# **Abstract**

This paper outlines the development of enhanced bivariate polar plots that allow the concentrations of two pollutants to be compared using pair-wise statistics for exploring the sources of atmospheric pollutants. The new method combines bivariate polar plots, which provide source characteristic information, with pair-wise statistics that provide information on how two pollutants are related to one another. The pair-wise statistics implemented include weighted Pearson correlation and slope from two linear regression methods. The development uses a Gaussian kernel to locally weight the statistical calculations on a wind speed-direction surface together with variable-scaling. Example applications of the enhanced polar plots are presented by using routine air quality data for two monitoring sites in London, United Kingdom for a single year (2013). The London examples demonstrate that the combination of bivariate polar plots, correlation, and regression techniques can offer considerable insight into air pollution source characteristics, which would be missed if only scatter plots and mean polar plots were used for analysis. Specifically, using correlation and slopes as pair-wise statistics, long-range transport processes were isolated and black carbon (BC) contributions to PM<sub>2.5</sub> for a kerbside monitoring location were quantified. Wider applications and future advancements are also discussed.

### 1. Introduction

Determining how variables are related to one-another is a key component of data analysis and statistics. Within the atmospheric sciences, exploring the relationships between chemical constituents and meteorological parameters is extremely common and the techniques for comparing, correlating, and determining relationships are very diverse. Analysis involving the correlation of two pollutants can often be insightful because it can lead to the identification of emission source characteristics, as can investigation into ratios or slopes from regression analysis between two pollutants (Statheropoulos et al., 1998). Within atmospheric disciplines, data analysis can also benefit from being able to integrate wind behaviour (Elminir, 2005). The use of wind speed and direction can be informative because it often leads to the suggestion of source locations and source characteristics, such as height of emission above the surface (Henry et al., 2002; Westmoreland et al., 2007).

Exploration of relationships among variables can be achieved with many different methods 13 that can range from the simple to numerically complex. However, a technique that is used 14 very widely is the simple x-y scatter plot (Bentley, 2004). Scatter plots are useful because 15 they allow for the visualisation of variables and model fitting can be evaluated quickly and 16 simply with visual feedback. Regression techniques, most commonly ordinary least-squared 17 regression, are often employed to formally quantify how x and y are related. The use of 18 least-squared regression is however technically questionable in many cases, and despite a 19 large collection of alternative techniques available, its use remains a persistent feature of 20 air quality data analysis. The use of simple scatter plots is usually carried out with entire 21 datasets or with simple or superficial filtering and therefore have potential to hide some 22 discrete relationships which are present in the global data if they do not conform to the mean rate of change (Cade and Noon, 2003). 24

Slopes from regression models relating two pollutants to one another are often used in applications that use monitoring data such as emission inventories and pollutant models.

When measurements are not available, slopes for the unknown pollutants are often substituted from the literature, short-term monitoring, or data collected at a near-by location. However, the use of simple and static ratios is likely to be deficient in many situations because they 29 can be expected to be highly dependent on source (Manoli et al., 2002). To differentiate 30 sources in air quality data, techniques other than simple scatter plots often need to be used. 31 A common method for source characterisation is the use of bivariate polar plots (Carslaw 32 et al., 2006; Westmoreland et al., 2007; Carslaw and Beevers, 2013; Uria Tellaetxe and 33 Carslaw, 2014). Polar plots are typically used to visualise and explore mean pollutant concentrations for single species based on wind speed and wind direction. In the atmospheric sciences, it is intuitive to plot wind direction (from 0 to 360° clockwise from north) on the 36 angular 'axis' and wind speed to be used for the radial scale. Aggregation functions other 37 than the arithmetic mean can be used and different variables apart from wind speed can be used for the radial scale. For example, atmospheric temperature or stability are often useful 39 variables to use. The main attribute for the choice of radial-axis variable is that it helps to 40 differentiate between different source characteristics in some way due to different source types 41 responding differently to values of the angular scale. Despite the range of potential options, 42 wind speed is widely used to help discriminate different source types and is particularly 43 useful when used together with wind direction and the concentration of a species (Harrison 44 et al., 2001; Kassomenos et al., 2012). 45 This type of polar plot analysis has, in part, become wide-spread due to the open-source 46 polarPlot function available in the openair R package (Carslaw and Ropkins, 2012; R Core 47 Team, 2016). Other similar techniques such as non-parametric wind regression have also 48 shown their ability to determine source locations for various pollutants by using polar plots (Henry et al., 2002, 2009; Donnelly et al., 2011).

