(Received 27 October 2016; published 3 March 2017)

The $^{16}\text{O}(\alpha, \alpha')$ reaction was studied at $\theta_{\text{lab}} = 0^\circ$ at an incident energy of $E_{\text{lab}} = 200$ MeV using the K600 magnetic spectrometer at iThemba LABS. Proton decay and α decay from the natural parity states were observed in a large-acceptance silicon strip detector array at backward angles. The coincident charged-particle measurements were used to characterize the decay channels of the 0_6^+ state in ^{16}O located at $E_x = 15.097(5)$ MeV. This state is identified by several theoretical cluster calculations to be a good candidate for the 4- α cluster state. The results of this work suggest the presence of a previously unidentified resonance at $E_x \approx 15$ MeV that does not exhibit a 0^+ character. This unresolved resonance may have contaminated previous observations of the 0_6^+ state.

Light nuclei are expected to exhibit clusterlike properties in excited states with a low-density structure. Such states should exist particularly at excitation energies near the separation energies for these clusters, as described by the diagram of Ikeda *et al.* [1]. The Hoyle state, the 0_2^+ state at $E_x = 7.654$ MeV in ^{12}C , is considered the archetype of a state that exhibits α -particle structure, with one option being a 3- α gaslike structure similar to a Bose-Einstein condensate consisting of three α particles all occupying the lowest $0S$ state [2]. It is expected that equivalent Hoyle-like states should also exist in heavier α -conjugate nuclei such as ^{16}O and ^{20}Ne [3]. Early discussions of extended structures in ^{16}O were instigated by the seminal work of Chevallier *et al.* [4] who investigated low-energy $\alpha + ^{12}\text{C}$ scattering. The search for analogues of the Hoyle state in heavier α -conjugate nuclei is ongoing. Candidate states in ^{16}O below the four- α -particle breakup threshold ($S_{4\alpha} = 14.437$ MeV) include the 0_4^+ state at $E_x = 13.6(1)$ MeV, discovered in 2007, observed via inelastic scattering at $E_{\text{lab}} = 400$ MeV [5]. Another candidate is the 0_5^+ state at $E_x = 14.032(15)$ MeV [6], known to be strongly excited via monopole transitions from the ground state. A potential Hoyle-like candidate above the four- α -particle breakup threshold in ^{16}O has been identified by Funaki *et al.* [7], who solved a four-body equation of motion based on the orthogonality condition model that succeeded in reproducing the observed 0^+ spectrum in ^{16}O up to the 0_6^+ state. It was suggested that the 4- α condensation state could be assigned to the 0_6^+ state at $E_x = 15.097(5)$ MeV [8] (see Table I). The 0_6^+ state obtained from the calculation is 2 MeV above

the four- α -particle breakup threshold and has a large radius of 5 fm, indicating a dilute density structure. Ohkubo and Hirabayashi showed in a study of $\alpha + ^{12}\text{C}$ elastic and inelastic scattering [9] that the moment of inertia of the 0_6^+ state is drastically reduced, which suggests that it is a good candidate for the 4- α cluster condensate state. Calculations performed with the Tohsaki-Horiuchi-Schuck-Röpke (THSR) α -cluster wave function [10] also support this notion with an estimated total width of 34 keV for the 0_6^+ state [11], much smaller than the experimentally determined value of 166(30) keV [12].

Recent unsuccessful attempts to measure particle decay widths of the 0_6^+ state in ^{16}O [17,18] highlighted the need for an experiment that combines α -particle decay measurements with a high-energy-resolution experimental setup and a reaction capable of preferentially populating 0^+ states. In contrast to transfer reaction measurements, inelastic α -particle scattering at zero degrees has the advantage that it predominantly excites low-spin natural parity states. A measurement of the $^{16}\text{O}(\alpha, \alpha')$ reaction at zero degrees, coupled with coincident observations of the ^{16}O decay products, was performed at the iThemba Laboratory for Accelerator-Based Sciences (iThemba LABS)

