9

10 ABSTRACT Microorganisms are essential agents of Earth's soil *weathering engine* who help
11 transform primary rock-forming minerals into soils. Mycorrhizal fungi, with their vast
12 filamentous networks in symbiosis with the roots of most plants can alter a large number of
13 minerals via local acidification, targeted excretion of ligands, submicron-scale biomechanical
14 forcing and mobilization of Mg, Fe, Al and K at the hypha-biotite interface. Here, we present
15 experimental evidence that *Paxillus involutus* –a basidiomycete fungus- in ectomycorrhizal
16 symbiosis with Scots pine (*Pinus sylvestris*), is able to oxidize a substantial amount of structural
17 Fe(II) in biotite. Iron redox chemistry, quantified by X-ray Absorption Near Edge Spectra on 13
18 fungi-biotite sections along three distinct hypha colonizing the [001] basal plane of biotite,
19 revealed variable but extensive Fe(II) oxidation up to $\sim 2\mu\text{m}$ in depth and a Fe(III)/Fe_{total} ratio of
20 up to ~ 0.8 . The growth of Fe(III) hydroxide implies a volumetric change and a strain within the
21 biotite lattice potentially large enough to induce micro-crack formation, which are abundant
22 below the hypha-biotite interface. This Fe(II) oxidation also leads to the formation of a large
23 pool of Fe(III) (i.e., structural Fe(III) and Fe(III) oxyhydroxides) within biotite that could
24 participate in the Fe redox cycling in soils.

38 INTRODUCTION

39 Fungi represent a substantial portion of Earth's biosphere. In soils, they play a significant role in
40 the weathering of primary rock-forming minerals into secondary clay minerals ¹. The symbiosis
41 (i.e., mycorrhiza) that fungi can form with the root system of most plants - 80% of land plant
42 species ^{2,3} – is sustained by a substantial fraction (up to 30%) of net photosynthesis ⁴. This
43 energy supply from the host plant sustains a massive network of microscopic filaments -hypha-
44 which can reach 200 m cumulative length per gram of soil, a much larger interfacial reactive
45 surface with the soil environment than plant rootlets ⁴. A series of recent experimental studies
46 have pushed the notion that the fungal biomass can enhance weathering of rocks or minerals
47 commonly found in soils. These include biotite⁵, chlorite ⁶, apatite ⁷ and rocks such as limestone,
48 basalt and gabbro ⁸, however this has been questioned for apatite in a field study ⁹.

49 Two of the most common rocks, granite and basalt, that represent the bulk of the continental and
50 oceanic crusts, are Fe rich. Most of the Fe contained in their constitutive primary minerals,
51 including biotite, is in the ferrous form, Fe(II). When exposed to the oxidative conditions at the
52 Earth's surface, this structural Fe(II) tends to oxidize and due to their low solubility readily
53 precipitate as various, most often poorly ordered Fe(III) oxyhydroxides. Biotite belongs to the
54 Fe(II)-rich phyllosilicates within the mica group and forms a solid-solution series between an
55 iron-end member, annite, and the magnesium-rich phlogopite. As one of the three main
56 constituents of granite, biotite is widespread at the Earth' surface where it represents ~7% of the
57 exposed continental crust ¹⁰. Experiments of biotite weathering in aqueous solution^{11,12}, in
58 presence of bacteria¹³, in interaction with fungi alone¹⁴ or in symbiotic association with plant
59 roots ^{5,15} have all shown that this mineral can be a source of K, Mg, Al and Fe which are

60 potentially bioavailable for soil biota. The abiotic aqueous weathering sequence of biotite, is
61 dominated in the first stages by the release of interfoliar K ^{16,17}. This triggers its transformation
62 towards vermiculite, while the structural Fe(II), mainly in the octahedral sheets, is oxidized into
63 Fe(III)¹⁸.

64 Soil biota have the potential to enhance biotite weathering. Roots, bacteria and fungi can indeed
65 modify the chemical composition and lower the pH of fluids in their near-environment through
66 (i) the exudation of protons to balance for uptake of cations ¹⁹ and/or the (ii) production of
67 ligands and CO₂-producing dissimilatory reactions ²⁰. All of these biological processes will
68 enhance mineral dissolution reactions beyond the abiotic levels in the near-environments of
69 active microorganisms ^{5,8,21}. Bacteria have also been shown to affect the Fe redox state within
70 biotite. For example, nitrate-reducing bacteria can oxidize up to ~5% of the total structural Fe(II)
71 of biotite ²². Similarly, *Shewanella putrefaciens* - a well known Fe(III) reducing bacteria ²³ - can
72 reduce up to 36% of the initial Fe(III), which can account in itself for up to ~20% of the total Fe
73 in the biotite crystalline structure ²⁴. Early studies have also demonstrated the capacity of some
74 fungi species- mostly the nitrate-reductase inducible taxa- to reduce Fe(III) oxides ²⁵.

75 However, very few studies focused on the oxidation potential of fungi towards Fe(II) or, for that
76 matter, of any other redox sensitive elements in the crystalline structures of minerals. Although,
77 several studies ²⁶⁻²⁸ have qualitatively assessed the oxidation of Fe(II) in biotite in the presence
78 of mycorrhiza, so far no quantification of the extent of such an Fe(II) oxidation or the
79 localization of an oxidative front are available. This is despite the fact that Fe oxidation reactions
80 often initiate mineral weathering i.e., when primary minerals interact first with oxygenated fluids
81 iron is one of the first and fastest reacting redox element often leading to the formation of poorly

82 soluble Fe(III) oxyhydroxides. Interestingly, the formation of secondary Fe(III) phases due to the
83 oxidation of Fe(II)-bearing minerals including biotite and pyroxenes was shown to also increase
84 strain (due to volumetric changes) within mineral lattice structures, leading to micro-crack
85 formation²⁹⁻³¹. Ultimately in soils, this phenomenon increases porosity, allowing for water
86 infiltration, which further favors and enhances subsequent mineral dissolution. What is however,
87 still unknown is what the role and effect of fungal colonization on the iron speciation in pristine
88 Fe(II) rich minerals during weathering.