#### 1.1. Objectives 51

50

Combining correlation and regression techniques with those that provide information on 52 source apportionment potentially offers considerably more insight into air pollution sources. The use of wind behaviour has the potential to evaluate correlation and slopes based on source locations and therefore different processes. It is common for emission inventories to use ratios for pollutants when they are not measured or when high quality data is lacking. It is hypothesised that the combination of correlation, regression, and polar plots could lead to significant additions to data analysis by understanding how different pollutants are related to one another depending on source.

In this paper, the combination of bivariate polar plots approaches with correlation and 60 regression techniques is considered for comparing two pollutants. This combination of 61 methods is then used to aid the interpretation of air quality data. The primary objectives of 62 this paper are as follows. First, to develop methods to combine bivariate polar plot techniques with correlation and a range of linear regression approaches. Second, apply the methods to 64 commonly available measurements of air pollutants to demonstrate the new insights made 65 possible by these techniques. Third, to consider the wider potential uses of the approaches 66 in air quality science. The software developed has been released with an open-source licence 67 and can be found in the polarplotr R package (Carslaw and Grange, 2016). 68

# 69 2. Methods

- 70 2.1. Function development
- 2.1.1. Kernel weighting and scaling

The plotting mechanism for polar plots when using wind direction as the polar axis 72 generally involves first aggregating a time-series into wind speed and direction intervals 73 (or 'bins'). The specific intervals and numbers of the bins can be altered for a particular application, but all combinations of the two types of bins are summarised by an aggregation 75 function such as the mean or maximum. In the openair polarPlot function, a smoothed 76 surface is fitted to these binned summaries using a generalised additive model (GAM) to create a continuous surface which can be plotted with polar coordinates. Further details of 78 the approach can be found in Carslaw and Beevers (2013) and Uria Tellaetxe and Carslaw 79 (2014).80

When applying a simple aggregation function, the number of observations in a time-series which compose a discrete wind speed and direction bin is not critical for the calculation or the

visual presentation of the surface, except at the edges of the plot where there are (usually) few observations. However, when calculating correlations or relationships between two variables, 84 it becomes important to consider the minimal number of observations which would create a 85 valid summary. If there are too few observations for a particular bin and a statistic such as 86 the correlation or slope is calculated between a pair of variables, it is likely that unreliable summaries will be generated due to large variations between neighbouring bins. To overcome 88 this limitation, for each wind speed and direction bin, the entire time-series was evaluated 89 but observations were weighted by their proximity to a wind speed and direction bin i.e., 90 wind speed or direction values further from the bin centre are weighted less than those closer 91 to the centre of the bin. Like previous works such as Henry et al. (2002, 2009), a weighting kernel was used to create weighting variables. 93

The weighting kernel used was the Gaussian kernel (Equation 1). The Gaussian kernel has infinite tails and therefore all input bins are given a non-zero weighting, but observations furthest from the bin being analysed have very small weights associated with them. The Gaussian kernel was used for weighting both wind speed and direction because it is considered more utilitarian than many other kernels such as the Epanechnikov kernel which have finite bounds and therefore at times, will give observations weights of zero which can cause ambiguity issues.

$$K(u) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}u^2} \tag{1}$$

To ensure the weighing variable was appropriate for the particular wind speed and direction application, the input wind speed and direction variables required scaling. The scaling process used was simple; the wind variables were multiplied by an integer to increase their bounds and therefore influence within the weighting kernel. The variables were also normalised to ensure that all observations had values between zero and one. This normalisation step is not strictly necessary when the Gaussian kernel is used, but is needed for some other kernels and ensures the output of process always had a known range.

