indicate moderate stability of self-management ability and HRQoL over time.

Net of autoregressive effects, the results of the path analysis showed that there was no causal effect of self-management ability on HRQoL at baseline, however a significant effect was detected ($-0.36, p < 0.01$) at three-month follow-up after the pain management support provided by health professionals in the pain clinics. In addition, it is noteworthy that the self-management ability had a one way effect on HRQoL, and no evidence was found to support an effect in the opposite direction. Thus patients with greater self-management ability were more likely to have better HRQoL. The results also showed that the patient-professional partnership had no direct effect on HRQoL ($-0.06, p > 0.1$). However, it is positively...
associated with self-management ability as predicted \((0.24, p < 0.01)\). Thus, patients having
greater partnerships with health professionals have higher levels of self-management ability.
The adjusted model also highlighted that the patient-professional partnership failed to
contribute independently to explaining variance in HRQoL in the model, suggesting a
mediating effect \((-19.89, p < 0.01)\) in which higher levels of self-management ability
accounts for the relationship between greater partnership and better HRQoL.

**Discussion**

This study shows that the increase in patients’ self-management ability leads to the
improvement in HRQoL after the pain management support provided in a good patient-
professional partnership. However, a patient-professional partnership alone is not sufficient
to improve patients’ HRQoL directly, but the positive effect is found from an indirect pathway
where self-management is a mediator. This may suggest that patient-professional
partnerships play an important role in stimulating and nurturing patients’ internal resources to
change behaviors associated with chronic pain, which consequently improve their health.
The findings of this study support the view that patients’ self-management ability has a
significant positive impact upon their health, whilst simultaneous reciprocal causality does
not occur between them. This is consistent with Braden’s Self-help Model (Braden, 1993,
LeFort, 2000), which specifies that self-help supported by a set of enabling skills allows
people with chronic conditions to achieve improved quality of life. Such consistency is
particularly noteworthy, given the different measures were used for health outcome. It
suggests that despite some differences in measurement in the study samples, the pattern of
relationships among the constructs appears stable and robust in different clinical populations.
More studies using pain-specific measures for health status may be needed to enable further
comparisons. The lack of impact of HRQoL on self-management ability also suggests that
pain self-management support could still improve health outcomes for patients suffering from
even extreme negative impact of pain.
It is worth noting that the positive impact of self-management skills on patients’ HRQoL was not significant at baseline, however this impact appeared to be significant three months later when a patient-professional partnership was established and developed during the time patients were attending the clinic. This finding provides additional support for the Chronic Care Model (Wagner et al., 1999, Wagner et al., 2001), which illustrates that improved health outcomes for disease management, as the results of self-management support, may only be achieved through productive interactions between informed activated patients and the prepared proactive health professionals. Similar effects of good patient-professional partnerships have been shown on symptom management for different patient groups. For instance, chronic obstructive pulmonary disease, depression and diabetes (Bury, 2004, Powell et al., 2009). Given the fact that patients with chronic conditions are likely to suffer from other health problems, further research may be needed to demonstrate the influences of building partnership on health outcome of patients with multiple conditions in primary care settings.

Our path analysis suggests that there is moderate stability in both self-management ability and HRQoL over time. These results indicate that the development of self-management of chronic back pain may be a consequence of establishing good patient-professional partnerships that involve collaborative care and self-management education. This is consistent with Lorig and Holman’s theory of self-management education that argues forming a partnership between patients health professionals is a core self-management skill (Lorig and Holman, 2003). However, we could not completely exclude the possibility that the increase in self-management ability may also enhance patient-professional partnerships. This is likely to occur when patients intend to establish a good partnership with health professionals with the purpose of gaining more support in managing their conditions, or being involved in decision-making about their treatment. However, to our knowledge, research to date has not explicated a direct theoretical pathway between self-management ability and patient-professional partnerships. It is worth noting that a patient-professional
partnership differs from traditional patient education and familiarity developed during the consultation. The key to successful partnership is to recognise that patients are experts in their conditions and life situation, and their partnerships are developed based on mutual respect for each other's competencies and recognition of the advantages of combining these resources to achieve beneficial outcomes (Coulter, 1999, Coulter and Collins, 2011, Coulter and Ellins, 2007). Additionally, self-management education embedded in a patient-professional partnership also differs from traditional patient education that solely focuses on having health professionals teach and pass on disease-specific skills and information. Instead, it is based on patient concerns and problems, allowing patients to identify their health needs and make a decision about their condition (Bodenheimer et al., 2002, Lorig and Holman, 2003). Through this approach, patients are provided with information and individualised exercises in the context of pain management, including problem definition, generation of possible solutions, solution implementation and evaluation of results. This is more likely to increase patients' self-efficacy and their individual confidence to undertake a behaviour necessary to achieve a desired goal (Bandura, 1997). This way of delivering patients' education has also been echoed in how health professionals provided their support in the pain management service of this study. Health professionals worked together with patients to undertake health needs assessment during the initial consultation, and then created individualised care plans to follow up their needs.