89 In this study, we measured the capacity of mycorrhizal fungi to oxidize structural Fe(II) in biotite
90 that was colonized by fungal networks in plant-mycorrhiza-mineral continuum systems. We
91 quantified submicron-scale changes in ferric to total iron (Fe(III)/Fe_{total}) speciation and
92 complemented these measurements with assessments of changes in C-rich compounds at the
93 interface between ectomycorrhizal hypha and the basal [001] plane of biotite. With this study, we
94 do not only provide a first comprehensive and spatially-resolved high resolution dataset of fungal
95 Fe(II) oxidation of a Fe-rich silicate minerals in close-to-natural conditions, but we also elucidate
96 whether the presence of Fe(III) oxides sub-domains can cause strain and mechanical forcing of
97 the biotite crystalline structure, which in turn leads to further weathering.

98 **MATERIALS AND METHODS**

99 *Microcosm setup.* Biotite mycorrhizal weathering experiments were carried out in monoxenic
100 microcosms following the methods described in^{5,27,32} (Fig. 1). Briefly, *Paxillus involutus* – an
101 ectomycorrhizal fungi- and *Pinus sylvestris* - Scots pine- were initially grown separately, then
102 both transferred into the same Petri dish to initiate symbiosis. Symbiotic pairs were subsequently
103 transferred into experimental microcosms, where freshly-cleaved biotite flakes (~ 0.5 X 0.5 cm

104 and 1 mm thick, positioned away from roots) were the main source of nutrients (i.e., K, Mg, Fe)
105 as illustrated in Fig. 1A. Microcosms were incubated for ~4 months at 15°C (days) and 10°C
106 (nights) with an 18h photoperiod with a photon flux density of 550 $\mu\text{mol m}^{-2} \text{s}^{-1}$ following the
107 methods described previously^{5,27}.

108 *Sampling of hypha-biotite interface.* Three biotite flakes colonized by mycelia connected to the
109 plant roots however not in contact with the rootlets were collected from three different
110 microcosms. The separated biotite-fungal samples were sectioned using a Focus Ion Beam (FIB,
111 dual beam FEI Nova 200 NanoLab) following the procedure described in Bonneville et al.
112 (2009). In each sample, 3-4 sections were cut along single, isolated and continuous hypha (700 to
113 900 μm long). Sections were cut starting in each case from the tip (Fig 1B) and progressing away
114 from the tip (Fig 1C) to obtain a time sequence of exposure. On each biotite surface at least ~100
115 μm away from any hypha a control section was also cut. In total, 13 ultrathin FIB sections along
116 three hyphae ('A', 'B' and 'C') starting from the fungal tip towards the older parts were prepared
117 (Table S1). These FIB sections were subsequently imaged and analysed using Transmission
118 Electron Microscopy (TEM) as described in Bonneville et al.²⁷ and spectrally analysed using
119 Scanning Transmission X-ray Microscopy (STXM).

120 *Carbon, potassium, and ferrous/ ferric iron ratio mapping.* STXM mapping and collection of X-
121 ray Absorption Near Edge Spectra (XANES) at the Fe L_{2,3} edges (700 – 730 eV) and for both C
122 K-edge and K L_{2,3} edges (between 285 and 305 eV) were performed on all 13 FIB sections either
123 at the PolLux beamline (Swiss Light Source) or at beamline 5.3.2 at the Advanced Light Source
124 (USA).

125 Monochromatic X-rays focused on the sample using a Fresnel zone plate were used to collect 2-
126 D images by scanning the sample stage at a fixed energy with a spot size of ~40 nm. Combining
127 the images from each energy steps (0.1 eV in fine regions or 0.25/0.5 eV in pre- or post-edge)
128 produced 3D image ‘stacks’ of the differential absorption of X-rays of the FIB sections. XANES
129 line-scans were also acquired across the hypha-biotite interface. Maps of Fe(III)/Fe_{total} ratios, as
130 well as maps of potassium and of the various carbon functional groups were acquired and
131 processed³³. To quantify the Fe speciation in linescans (with aXis 2000) and stacks (with Matlab
132 routines), Singular Value Decomposition was performed using Fe(II) -siderite- and Fe(III) –
133 goethite- as reference spectra. For C, the peak area at 285.4 eV (due to the transition C 1s → π*
134 (* excited states) of the sp² hybridized carbon (i.e., C=C bonds), the peak at 288.5 eV
135 characteristic of the C 1s → π*_{-(C*=O)OH} transition for –COOH groups^{33,34} were integrated (Fig.
136 S-1). Fe and C-related Matlab scripts are available online from³⁵ and³⁶ respectively. All STXM
137 measurements were performed with dwell times of <3.5 ms (per energy step per pixel), which
138 was shown to induce negligible Fe(II) oxidation due to X-ray beam damage in chlorite, a
139 phyllosilicate closely related to biotite³⁷.