101

102

103

104

105

106

107

108

If the weighting operated too locally, the inherently variable nature of wind behaviour

was represented in the plotted surface as noise. Conversely, if weighting was extended too far, 109 isolated areas of 'real' peaks were obscured due to over-smoothing. It is difficult to determine 110 an optimal set of scaling values for wind speed and direction for every application, therefore 111 a series of heuristic simulations were performed to determine the ideal integer scaling values. 112 It was found that within a central range the final output was rather insensitive to the 113 scaling values. One reason for this relative insensitivity will be due to the inherent random 114 variability of concentrations as a function of either wind speed or wind direction due to 115 atmospheric turbulence. This indicates that within a central band of values, the scaling 116 process is not particularly influential. It is possible for other applications these scaling magnitudes will have to be tuned and therefore the defaults can be altered by the user. 118 An example of the scaling defaults used in the polarPlot function are shown in Figure 1. 119 Figure 1 allows visualisation of the Gaussian weighting kernel for both the wind speed and direction variables as well as the extent of the default scaling procedure for a single bin for 121  $4.8\,\mathrm{m\,s^{-1}}$  and 230 degrees.

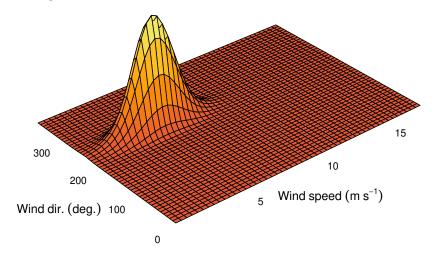

Figure 1: Three-dimensional surface of weights for a single wind speed and direction bin  $(4.8 \,\mathrm{m\,s^{-1}}$  and 230 degrees respectively). The surface is normalised and therefore intensity units are not informative.

After the appropriate weights have been calculated, the calculation of any pair-wise statistic that allows for weighting could be calculated between two pollutants. The first methods implemented were the Pearson correlation coefficient and two linear regression methods. Using these two groups of techniques allowed for the investigation of the correlation

123

124

between two pollutants and the investigation of the slope between pollutants, but with the inclusion of wind speed and direction.

### 2.1.2. Correlation

Correlation is a measure of how well two (or more) variables are associated to one-another.

Correlation is a useful measure for air pollutants because pollutants which demonstrate high levels of correlation are often emitted from the same source, or undergo similar chemical and physical transformations in the atmosphere. For use in polar plots, the correlation statistic implemented was the weighted Pearson correlation coefficient (r) (Davison and Hinkley, 1997; Canty and Ripley, 2016).

# 136 2.1.3. Regression

137

138

139

140

141

142

144

152

Regression is a very common statistical technique and is often used to describe and investigate relationships among variables (Kariya and Kurata, 2004). Regression is a large topic and only the linear regression techniques considered for the polar plot function will be discussed. Of particular interest is the estimate of the slope from a linear regression between two species. The slope will often reveal useful information concerning source characteristics, for example, the amount of  $PM_{10}$  that is in the fine fraction ( $PM_{2.5}$ ), or the ratios of combustion products such as CO and  $NO_x$  which can be compared with emission inventory estimates.

The first regression technique implemented was weighted least-squares linear regression.

This is very similar to ordinary least-squares linear regression, but the weighted sum of squares are minimised which has the effect of creating a model which preferentially represents a local area of the input data rather than the entire set. Because of the common presence of outliers in air pollution time-series measurements, other regression methods such as robust regression can offer advantages over the least-squares regression for use in the enhanced polar plots.