Despite the paucity of evidence that having a good patient-professional partnership has a direct impact on health outcomes (Street et al., 2009), our results suggest that the impact of patient-professional partnerships on HRQoL is mediated by the development of chronic back pain self-management. This non-significant direct effect of patient-professional partnership may provide additional evidence supporting the point that the relationship between continuity of care and outcomes are more uncertain (Cabana and Jee, Saultz and Albedaiwi, 2004, Saultz and Lochner, 2005). Health professionals at the pain clinics in this study worked as a team and provided the care and support at different stages of the treatment process.
Services and care delivered by different health professionals in disease management are often referred as a continuity of care (Haggerty et al., 2003). With sufficient resources, it may be necessary to provide systematic education and training for health professionals on the self-management of chronic pain in order to help patients develop more trust in and better partnerships with health professionals. The demographic characteristics of the participants were similar to those of population with chronic back pain reported in previous studies, such as the Health Survey for England (Health and Social Care Information Centre, 2011), Survey of Chronic Pain in Europe (Breivik et al., 2006) and the Institute of Medicine in the US (Institute of Medicine, 2011). The majority were females, and many were less able or unable to work outside. Most of them took medication for pain relief, and had a current mental health problem. The estimation of these individual-level effects in this study makes it possible to provide empirical evidence to support the influence of partnerships on chronic back pain self-management.

There has been considerable interest on initiating health policies for increasing patients’ involvement in their healthcare and collaboration with health professionals in the UK (NHS Executive, 2000, NHS Executive, 1999), the United States (US) (Koch, 1992), the Netherlands (Den Brink-Muinen et al., 2006) and Australia (Queensland Health, 2002). The World Health Organisation (World Health Organisation, 2002) has also recognised and supported patients to play an active and participatory role in improving their well-being and increase the efficiency of the health care system (Coulter et al., 2008, World Health Organisation, 1997). This study also confirms the beneficial impact of, and supports the worldwide application of self-management programmes that were originally developed from the Arthritis Self-Management Programme (Lorig, 1986, Lorig, 2003, Lorig, 1993). Patients take a lead role in managing their chronic conditions, with effective self-management support accomplished by health professionals working collaboratively to support and empower patients to use the effective self-management strategies (Lukewich et al., 2015). In line with these policies, the findings of this study contribute to a growing literature highlighting the
importance of patient-professional partnerships in the self-management of chronic pain and confirm causal relations between patient-professional partnerships, self-management of chronic back pain and health outcomes.

**Limitations and conclusions**

As with any research, this study has some limitations which need to be discussed. First, the time interval between baseline and follow-up is relatively short, so longer-term follow-up is needed to provide further data on the maintenance of self-management development and health improvement. Second, the relatively small sample size affects the power of the study and its ability to detect effects. The sample of patients is limited to those able to understand English, thus the generalisability to other cultural groups may be questionable. Also, there were 32 people who were discharged due to the service attendance policy, therefore it was uncertain whether follow-up data would have strengthened or weakened the study findings if these people had been followed up. However, no significant difference was detected between patients who completed this study and those who participated only at baseline, therefore missing data were likely to have been missing by chance. This may suggest that our estimates and conclusions were robust to omitting those non-attenders. Given the fact that the severity of certain medical conditions (e.g. pain) is subjective and may be difficult to measure through objective tests, self-reported retrospective measures used in this study may further overestimate as well as underestimate the outcomes (Prince et al., 2008) due to the asymptomatic nature of many comorbidities such as pain, hypertension, diabetes, heart disease and cancer at moderate and sometimes very elevated levels.

Despite these limitations, this study suggests that the increase in patients’ self-management ability may lead to improvement in their health outcomes after pain management support provided through a partnership with health professionals in primary care. It also suggests that a patient-professional partnership is beneficial for patients’ health outcome via an indirect pathway where self-management was a mediator. The findings of this study extend the understanding of the practice of self-management in the treatment of chronic pain and in
the improvement of patients’ health outcomes. This study highlights that the self-management support alone may not be sufficient and partnerships in care can make an essential contribution to ensure improved health outcomes. Given the increasing recognition of the value of professional-patient partnership in supporting patients to live the best possible quality of life with their chronic condition (Barnes and Hudson, 2006), this study provides empirical evidence that assessment of PPiC is valuable and that measuring patient-reported professional-patient partnership is key to improving self-management by patients with chronic conditions. The primary clinical implication of the study is the demonstration that a good patient-professional partnership is beneficial as an augmentation to self-management practice for patients with chronic pain. Both patients and health professional should be aware that not only is pain self-management support useful, but also their partnerships during the care process is a necessary component to facilitate the journey from receiving pain management support and care to improved health outcomes. Moreover, rather than relying almost exclusively on taught physical exercise, health professionals should emphasise the effective communication skills required understand patient’s expectations and preferences and work together with patients to set up achievable goals and recommend individualised treatments. There may also be a need for clinical leads to gain feedback from patients and health professionals on their partnerships. More research may be needed to be able to confirm the results of this study in a larger sample of patients. Further studies are also needed to assess the cost-effectiveness of pain management clinics of this kind, the results of which may reduce doctor visits and financial burden to health services.

Acknowledgements

We would like to thank all the patients who took part in the study and health professionals for their support of this study. We would also like to thank CFEP UK Surveys Ltd, The Flinders Program™ for granting permission to the use of the PPiC and PIH scales.

Conflict of interest: None declared.

Funding: Funded internally within the School of Healthcare, University of Leeds, UK.