140 **RESULTS AND DISCUSSION**

141 Our data shows that at or close to the contact with ectomycorrhizal hypha, structural Fe(II)
142 oxidation was extensive in the biotite. Control sections had an average Fe(III)/Fe_{total} ratio of ~
143 0.17 ± 0.06 SD (n = 53) with values ranging from 0.04 to 0.26 (Fig. S-2 for control FIB section
144 corresponding to hypha ‘A’). These are in line with bulk Fe(III)/Fe_{total} ratio of 0.175 reported for
145 the Moen biotite³⁸. The measured ranges of Fe(III)/Fe_{total} ratios highlights the inherent
146 heterogeneous nature of the Fe valency within the biotite structure. Upon hypha colonization,

147 the biotite Fe(III)/Fe_{total} ratios increases by a factor of 3 to 5, reaching values up to ~0.8 under
148 hypha 'B' and 'A' (near the interface with the hypha) and a value over 0.6 under hypha 'C' (Fig.
149 2). Despite the fact that Fe(II) oxidation was observed underneath all three hypha, the data
150 revealed that the evolution and extent of this redox change along each hypha was quite variable.
151 For instance in hypha 'A' (Fig. 2A), Fe(III)/Fe_{total} maps showed a TIP section underneath which,
152 relative to the control section, little Fe(II) oxidation was observed (Fe(III)/Fe_{total} ratios between
153 0.05 and 0.35; Fig. S-2). In contrary, the section located ~300 μm away from the tip ('A' TIP+1)
154 showed a larger Fe(II) oxidation with Fe(III)/Fe_{total} ratios of ~ 0.4-0.6. Interestingly, the 'A'
155 TIP+2 section – the furthest away from the tip (~625 μm) - was slightly less oxidized than the
156 middle section, with Fe(III)/Fe_{total} ratios between 0.25 – 0.5. For hypha 'B' and 'C', the trends of
157 Fe(II) oxidation were different with the biotite beneath the tip being generally more oxidized
158 than under the older sections of the hypha (Fig. 2A and 2B). When considering the Fe(III)/Fe_{total}
159 depth profiles (Fig. 2), there is also a large variability from one FIB section to another regardless
160 if the measurements were carried out on the same or on different biotite flakes. For example,
161 TIP, TIP+2 and TIP+3 of hypha 'C' and TIP of hypha 'B' did not show variations with depth,
162 while other sections (TIP+2 for hypha 'A', TIP+1 and TIP+2 for hypha 'B' and TIP+1 hypha
163 'C') showed an increase in the Fe(III)/Fe_{total} ratios towards the interface with the hypha (Fig. 2).
164 On the contrary, two sections in hypha 'A' (TIP+1 and, to a lesser extent, TIP) showed a
165 decrease in Fe(III)/Fe_{total} ratios towards the interfacial regions compared to deeper portion of the
166 sections.

167 We interpret these discrepancies in the extent of Fe(II) oxidation to be the consequence of either
168 differences in exposure time between the mineral and the hypha or in temporal variations in the
169 biological activity of each hypha. It is worth noting that the tip of a hypha and, naturally its most

170 proximal region, are the most active both physiologically³⁹, and in terms of excretion⁴⁰. Thus
171 these would be putatively the most ‘active Fe(II) oxidizing’ portion of the hypha. Apical growth
172 of hypha proceeds by sudden pulses irregularly spread in time and thus growth is far from
173 continuous⁴¹. This means that at any given point during the colonization of the biotite surface,
174 the period of interaction between the tip and the biotite surface (i.e., the time period when Fe(II)
175 oxidation occurs) can vary greatly. Thus, the Fe(III)/Fe_{total} ratios in biotite do not necessarily
176 increase from the tip along the hypha. The depth profile of Fe(III)/Fe_{total} in section TIP+1 ‘B’ (
177 Fig. 2B) shows an increase from the structural value of ~0.2 at ~600 nm to a maximum of ~0.8 at
178 the hypha-mineral interface. This suggests that the Fe(II) oxidation process is mediated from the
179 interface with the hypha. Previous studies have already shown that the interfacial electron
180 transfer from reduced dissolved cations – such as Fe(II) – to micas and clay mineral surfaces
181 occur readily and are fast⁴²⁻⁴⁴. The electron hopping rate or the conductivity along octahedral
182 sheets (i.e., parallel to (001) plane) are fast in annite (10^6 s^{-1})⁴⁵ and nontronite (10^{-5} s^{-1})⁴⁶. In the
183 latter, an electron would travel 0.5 μm in only 4 min along an octahedral sheet⁴⁶, however
184 electron transfer through tetrahedral sheets or across interfoliar space (perpendicular to (001)
185 plane) are much slower. For the Moen biotite (used in the present study), Rüscher and Gall⁴⁷
186 report electrical conductivities (σ) perpendicular to (001) plane three orders of magnitude slower
187 than parallel to (001) plane, nevertheless the former was still measured to be $\sim 10^{-13} \text{ S.cm}^{-1}$. The
188 same authors suggest that the conductivity perpendicular to (001) plane is controlled by defects
189 in the biotite lattice structure that create conducting bridges between T-O-T (tetrahedral-
190 octahedral-tetrahedral) layers. In Fig. 3D and also in Bonneville et al.²⁷ (in Fig. 3), numerous
191 micro-cracks and defects are visible to a depth of ~300 nm (and possibly deeper) in the biotite
192 lattice structure beneath hypha, we hypothesize that these defects facilitate the ‘upward’ electron

193 transfer and explain that substantial Fe(II) oxidation could affect ‘deep’ portions of the biotite
194 structure in the time-frame of the hyphal colonization.