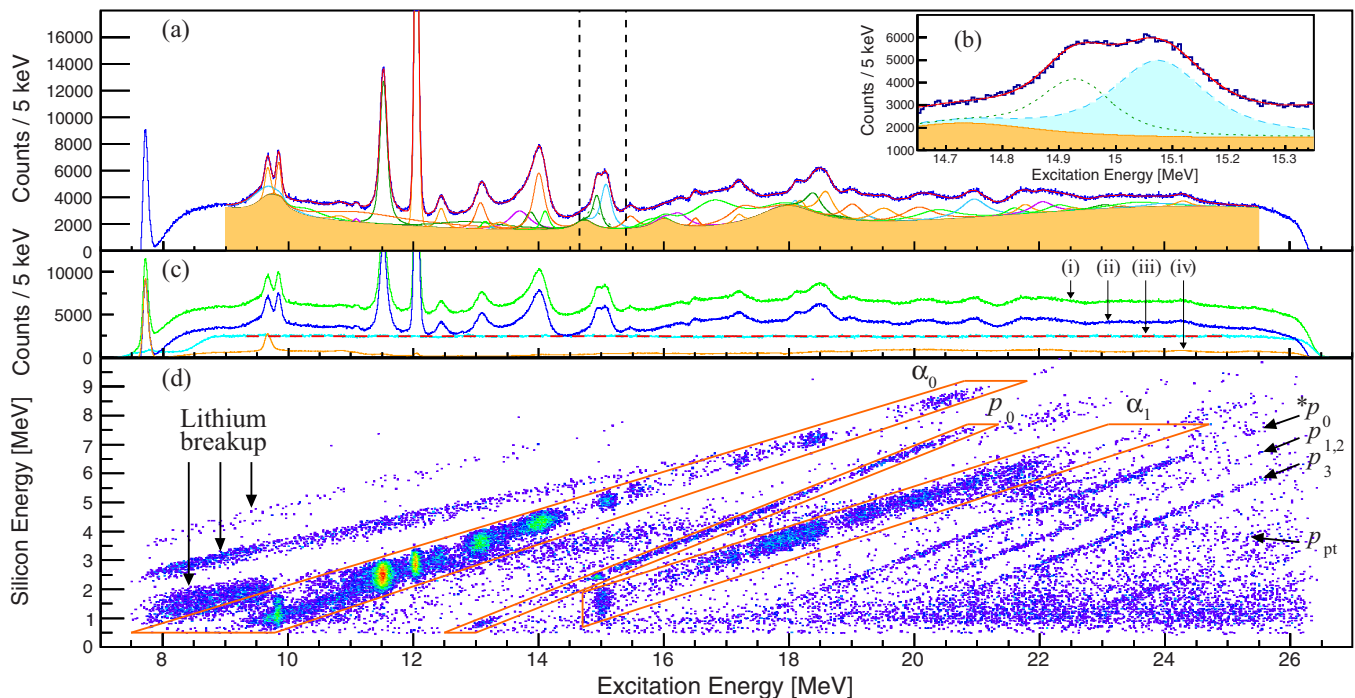

FIG. 1. (a) The background-subtracted inclusive excitation spectrum from the Li_2CO_3 target, with fitted R -matrix Voigt line shapes that are superimposed upon the background of fitted lithium resonances (filled in orange). (b) The excitation energy region of interest highlighting the 0_6^+ resonance (dashed blue line) and the neighboring $J^\pi = 2^+$ resonance (dotted green line). (c) The raw (i), background-subtracted (ii), and instrumental background inclusive excitation (iii) spectra from the Li_2CO_3 target. Spectrum (iv) is the background-subtracted inclusive excitation spectrum from the ^{12}C target, normalized to spectrum (ii) through the 9.641(5) MeV resonance in ^{12}C . The linear fit of spectrum (iii), used for background subtraction, is displayed as a dashed red line. (d) The coincident matrix of silicon energy versus the excitation energy of the recoil nucleus for decay particles detected within the angular range: $156^\circ < \theta_{\text{lab}} < 163^\circ$ (two silicon strips within the array). The α_0 -, α_1 -, and p_{0-3} -decay lines from ^{16}O are indicated. The proton punch-through structure from the p_0 decay is labeled p_{pt} . The lithium breakup and the *p_0 -decay line from ^{12}C are indicated. A display color threshold of >1 is imposed.