Robust regression extends least-squares regression techniques in attempting to better handle situations where the parametric assumptions of the least-squares regression method

are violated. These violations are usually involved with the presence of outliers and heteroscedasticity (non-equal variances). Primarily, the power of robust regression lies in the 155 resistance to the influence of outliers. Robust regression achieves this by substituting the 156 least-squares estimator for a more robust estimator (Yohai, 1987). There are many types of 157 robust estimators, but they all operate by first classing observations as outliers or not-outliers 158 and then reducing the influence of the outliers on the regression model (Huber, 1973). The 159 procedures for calculating robust estimators are iterative and more computationally demand-160 ing when compared to the calculation of the least-squares estimator. This is noticeable to 161 a user of the polarPlot function because additional run-time is needed when the robust regression techniques are used. The robust regression functions were supplied by the MASS 163 package (Venables and Ripley, 2002) and the estimator used was the M-estimator because 164 this estimator allows the use of weights.

### 166 2.2. Data

181

Data analysis was conducted on hourly air quality monitoring data for two sites included 167 in the United Kingdom's Automatic Urban and Rural (AURN) Network. The two sites were 168 London Marylebone Road and London North Kensington (Table 1 and Figure 2). Monitoring 169 data for 2013 were downloaded using the openair importAURN function. Both monitoring sites measure a large complement of chemical and particulate species and achieve high data capture rates. The particulate matter measurements were focused on for polar plot analysis and 172  $\mathrm{PM}_{10}$  and  $\mathrm{PM}_{2.5}$  at London Marylebone Road and London North Kensington are monitored 173 by TEOM-FDMS (Tapered Element Oscillating Microbalance-Filter Dynamics Measurement 174 System) instruments. This enhanced method is not as susceptible to removing volatile and 175 semi-volatile components in the monitored air-stream as standard heated TEOMs (Allen 176 et al., 1997; Green et al., 2009). Hourly black carbon (BC) data were also used and these data were sourced directly from the AURN monitoring database after personal communication with Ricardo Energy & Environment. More detailed site and instrument details can be found 179 see at https://uk-air.defra.gov.uk/. 180

Meteorological data for 2013 from London Heathrow (a major airport) in western London

Table 1: Details of locations of air quality and meteorological monitoring sites in London providing data for this study.

Site name	Latitude	Longitude	Elevation	Site type
London North Kensington	51.5211	-0.2134	5	Urban background
London Marylebone Road	51.5225	-0.1546	35	Urban traffic
London Heathrow	51.4780	-0.4610	25.3	Meteorological only

Figure 2: Locations of air quality and meteorological monitoring sites in London providing data for this study. The map's internal polygons show London's Boroughs, the City of London, and the River Thames.

were used to represent regional conditions for the two air quality monitoring sites. Hourly
data from the London Heathrow site were obtained from the NOAA Integrated Surface
Database (ISD) and access was gained with the *worldmet* R package (NOAA, 2016; Carslaw,
2016). The data from Heathrow Airport were used in preference to other local surface
measurements, which tend to be strongly influenced by local buildings.

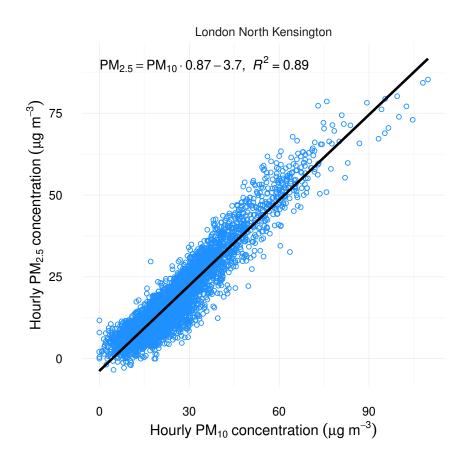

Figure 3: Simple x-y scatter plot of  $PM_{2.5}$  and  $PM_{10}$  for 2013 at London North Kensington. Fitted line and equation represents the ordinary least-squared regression model.