195 A recent AFM study showed that *P. involutus* tips colonizing chlorite [001] basal plane grow on
196 a 40-80 nm thick layer of hydrated extracellular polymeric substances⁴⁸, which are also visible
197 in sections in Fig. 3C (arrows) and Fig. S-3. We suggest this ‘biolayer’ to be the location of the
198 oxidative compounds at the surface of the biotite. This is not surprising because our fungi
199 species, *P. involutus*, can secrete or express genes coding for various organic compounds
200 susceptible to oxidize Fe(II) such as laccase⁴⁹ and hydroxymate-bearing compounds⁵⁰.
201 Furthermore, during respiration, reactive oxygen species (ROS i.e., O₂⁻, H₂O₂ and OH[·]) can
202 easily be formed by the interaction of O₂ with common cellular constituents like flavoproteins
203 and quinones⁵¹. In most cases, ROS are quickly degraded back to O₂ by dismutase and catalase.
204 However, when excreted, ROS can have a profound effect on redox sensitive elements in the
205 hypha near-environment. For instance, *Stilbella aciculosa* (Ascomycete) is known to excrete O₂⁻
206 that oxidizes dissolved Mn(II) leading to the precipitation of Mn(IV) oxide⁵². A recent study by
207 Keiluweit and coworkers⁵³ further demonstrates that the Mn(II) oxidative capability of fungi is
208 key to the long-term organic matter degradation in soils.

209 In the current study, we complemented the iron speciation measurements with μ-XANES
210 measurements at the C 1s edge to detect organic compounds potentially present within the biotite
211 or at the biotite-hypha interface (Fig. 4). To visualize this biotite-hypha boundary, the K maps of
212 the hypha ‘A’ sections are useful (Fig. 4, maps at right). For hypha ‘B’ and ‘C’, the Fe peak area
213 integrations were used to pinpoint the hypha-biotite interface in linescans (as illustrated in Fig.
214 S-2 for the control section sampled close to hypha ‘A’). In our previous study⁵, we showed that

215 Fe and K removal from biotite at the interface with hypha were only effective in the topmost 40
216 nm of the biotite in direct contact with the hypha. This is however also about the spatial
217 resolution of the STXM rastering images/linescans. Therefore, the interface between the Fe/K-
218 rich biotite and the K-‘depleted’ fungi appears here much less sharp (~150-200 nm in thickness
219 i.e. the equivalent of 3-4 pixels, Fig. 2 and Fig. 4). In addition, the biotite [001] basal planes were
220 probably not exactly parallel to the incident X-ray beam, and thus this misalignment effectively
221 enlarged the visualization of the physical hypha-biotite interface. The -C=C- maps (Fig. 4 at left)
222 show the opposite pattern to K, with no signals in the biotite and high levels in the fungi. Note
223 that the Pt layer deposited on top of the fungi during the FIB sectioning (~1.5 μm thick, see also
224 Fig. 2A) contains some O and is rich in C, originating from the precursor gas ($\text{C}_5\text{H}_5\text{Pt}(\text{CH}_3)_3$)
225 used for the Pt deposition process⁵⁴. The Pt deposit makes a clear distinction of the hypha very
226 difficult in our chemical maps – however based on the process SEM images taken during the FIB
227 sectioning (not shown but see Fig. 1B), the hypha on top of biotite were about 250 nm thick and
228 thus this value was transferred also to the chemical maps reported in Fig. 2 and 4. The -COOH
229 maps show a weak to moderate signal in the biotite portions of the three FIB sections of hypha
230 ‘A’ (Fig. 4). At first, we interpreted this -COOH signal within biotite to be due to electron/ion
231 beam induced deposition (E/IBID) during FIB sectioning⁵⁵. However, the amorphous carbon
232 (graphite C) resulting from E/IBID would have given a signal of sp^2 hybridized carbon map,
233 which was not the case. This leaves open the possibility of -COOH containing compounds to be
234 present within the biotite as a result of hypha colonization. Further research is needed to
235 characterize *in situ* the composition of this hyphal ‘biolayer’ and its potential role in the fungal
236 weathering process.

237 The implications of this large biotite Fe(II) oxidation are far reaching in terms of fungal
238 weathering. Structural Fe(II) oxidation triggers (i) the loss of the Fe(III) from the octahedral
239 sheets concomitant with the conversion of coordinating hydroxyl into oxide groups, and as a
240 result (ii) the formation of amorphous Fe(III) oxides in the interlayer space ^{18,27,56-58}. The growth
241 of Fe(III) oxide subdomains in biotite imply a local increase in volume inducing strain in the
242 biotite lattice ^{29,30}. Structural defects in biotite lattices resulting from Fe(II) oxidation alone have
243 been also suggested ⁵⁹. Furthermore, according to Fletcher et al. ³⁰, as biotite Fe(II) oxidation
244 proceeds and ferrihydrite is formed, elastic energy strain (per unit surface) accumulates until it
245 reaches values equivalent to the surface energy of fracture (2Γ – Table S2). Once this value is
246 reached, a crack forms. Interestingly, we showed previously ²⁷, based on HR-TEM micrographs
247 of FIB section across similar hyphae-biotite interfaces, that the fungal colonization leads to a
248 substantial diffraction contrast (biotite crystal structure close to the interface was misorientated
249 by a 14° angle relative to bulk biotite) as well as numerous micro-cracks resulting from a
250 mechanical forcing of the biotite lattices. In some instances, rupture of the tetrahedra-octahedra-
251 tetrahedra (T-O-T) [001] biotite planes were associated with subdomains of ferrihydrite (Fig. 3D
252 in ²⁷). Such micro-cracks and diffraction contrasts were also observed in the FIB sections
253 described in the current study (e.g., Fig. 3D and Fig. S3). Using Fletcher's approach ³⁰ (See
254 Supporting Information for calculation), we tested whether the elastic energy strain due to Fe(III)
255 hydroxide formation in biotite could trigger crack formation. Fletcher et al. ³⁰ assumed that *all* of
256 the oxidized Fe(II) would form Fe(III) hydroxides within the biotite. This is questionable
257 because Rancourt et al. ⁵⁷ showed (for annite) that Fe(III) hydroxides started to form only once
258 the Fe(III)/Fe_{total} ratio reached a value of ~ 0.66 and that Fe(III) hydroxides represented *at*
259 *maximum* 11% of the total Fe in the phase. Using the 11% as a maximum value, we calculated