in South Africa. A 200-MeV dispersion-matched α -particle beam was provided by the separated sector cyclotron. The α particles that were inelastically scattered off a $^{\text{nat}}\text{Li}_2\text{CO}_3$ target were momentum analyzed at zero degrees with the K600 magnetic spectrometer [19]. The energy resolution obtained was 85(1) keV full width at half maximum (FWHM), determined from the 12.049(9) MeV resonance in ^{16}O . The error on the calculated excitation energy was $\delta E_x < 9$ keV. The 510- $\mu\text{g}/\text{cm}^2$ -thick $^{\text{nat}}\text{Li}_2\text{CO}_3$ target was prepared on a 50- $\mu\text{g}/\text{cm}^2$ -thick ^{12}C backing. The total $^{\text{nat}}\text{Li}$ content was approximately 50 $\mu\text{g}/\text{cm}^2$ [20]. The solid-angle acceptance of the spectrometer (3.83 msr) was defined by a circular collimator with an opening angle $\pm 2^\circ$. A comprehensive description of the experimental and analysis techniques is reported elsewhere [21].

The inclusive excitation energy spectra are displayed in Figs. 1(a), 1(b), and 1(c). To extract the excitation energy spectrum for the $^{16}\text{O}(\alpha, \alpha')$ reaction, the instrumental background must be taken into account and the contributions from the carbon and lithium present in the target must be identified. The flat and featureless instrumental background, indicated as spectrum (iii) in Fig. 1(c), is typical for measurements at zero degrees. It results from small-angle elastic scattering off the target foil that is followed by rescattering off any exposed part inside the spectrometer [19]. To subtract this

background contribution, the spectrometer was operated in focus mode where the quadrupole at the entrance to the spectrometer was used to vertically focus reaction products to a narrow horizontal band on the focal plane. The background spectrum was generated by using the sections of the focal plane above and below the vertically focused band. A linear fit was employed to approximate the background and was subtracted from the raw spectrum (i) to produce spectrum (ii). The background-subtracted focal plane spectrum from the ^{12}C target (iv) was normalized to spectrum (ii) through the 9.641(5)-MeV resonance in ^{12}C . The smooth contribution observed from ^{12}C in the excitation energy region of interest ($E_x \approx 15$ MeV) combined with the broad resonances of ^7Li and ^6Li indicated by the orange band in Figs. 1(a) and 1(b) ensure that the distinctly observed resonances can be assigned to ^{16}O . At $E_x \approx 15$ MeV, the decay modes from ^{16}O are not affected by the lithium breakup indicated in Fig. 1(d).

The decay products were observed with the Coincidence Array for K600 Experiments (CAKE) [22], consisting of four TIARA HYBALL MMM-400 double-sided silicon strip detectors (DSSSDs). Each of the 400- μm -thick wedge-shaped DSSSDs consisted of 16 rings and 8 sectors and were positioned at backward angles with the rings covering the polar-angle range of $114^\circ < \theta_{\text{lab}} < 166^\circ$, resulting in a solid-angle coverage of 20.4(5)% of 4π . For each focal-plane event,

FIG. 2. (a) The coincident matrix of silicon energy versus the excitation energy of the recoil nucleus, highlighting the decay modes observed at the excitation energy region of interest at $E_x \approx 15.1$ MeV. The excitation energy projections of the α_0 -, p_0 -, and α_1 -decay lines are displayed in panels (b), (c), and (d), respectively. The resonance energies, extracted with single-channel R -matrix fits, are indicated.

all signals from CAKE within a time window of 6 μ s were digitized, yielding both K600 inclusive as well as K600 + CAKE coincidence events. A beam pulse selector at the entrance of the cyclotron (which accepted one in five pulses) was employed to ensure a sufficient time window (273 ns) for coincidence measurements.

The detection of coincident charged-particle decay with the CAKE array enables the characterization of resonances through the measurement of branching ratios and angular correlations of various decay modes. The associated decay lines of the ^{16}O nucleus are displayed in Fig. 1(d): α decay and proton decay to the ground state of the residual nucleus are designated α_0 and p_0 , respectively, while α decay to the first excited state is designated α_1 . By gating upon a particular decay line and projecting onto excitation energy, the resonance line shape corresponding to a particular decay mode can be observed in isolation. The excitation energy spectra around $E_x \approx 15$ MeV corresponding to the α_0 -, p_0 -, and α_1 -decay modes are displayed in Figs. 2(b), 2(c), and 2(d), respectively. The extensive decay data for other resonances shall be published in a more comprehensive paper.