# 3. Results & discussion

# 3.1. London North Kensington $PM_{10}$ and $PM_{2.5}$

London North Kensington is an urban background site (Table 1 and Figure 2) and it is expected that a wide range of sources will contribute particle concentrations, including both local (London) and long-range (continental Europe) sources. A scatter plot of PM<sub>2.5</sub> and PM<sub>10</sub> shows that the two particle size fractions showed a good degree of correlation during 2013 (Figure 3). From Figure 3 alone there is no obvious indication that different source types contribute to the overall scatter of points. The mean ratio between PM<sub>2.5</sub> and PM<sub>10</sub> was 0.87, as determined by the ordinary least-squares linear regression model and it explained 89% of the variation (Figure 3).

The usual use of polar plots, by calculating the mean concentration for wind speed and 197 directions bins, show that the there were multiple sources of  $PM_{10}$  and  $PM_{2.5}$  at London 198 North Kensington in 2013 (Figure 4a and Figure 4b). Figure 4 suggests that locally-sourced 199 particulate matter were present, as potentially indicated by the elevated concentrations at 200 low wind speeds, but the highest concentrations were experienced with easterly winds when 201 wind speeds were high ( $\approx 10 \,\mathrm{m\,s^{-1}}$ ). By contrast, NO<sub>x</sub>, a pollutant which is dominated 202 by local (London) emissions, showed that only when wind speeds were low, were elevated 203 concentrations experienced due to a lack of pollutant dispersion (Figure 4c). However, when 204 the PM<sub>2.5</sub> and PM<sub>10</sub> data are plotted with a correlation statistic binned by wind speed and 205 direction, the situation is more revealing than the scatter plot and mean polar plots would 206 suggest alone (Figure 5). 207

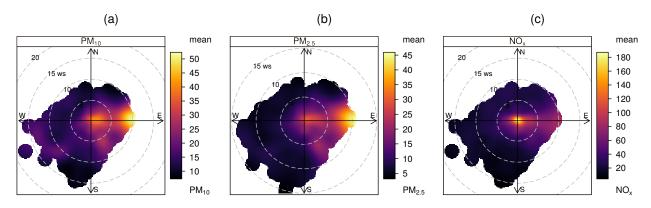

Figure 4: Polar plots of mean concentrations of  $PM_{10}$  (a),  $PM_{2.5}$  (b), and  $NO_x$  (c) for 2013 at London North Kensington.

208

209

210

211

212

213

214

The correlation polar plot of  $PM_{2.5}$  and  $PM_{10}$  demonstrates that during easterly winds, the London North Kensington  $PM_{2.5}$  and  $PM_{10}$  concentrations were very highly correlated with  $r \approx 0.9$  (Figure 5). The zone of high correlation is interpreted to be due to long-range transport which is characterised by the majority of  $PM_{10}$  being made up of  $PM_{2.5}$ . In London, and most areas of the UK, long-range transport is most important under easterly conditions where air-masses originate from continental Europe (Buchanan et al., 2002; Abdalmogith and Harrison, 2005; Liu and Harrison, 2011). Under these conditions the concentrations of fine particulate sulphate and nitrate can dominate absolute particle concentrations. The surface of

Figure 5 is also smooth and covers a wide range of wind speed and directions which indicates a general, and large-scale process which is being appropriately smoothed and represented by the weighting procedure (Section 2.1). Other monitoring locations, including London Marylebone Road that also measure PM<sub>2.5</sub> and PM<sub>10</sub> showed similar easterly behaviour (not shown).