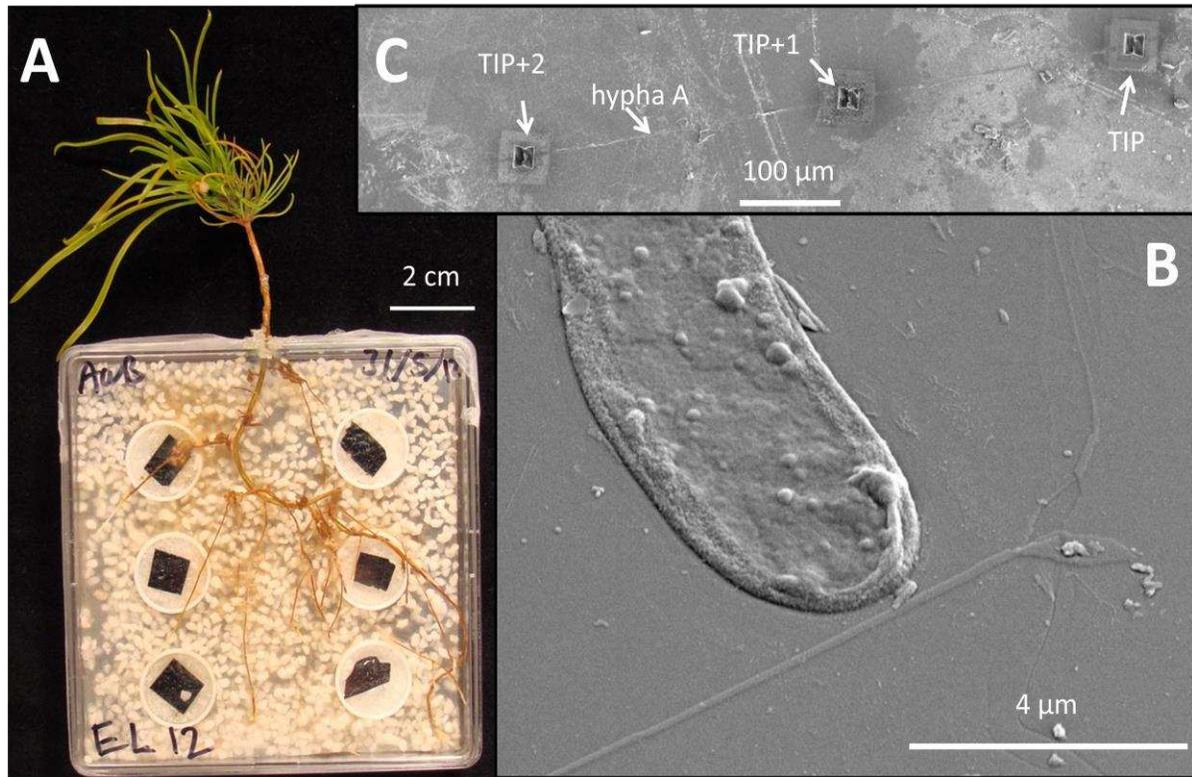

260 the threshold (2Γ) required for crack formation within the top ~30 nm of the oxidized biotite-
261 hyphae interface. In other words, when the $\text{Fe(III)/Fe}_{\text{total}}$ exceeded the ratio of ~ 0.66 and
262 ferrihydrite made up 11% of the Fe_{total} in the biotite structure, the formation of micro-cracks at
263 ~30 nm intervals was feasible within an oxidation front progressing deeper into the biotite. The
264 calculated values are consistent with our observation of micro-cracks at depth within the biotite,
265 yet such micro-cracks were not systematically distributed or present in all FIB sections possibly
266 due to insufficient Fe(II) oxidation and Fe(III) hydroxides formation (Fig. 3D and Fig. S3).
267 Nevertheless, when present, these micro-cracks were not isolated and appeared in large numbers
268 even at depth corresponding to areas where large Fe(II) oxidation could still occur up to 200-300
269 nm from the interface with hypha (Fig. S-3). Although difficult to quantify, the formation of
270 such network of crack parallel to the [001] planes beneath the hypha and the secreted biolayer
271 resulting from extensive Fe(II) oxidation will likely weaken the overall cohesion of the biotite
272 and favor the exfoliation process (Fig. 3C and 3D). We also hypothesize that such crack
273 networks, when present, participate in the formation of channels beneath hypha once the
274 colonization of the biotite surface occurred (see in Fig. S-4 and ¹⁴). Similar surface features were
275 reported as well in fungal weathering experiments with chlorite ⁶ and on muscovite in field
276 conditions ⁶⁰. Alternatively, the formation of a crack network could facilitate the penetration of
277 hypha within pre-existing fracture of the biotite surface (Fig. 5).

278 Although caution is required in extrapolating the results from our monoaxenic microcosms (free
279 of bacteria) to natural settings, the ability of common mycorrhiza to oxidize large amounts of
280 Fe(II) within the structure of biotite suggests that fungi could play an important role in Fe-
281 phyllosilicate redox cycling in soils. Indeed, Fe-phyllosilicates can serve both as electron donors
282 for Fe(II)-oxidizing microbial communities hence producing oxy-biotite or Fe(III) oxides ²² and

283 later as electron acceptors during dissimilatory Fe(III) reduction when anaerobic conditions may
284 develop in soils²⁴. In contrast to microbial biotite Fe(II) oxidation, which forms limited amounts
285 of Fe(III) and which is coupled to NO₃⁻ reduction²², the extent of mycorrhizal Fe(II) oxidation in
286 biotite is much larger (Fe(III)/Fe_{total} up to 0.8) and is fuelled (through mycelia growth) by the
287 photosynthetic activity of the host plants. More detailed studies on the coupling of mycorrhizal
288 and microbial processes in relation to phyllosilicate Fe redox cycling and weathering are
289 required to evaluate the significance of this phenomenon.