Resonances in the energy range of interest exhibit an R -matrix Lorentzian line shape:

$$N(E) \propto \frac{\Gamma(E)}{[E - E_R]^2 + [\Gamma(E)/2]^2}, \quad (1)$$

where E_R is the resonance energy (location parameter) and the total width, $\Gamma(E)$, is a sum of the energy-dependent partial widths. For the i th decay channel, the partial width is given by

$$\Gamma_i(E) = 2\gamma_i^2 P_l(E), \quad (2)$$

where γ_i is the reduced width and $P_l(E)$ is the associated penetrability, corresponding to the orbital angular momentum of decay l and the chosen external radius given by $R = 1.2 \times (A_1^{1/3} + A_2^{1/3})$. Given the inherent resolution of the focal plane detector system, the experimentally observed line shape of a resonance takes the form of a convolution between a Gaussian and the aforementioned R -matrix Lorentzian line shape, approximated by a Voigt line shape [23] with an R -matrix energy-dependent width, $\Gamma(E)$.

A single-channel R -matrix fit was implemented across the entire range of the focal plane considering possible resonances from all four target nuclei: ^{16}O , ^{12}C , ^7Li , and ^6Li . The Voigt line shapes within the fit were assigned the experimental energy resolution of $\text{FWHM} = 85(1)$ keV. For all fitted resonances, the decay parameters of each line shape were chosen to correspond to the decay channel with the lowest orbital angular momentum. For each resonance with unknown branching ratios, the line shape was prescribed the decay channel parameters corresponding to the most strongly observed decay mode of the resonance (from this work). The fitted resonance energy, E_R , of each known resonance was constrained to within 3σ about its literature value (excluding the resonances at $E_x \approx 15$ MeV). An upper limit on the width, known as the Wigner limit [24], was imposed on each decay channel. The extracted total width of each resonance, $\Gamma(E)$, is evaluated at the associated resonance energy E_R [see Eq. (2)]. In the inclusive spectrum displayed in Figs. 1(a) and 1(b), a prominent resonance was observed at $E_x = 15.076(7)$ MeV with an associated width of 162(4) keV. This is in good agreement with previous measurements of the 0_6^+ resonance, as displayed in Table I. In contrast, the observed width of 101(3) keV for the neighboring $J^\pi = 2^+$ resonance at $E_R = 14.926(2)$ MeV does not agree well with the corresponding literature value of 54(5) keV. By fitting the focal plane spectra gated on the α_0 -, p_0 -, and α_1 -decay modes, the resonance energies and widths from the resonances at $E_x \approx 15$ MeV were extracted, as displayed in Table II.

By gating on events detected in particular rings in the CAKE array, angular correlations of decay can be extracted in the laboratory reference frame, as shown in Fig. 3. Self-consistency of the R -matrix fits for the angular correlations was achieved by fixing the resonance energies and widths to the values extracted from the total fit of the relevant decay mode. To calculate the theoretical angular correlations of decay in the laboratory frame, the differential cross sections for the population of natural parity states through the $^{16}\text{O}(\alpha, \alpha')$ reaction were calculated in the distorted-wave Born approximation with the code CHUCK3 [25]. Both the m -state population ratios and the angular correlations of subsequent particle decay from the recoil nucleus were then calculated with ANGCOR [26] in the inertial reference frame of the recoil nucleus. Considering the $^{16}\text{O}(\alpha, \alpha')$ reaction with an incident energy of $E_{\text{lab}} = 200$ MeV and a recoil excitation energy of $E_x = 15.0$ MeV, the angular acceptance of the ejectile α particle corresponds

TABLE II. Extracted single-channel R -matrix fit parameters from the inclusive and coincidence spectra.