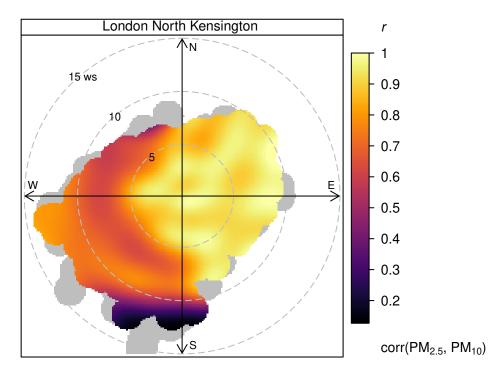

Figure 5: Polar plot of the correlation between  $PM_{2.5}$  and  $PM_{10}$  for 2013 at London North Kensington.

221

222

223

224

225

226

227

228

230

Previous studies such as Querol et al. (2004); Charron and Harrison (2005); Harrison et al. (2001); Liu and Harrison (2011) have reported high PM<sub>2.5</sub>–PM<sub>10</sub> ratios for European sourced particulate matter in the UK and the correlation presented in Figure 5 is consistent with these past works which reported high PM<sub>2.5</sub>–PM<sub>10</sub> ratios. When HYSPLIT (Stein et al., 2015) back-trajectories for 2013 were clustered and joined to coincident pollutant observations, the cluster representing air-masses from Europe also had the highest PM<sub>2.5</sub>–PM<sub>10</sub> ratio of all clusters, consistent with the conclusions inferred from Figure 5.

The polar plot of the slope between  $PM_{2.5}$  and  $PM_{10}$  at London North Kensington demonstrates a similar surface pattern as the correlation polar plot (Figure 6). The long-range sourced particulate from the east was indeed primarily composed of  $PM_{2.5}$ , as shown

by a  $PM_{2.5}$  to  $PM_{10}$  slope of about 90%. For other wind directions, coarser particulate matter was a more important contributor to PM<sub>10</sub> and the PM<sub>2.5</sub> contributions drop to 232 approximately 30 % (Figure 6). This reduction of  $PM_{2.5}$  to  $PM_{10}$  slope was most likely caused 233 the local process of mechanical resuspension. Even though the scatter plot of PM<sub>2.5</sub> and 234  $PM_{10}$  (Figure 3) does not indicate different source influences, it is clear from Figure 6 in 235 particular that there are at least two major source types affecting particulate concentrations 236 at the London North Kensington site. It should be noted that a careful wind speed, wind 237 direction subset of the data shown in Figure 3 does confirm the behaviour seen in Figure 6 238 with a much lower  $PM_{2.5}$  to  $PM_{10}$  slope for south-westerly winds above  $5 \,\mathrm{m \, s^{-1}}$ .

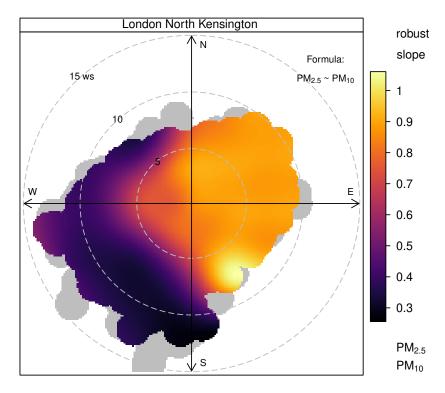

Figure 6: Polar plot of the robust slope between  $PM_{2.5}$  and  $PM_{10}$  for 2013 at London North Kensington.

# 3.2. London Marylebone $PM_{2.5}$ and BC

241

242

Unlike PM<sub>10</sub> and PM<sub>2.5</sub> at London North Kensington, the London Marylebone Road BC and PM<sub>2.5</sub> correlation was poor in 2013, as shown in Figure 7. Although BC exists primarily within the fine particle fraction (Petzold et al., 1997; Viidanoja et al., 2002) and would be