293

294 **Figure 1:** (A) Experimental microcosm after 4 months of growth. The mycelium that colonizes
295 the biotite flakes appears as an orange haze around roots. (B) SEM micrographs of the tip of
296 hypha 'A' before FIB milling respectively. (C) SEM micrographs of hypha 'A' sampled and of
297 the three FIB sections.

298

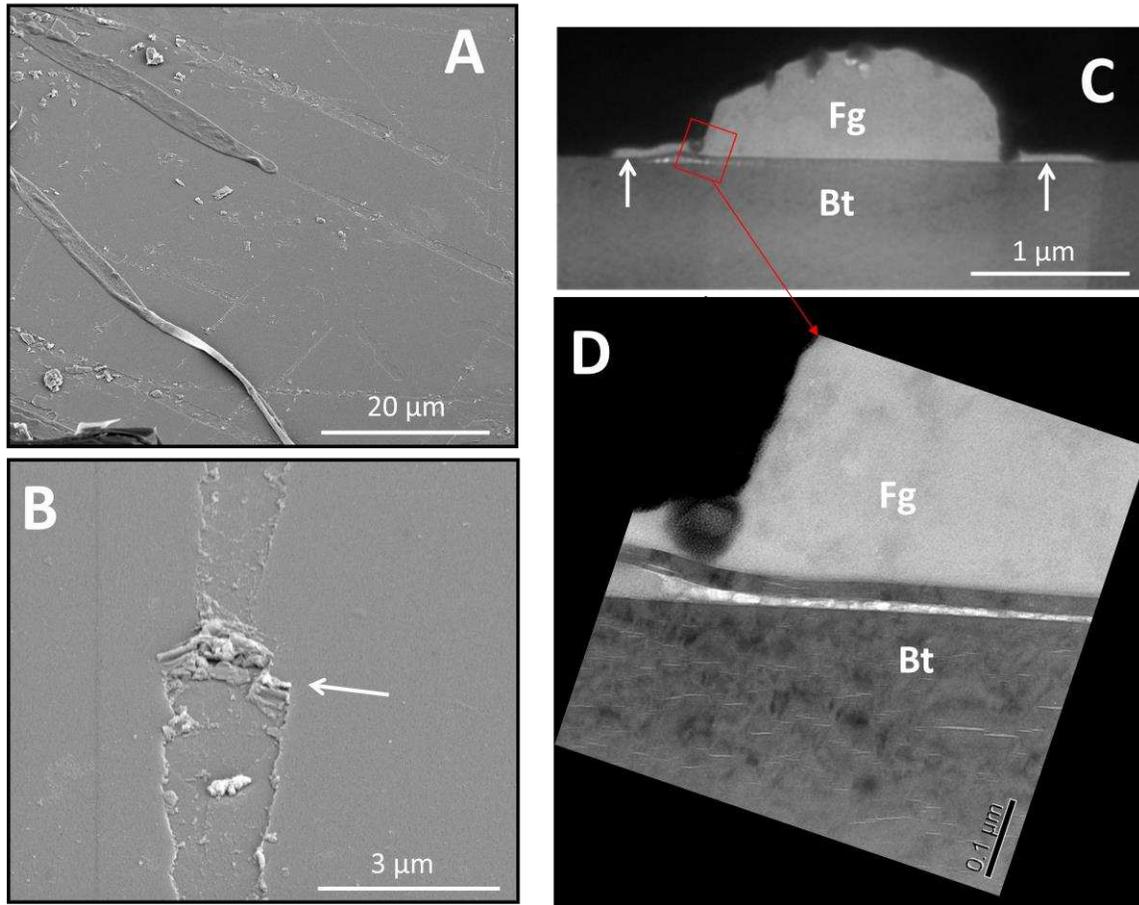

299
300

301

302 **Figure 2:** (A) $\text{Fe(III)/Fe}_{\text{total}}$ ratio maps in the three FIB sections cut along hypha ‘A’ with dashed
 303 lines highlighting the estimated position of the physical interfaces between fungi and biotite and
 304 between the fungi and the Pt deposit. Bottom image: red rectangle highlights the position of
 305 hypha analyzed in ‘A’ TIP. (B) and (C) depth profiles of $\text{Fe(III)/Fe}_{\text{total}}$ in the topmost 2 μm of
 306 biotite in contact with hypha or Pt deposit (controls) based on linescans (695-730 eV) on the FIB
 307 sections sampled on hypha ‘B’ and ‘C’. (\circ) TIP FIB section; (Δ) TIP+1 FIB section; (\diamond)
 308 TIP+2 FIB section; (\square) TIP+3 FIB section (only for hypha C).