J^π	Decay mode	E_R (MeV)	Γ_{total} (keV)	Branching ratio (%)
2^+	Inclusive	11.520(9)	80(1)	—
	α_0	11.521(9)	82(1)	109(3)
0^+	Inclusive	12.049(9)	5(1)	—
	α_0	12.049(8)	12(1)	96(3) ^a
2^+	Inclusive	14.930(8)	101(3)	—
0^+	p_0	14.929(8)	40(1)	21(1)
	Inclusive	15.076(7)	162(4)	—
	α_0	15.090(7)	162(4)	72(2) ^b
	α_1	15.046(8)	216(10)	67(3) ^b

^aThe α_1 -decay channel was not observable within this work due to electronic thresholds of the CAKE array.

^bThe α_0 and α_1 branching ratios are calculated under the assumption that they both originate from a single $J^\pi = 0^+$ resonance. The summed branching ratios far exceed 100%, indicating that this assumption is false.

to recoil nuclei (^{16}O) with minimum and maximum kinetic energies of 80 keV ($\theta_{\text{lab}} = 0^\circ$) and 140 keV ($\theta_{\text{lab}} = 40^\circ$), respectively. To account for the velocity of the recoil nuclei, the calculated correlations are then relativistically transformed to the laboratory frame by taking into account the angular acceptance for the ejectile nuclei by the spectrometer. The solid-angle correction factors for the CAKE array are obtained with a GEANT4 [27] simulation which accounts for a potential ± 2 mm positioning error that has been propagated through to the total error of the data points. Calculated angular correlations are shown in Fig. 3.

The data suggest the presence of a previously unidentified resonance at $E_x \approx 15$ MeV. Fig. 3(e) shows that the angular distribution of α_0 decay observed at $E_R = 15.090(7)$ MeV is distinctly anisotropic. This can only result from the presence of a previously unidentified resonance with nonzero spin, which may be obscuring the isotropic decay of the $J^\pi = 0_6^+$ resonance. The calculated angular correlations of α_0 decay from $J^\pi = 0^+, 1^-, 2^+, 3^-, 4^+$, and 5^- resonances at this resonance energy do not fit well to the data. The two best-fitting α_0 angular correlations correspond to a $J^\pi = 0^+$ and a $J^\pi = 1^-$ resonance, yielding $\chi_{\text{red}}^2 = 13.54$ and $\chi_{\text{red}}^2 = 16.65$, respectively. Given the possibility of two distinct but unresolved resonances, all possible pairs of the calculated correlations were incoherently summed and fitted to the data (with the relative contributions being free parameters). These calculations do not yield satisfactory reproduction of the data: the best fit corresponds to the incoherently summed α_0 -decay distributions from a $J^\pi = 1^-$ and a $J^\pi = 5^-$ resonance, yielding $\chi_{\text{red}}^2 = 7.67$. It is possible that the angular correlations of these inherently overlapping resonances may interfere. The anisotropy remains a clear identifier of a resonance with nonzero spin. To ensure that the anisotropy is not a consequence of the analysis, the angular correlations of decay from the most prominently observed resonances are also analyzed. The α_0 angular distribution of the $J^\pi = 0^+$