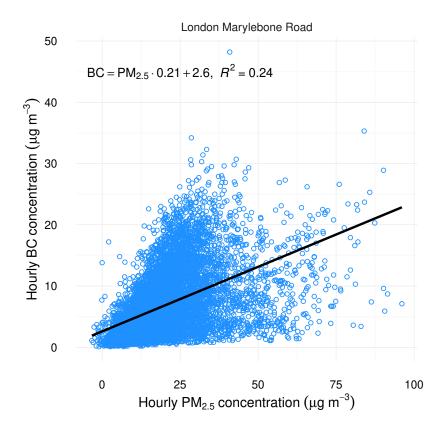

Figure 7: Simple x-y scatter plot of BC and PM<sub>2.5</sub> for 2013 at London Marylebone Road. Fitted line and equation represents the ordinary least-squared regression model.

expected to be an important component of PM<sub>2.5</sub> at a traffic-dominated location like London
Marylebone Road, PM<sub>2.5</sub> also has a diverse number of other sources including secondary
inorganic aerosol (Querol et al., 2004). Therefore, at times, BC will be a major contributor
to PM<sub>2.5</sub> while at others it will be a minor component depending on the strength of the
various sources. Using a scatter plot to investigate this relationship is not immediately useful
because the two variables do not follow a mean rate of change. Therefore, fitting a simple
linear regression line to these data is not informative (Figure 7).

The robust regression slope of BC and PM<sub>2.5</sub> binned by wind speed and direction at

The robust regression slope of BC and PM<sub>2.5</sub> binned by wind speed and direction at London Marylebone Road demonstrated patterns that were not observed by the simple scatter plot alone (Figure 8a). Figure 8a shows that the ratio between BC and PM<sub>2.5</sub> was highly dependent on wind direction. Winds from the south and west at London Marylebone

Road had a higher ratio of BC with  $\approx 50\%$  of PM<sub>2.5</sub> being composed of BC. BC-PM<sub>2.5</sub> ratios are sparsely reported, however London Marylebone Road's ratio is consistent with what Ruellan and Cachier (2001) reported for a traffic-dominated monitoring location in Paris (Porte d'Auteuil) with ratios of  $43 \pm 20\%$ . When winds were from the north and westerly directions, the BC-PM<sub>2.5</sub> ratio was lower, usually under 20%. Additionally, winds from the north were nearly completely free of BC particulate matter (Figure 8a).

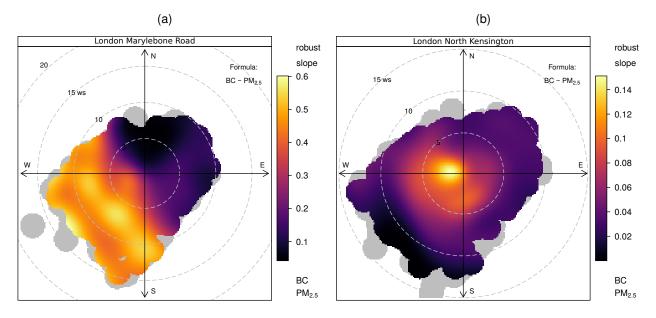

Figure 8: Polar plot of the robust slope between BC and  $PM_{2.5}$  at London Marylebone Road (a) and London North Kensington (b).

The wind direction dependencies inferred from the polar plot are somewhat counterintuitive given that the London Marylebone Road monitoring site is located one metre from
the kerb on the south-side of an arterial road. However, the site is also within a significant
street-canyon with a width of 40 m and a height of 41 m which is likely to lead to complex
recirculation patterns at a range of wind speeds (Charron and Harrison, 2005; Giorio et al.,
2015). Based on this evidence, accumulation of pollutants on the buildings' lee-side (south)
is an important process to consider at London Marylebone Road when interpreting source
processes.