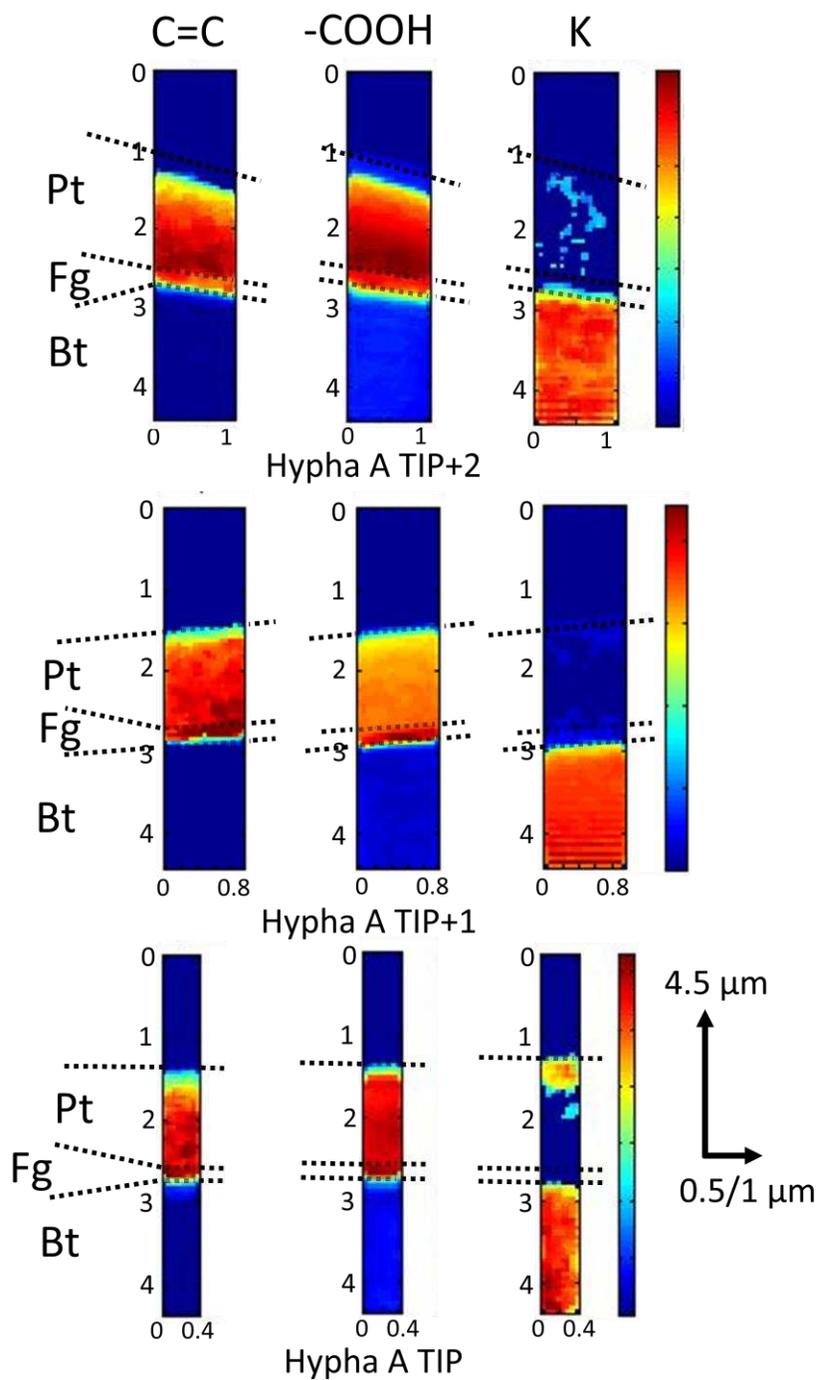

309

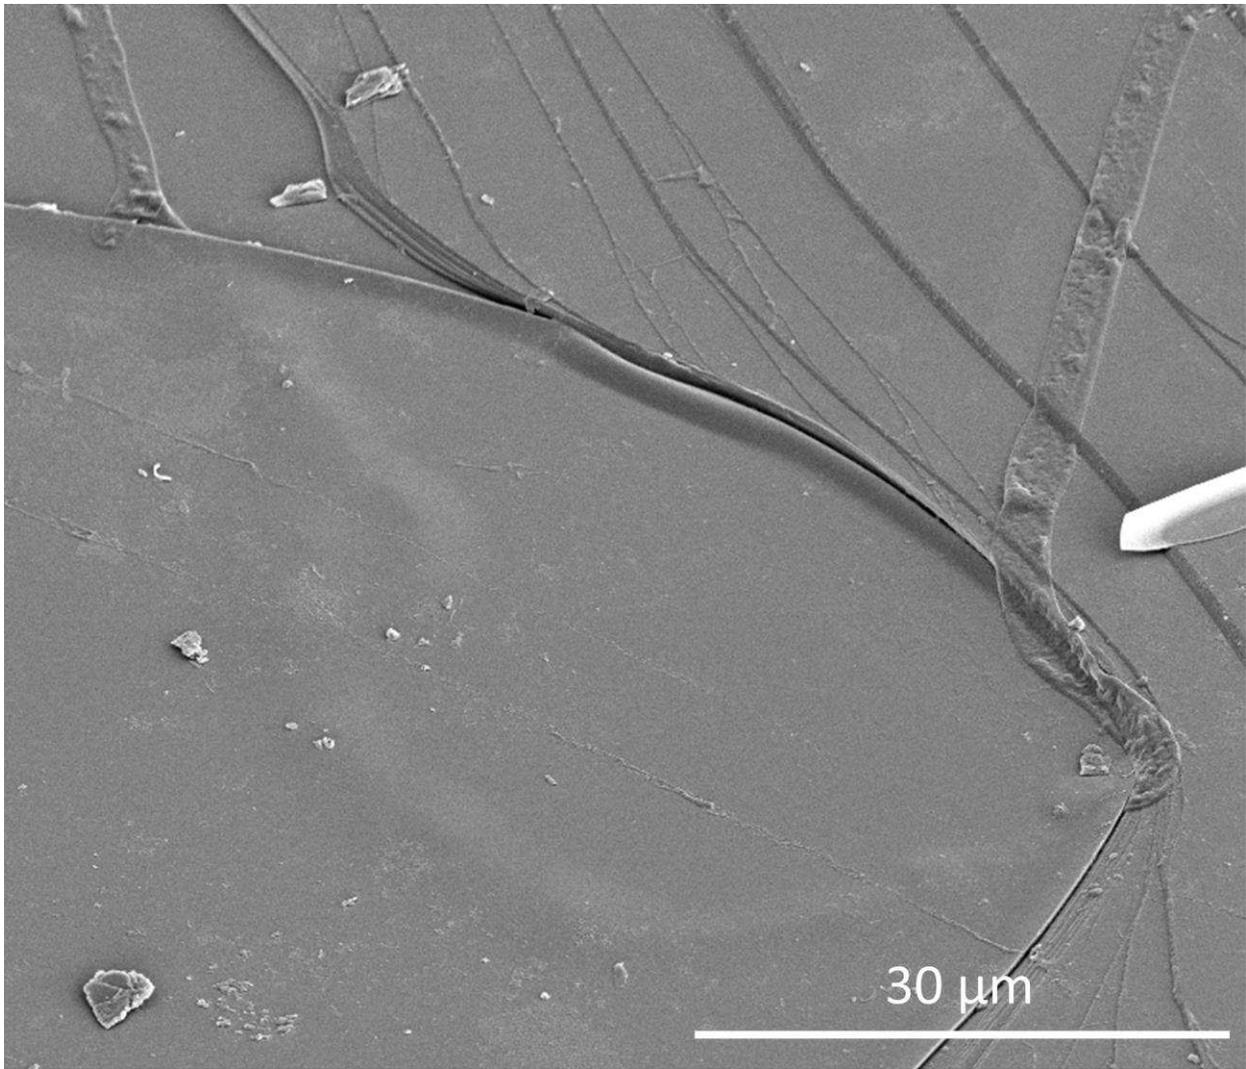

310

311 **Figure 3:** (A) SEM micrographs showing numerous channels (3-5 μm width) on the basal plane
 312 of biotite with (B) illustrating that some of the topmost biotite material is pushed away in the
 313 probable direction of hyphal pulsatile growth. (C) TEM bright-field micrographs of a FIB hypha-
 314 biotite section (not analyzed by XANES) showing a large crack near the interface with the hypha
 315 as well as an extensive “biolayer” (arrows) expanding from the central hypha. (D) Exfoliated
 316 layer and numerous micro-cracks at depth in the biotite. Note that all control FIB sections were
 317 free of such macro- and micro-cracks (see previous work ²⁷ for detailed TEM observation of
 318 control sections)

319

320
 321 **Figure 4:** Abundance maps of sp^2 hybridized carbon ($-C=C-$), carboxyl carbon, and potassium in
 322 three FIB sections along hypha 'A'. Maps were calculated from peaks integration (see Fig. S-1).
 323 Numbers on axis are length and width in μm of the area analyzed.

324
325

326 **Figure 5** : SEM micrograph of an hypha that penetrated a pre-existing fracture on the biotite
327 surface (top left and bottom right of the picture). This hypha has grown under the topmost layer
328 of biotite as evidenced by the bulged aspect of the surface showing the probable pathway of the
329 hypha within biotite.

330 ASSOCIATED CONTENT

331 **Supporting Information.** Include distances from tip of each FIB section sampled (Table S1), a
332 description of the “biotite oxidation and ferrihydrite formation reactions scheme”, as well as the
333 details of “calculation of cracks calculation” with associated parameters (Table S2). This
334 material is available free of charge via the Internet at <http://pubs.acs.org>.

335 AUTHOR INFORMATION

336 **Corresponding Author**