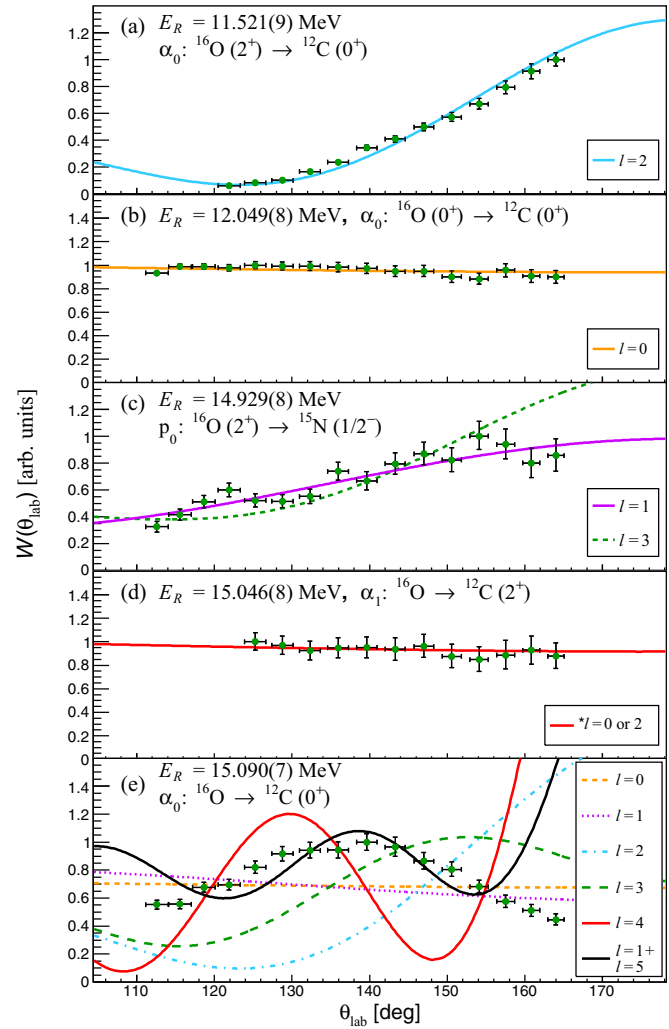

FIG. 3. Angular correlations of charged-particle decays from ^{16}O in the laboratory frame relative to the beam axis: (a) α_0 decay from the 11.521(9) MeV $J^\pi = 2^+$ resonance, (b) α_0 decay from the 12.049(8) MeV $J^\pi = 0^+$ resonance, (c) p_0 decay from the 14.929(8) MeV $J^\pi = 2^+$ resonance, (d) α_1 decay observed at 15.046(8) MeV, and (e) α_0 decay observed at 15.090(7) MeV. *The α_0 decays from $J^\pi = 0^+$ and 2^+ resonances, corresponding to $l = 0\hbar$ and $2\hbar$, respectively, exhibit the same angular correlations. Data points affected by the electronic thresholds of the CAKE array are omitted.

resonance at $E_x = 12.049(9)$ MeV, shown in Fig. 3(b), exhibits isotropy and the corresponding calculation fits the data with a reduced chi-squared of $\chi_{\text{red}}^2 = 1.01$, indicating that the experimental setup is well understood. Similarly for the α_0 angular distribution of the $J^\pi = 2^+$ resonance at $E_x = 11.520(9)$ MeV displayed in Fig. 3(a), the theoretical fit is reasonable and yields $\chi_{\text{red}}^2 = 1.42$.

The angular distribution of the α_1 -decay mode observed at $E_x = 15.046(8)$ MeV is observed to be isotropic, as displayed in Fig. 3(d). While only a $J^\pi = 0^+$ or 2^+ resonance can exhibit purely isotropic α_1 decay, inherently anisotropic decays from resonances of other spin-parities may experimentally appear isotropic given their multiple possible l values of decay. It is therefore assumed that this α_1 -decay mode originates from

the $J^\pi = 0_6^+$ resonance. The fit to the calculated α_1 $J^\pi = 0^+$ angular distribution yields $\chi_{\text{red}}^2 = 0.15$, which could indicate either an overestimation of the data errors or that the dominant error is a systematic scaling factor. This, however, does not affect the conclusions of the paper. The angular distribution of the p_0 -decay mode observed at $E_x = 14.929(8)$ MeV is displayed in Fig. 3(c). The proton decay from a $J^\pi = 2^+$ resonance to the $J^\pi = 1/2^-$ ground state of ^{15}N corresponds to orbital angular momenta of decay of either $l = 1\hbar$ or $3\hbar$, corresponding to calculated correlations which fit with $\chi_{\text{red}}^2 = 1.25$ and 4.57 , respectively.