London North Kensington also measures BC and PM<sub>2.5</sub> and the slope of these two pollutants binned by wind speed is rather different compared with London Marylebone Road

(Figure 8b). London North Kensington is an urban background site and lacks the large traffic source being in immediate proximity which London Marylebone Road experiences. Therefore, BC was a much smaller component of  $PM_{2.5}$ . In 2013, London North Kensington had a maximum contribution of  $\approx 15\%$  of BC to  $PM_{2.5}$  (Figure 8b). However, this maximum contribution only occurred when wind speeds were low and suggests that this contribution is reached only when local traffic emissions influence the monitoring site.

Based on these results for the two monitoring sites, the clear and consistent BC-PM<sub>2.5</sub> ratio at London Marylebone Road of around 50 % shown in Figure 8a in the south-west quadrant can be interpreted as a contribution dominated by local traffic sources. The lower ratio of between 10-20 % mostly to the east is dominated by regional source contributions where the concentration of PM<sub>2.5</sub> is relatively high but where air masses contain very little BC.

### 3.3. Future directions

284

285

286

288

289

The examples presented for a single year of data for two air quality monitoring sites in London were the first steps for enhancing polar plots to include the functionality of pair-wise statistics. The enhancements were able to substantially improve the information content available from routinely monitored air pollutants where simple scatter plots and 'standard' polar plots gave no suggestion of the processes subsequently illuminated by the correlation/slope polar plots.

The examples reported were for a few commonly measured species. However, it is expected
that the use of polar plots using pair-wise statistics for multi-species data such as metal
or VOC concentrations could be highly informative. Measurement of large numbers of
metals and other species at higher time resolutions (hourly) is becoming more common.
A 'correlation matrix of robust slope polar plots' would potentially reveal more detailed
information on common source origins.

The use of other statistics is another valuable future direction such as non-parametric measures of correlation such as Spearman. Other regression techniques such as quantile regression (Koenker and Bassett, 1978) could be implemented to provide slope information

across a range of quantile levels, potentially providing more comprehensive information on the relationship between two pollutants and give further options when determining pollutant 300 sources. The main advantage of quantile regression is likely to be related to resolving two 301 or more sources that overlap and where there is not a single dominant slope caused by 302 one source. In this case, considering the full distribution of slope values may help better resolve competing source contributions. Finally, the weighted statistics approach for paired 304 statistics could usefully be extended to model evaluation where two sets of data are compared 305 (observed and modelled). In this case, enhanced polar plot analyses could provide valuable 306 information concerning where model agreement is good or poor and indicate more clearly the conditions under which model performance is acceptable and provide enhanced information 308 on where model performance is poor. 309

#### 310 4. Conclusions

311

312

313

314

315

316

317

318

319

320

321

322

324

This paper outlined the development of enhanced bivariate polar plots to include pair-wise statistics to be used in the atmospheric sciences. Two groups of statistical techniques were implemented: correlation and regression. The new development brings together commonly used pair-wise statistics and relationships with wind speed and direction, which provides enhanced information on pollutant sources beyond currently used techniques.

Using a single year of data, in a single city, for routinely monitored pollutants demonstrated that the enhanced polar plots were capable of determining relationships and processes that were not suggested by simple scatter plots and the use of mean polar plots alone. Here we have reported that traffic dominated  $PM_{2.5}$  is composed of 50 % BC at a London monitoring site. This is an important observation and ratios between other pollutants such as elemental carbon and organic carbon (EC and OC) is an obvious future application for the enhanced polar plots.

It is expected in the future that enhanced polar plots will be widely used for the investigation of ratios for pairs of pollutants and further extended to be a valuable tool for teasing apart pollutant sources and processes.

- 328 This work was also partially funded by the 2016 Natural Environment Research Council
- 329 (NERC) air quality studentships programme.

# 330 Highlights

- Bivariate polar plots are a common method for exploring pollutant sources.
- Polar plots were enhanced with the addition of pair-wise statistics.
- Usage examples of the enhanced polar plots are given for two London monitoring sites.
- Processes were illuminated that were not detected by other plotting methods.
- Potential future applications and extensions are discussed for bivariate polar plots.