337 *Correspondence to : Steeve Bonneville (steeve.bonneville@ulb.ac.be) Biogéochimie et
338 Modélisation du Système Terre, Département Géosciences, Environnement et Société, Université
339 Libre de Bruxelles, 50 av. F. D. Roosevelt, CP160/02, 1050 Brussels, Belgium.

340 **Author Contributions**

341 The manuscript was written through contributions of all authors. All authors have given approval
342 to the final version of the manuscript. S.B., A.W.B. and L.G.B. conceived the project, designed
343 the study. S.B. carried out most of the data analysis and interpretation and wrote the manuscript.

344 ACKNOWLEDGMENT

345 D. Kylcoyne from the beamline 5.3.2 at Advanced Light Source (Lawrence Berkeley National
346 Laboratory) are acknowledged for their help during STXM measurements. The Advanced Light
347 Source is supported by the Director, Office of Science, Office of Basic Energy Sciences, of the
348 U.S. Department of Energy under Contract No. DE-AC02-05CH11231. We acknowledge also
349 the Paul Scherrer Institute, Villigen, Switzerland for provision of synchrotron radiation
350 beamtime at beamline PoLLUX of the Swiss Light Source and would like to thank J. Raabe for

351 assistance during STXM measurements. The authors thank John Harrington and Andy Brown
352 and the Leeds Electron Microscopy and Spectroscopy Centre for help with the FIB sampling. A.
353 Duran, M. Smits and J. Leake from the Department of Animal and Plant Sciences at the U. of
354 Sheffield are acknowledged for their help during the microcosm experiments. SB thanks R.
355 Behrends (GFZ Potsdam) for helpful discussions during the preparation of the manuscript.
356 Funding from the UK Natural Environment Research Council “Weathering Science Consortium”
357 grant NE/C004566/1 and a regular grant NE/J022365/1 to LGB are acknowledged. SB benefited
358 also from the support of the “Victor Brien”, “Van Buren” funds and the Fonds National de la
359 Recherche Scientifique (FNRS –PDR T.1012.14).