Additional evidence towards a previously unidentified resonance is given by the extracted resonance energies from the fitted line shapes for the α_0 - and α_1 -decay modes. The resonance energies corresponding to various decay modes from a resonance can provide insight into the spin and parity, particularly when only a single l value of decay is possible. For a $J^\pi = 0^+$ resonance in ^{16}O , an α particle emitted through either α_0 decay or α_1 decay carries exactly $l = 0\hbar$ or $2\hbar$ units of angular momentum, respectively. If the α_0 - and α_1 -decay modes observed at $E_x \approx 15$ MeV are from the same $J^\pi = 0^+$ resonance in ^{16}O , both the greater center-of-mass energy and the lack of a centrifugal potential barrier for α_0 decay suggest that the extracted resonance energy of the α_0 -decay line shape should be lower than that of the α_1 decay. From this work, the α_0 -decay mode observed at $E_x = 15.090(7)$ MeV is $44(3)$ keV higher in excitation energy than that of the α_1 -decay mode. It is therefore incompatible for the α_0 - and α_1 -decay modes to both originate from a single $J^\pi = 0^+$ resonance. In principle, this shift in resonance energies could be explained by the existence of either a single $J^\pi = 2^+$ resonance or a single $J^\pi = 3^-$ resonance: the minimal orbital angular momenta for α_0 and α_1 decay are $l = 2\hbar$ or $0\hbar$, respectively, for a $J^\pi = 2^+$ resonance and $l = 3\hbar$ or $1\hbar$, respectively, for a $J^\pi = 3^-$ resonance. Assuming the m -state population ratios calculated with a direct single-step reaction mechanism are correct, the calculated angular correlations of α_0 decay from both a $J^\pi = 2^+$ and a $J^\pi = 3^-$ resonance do not agree well with the data displayed in Fig. 3(e).

Finally, we note that the presence of a previously unidentified resonance at $E_x \approx 15$ MeV could explain why the extracted total width of the unresolved $J^\pi = 2^+$ resonance at $E_x = 14.930(8)$ MeV, extracted from the inclusive data to be $101(3)$ keV, is inconsistent with the p_0 -extracted width and literature value of $40(1)$ and $54(5)$ keV, respectively. The

observation of a smooth and featureless instrumental background spectrum (iii) in Fig. 1(c) ensures that this disparity of widths is not caused by experimental artifacts. Similarly, the inclusive excitation energy spectrum from the ^{12}C target, displayed as spectrum (iv) in Fig. 1(c), shows that the ^{12}C contribution at $E_x \approx 15$ MeV is negligible. Given the α -separation energies for ^6Li and ^7Li of $E_{\text{sep}} = 1.47$ and 2.47 MeV, respectively, the contributions of the lithium resonances to the focal plane spectra collectively form a slowly varying continuum, shown as the orange-filled line shape in Figs. 1(a) and 1(b). Furthermore, the presence of a contaminant nucleus which decays through charged-particle emission would be kinematically identified within the coincident matrix of silicon energy versus excitation energy, displayed in Fig. 1(d).

Itoh *et al.* studied the $^{16}\text{O}(\alpha, \alpha')$ reaction at $\theta_{\text{lab}} = 0^\circ$ and $\theta_{\text{lab}} = 4^\circ$, with an incident energy of $E_{\text{lab}} = 386$ MeV [28]. A multipole decomposition was performed on the differential cross section of the resonance within the excitation energy interval: $15.00 \text{ MeV} < E_x < 15.25 \text{ MeV}$. While the decomposition indicated the presence of a 0^+ resonance, the differential cross section is qualitatively different from that of the 0^+ resonance observed at $12.00 \text{ MeV} < E_x < 12.25 \text{ MeV}$. This is reflected by the larger fitted contribution of $L \geq 1$ angular momentum transfer reactions. Their work is therefore consistent with the existence of a previously unresolved resonance at $E_x \approx 15$ MeV that does not exhibit a 0^+ nature.

By studying the $^{16}\text{O}(\alpha, \alpha')$ reaction at $\theta_{\text{lab}} = 0^\circ$ with an incident energy of $E_{\text{lab}} = 200$ MeV, low-spin states in ^{16}O were strongly excited. The angular correlations observed with the CAKE array suggest the existence of a previously unresolved resonance at $E_x \approx 15$ MeV with nonzero spin. This is supported by the shift in resonance energies between the α_0 - and α_1 -decay modes (see Fig. 2). The existence of a previously unresolved resonance may explain the disparity between the theoretical and experimentally observed widths of 34 and $166(30)$ keV, respectively. A narrower and therefore longer-lived 0_6^+ resonance located above the $4\text{-}\alpha$ -particle breakup threshold ($S_{4\alpha} = 14.437$ MeV) could be considered a better candidate for a Hoyle-like state in ^{16}O .
