ABSTRACT

Supplemental information for a Letter reporting the rate of binary black hole (BBH) coalescences inferred from 16 days of coincident Advanced LIGO observations surrounding the transient gravitational wave (GW) signal GW150914. In that work we reported various rate estimates whose 90% credible intervals (CIs) fell in the range 2–600 Gpc⁻³ yr⁻¹. Here we give details of our method and computations, including information about our search pipelines, a derivation of our likelihood function for the analysis, a description of the astrophysical search trigger distribution expected from merging BBHs, details on our computational methods, a description of the effects and our model for calibration uncertainty, and an analytic method of estimating our detector sensitivity that is calibrated to our measurements.

The first detection of a gravitational wave (GW) signal from a merging binary black hole (BBH) system is described in [Abbott et al. \(2016d\)](#). [Abbott et al. \(2016g\)](#) reports on inference of the local BBH merger rate from surrounding Advanced LIGO observations. This Supplement provides supporting material and methodological details for [Abbott et al. \(2016g\)](#), hereafter referred to as the Letter.

1. SEARCH PIPELINES

Both the `pycbc` and `gstlal` pipelines are based on matched filtering against a bank of template waveforms. See [Abbott et al. \(2016c\)](#) for a detailed description of the pipelines in operation around the time of GW150914; here we provide an abbreviated description.

In the `pycbc` pipeline, the single-detector signal-to-noise ratio (SNR) is re-weighted by a chi-squared factor ([Allen 2005](#)) to account for template-data mismatch ([Babak et al. 2013](#)); the re-weighted single-detector SNRs are combined in quadrature to produce a detection statistic for search triggers.

The `gstlal` pipeline’s detection statistic, however, is based on a likelihood ratio ([Cannon et al. 2013, 2015](#)) constructed from the single-detector SNRs and a signal-consistency statistic. An analytic estimate of the distribution of astrophysical signals in multiple-detector SNR and signal consistency statistic space is compared to a measured distribution of single-detector triggers without

a coincident counterpart in the other detector to form a multiple-detector likelihood ratio.

Both pipelines rely on an empirical estimate of the search background, making the assumption that triggers of terrestrial origin occur independently in the two detectors. The background estimate is built from observations of single-detector triggers over a long time (`gstlal`) or through searching over a data stream with one detector’s output shifted in time relative to the other’s by an interval that is longer than the light travel time between detectors, ensuring that no coincident astrophysical signals remain in the data (`pycbc`). For both pipelines it is not possible to produce an instantaneous background estimate at a particular time; this drives our choice of likelihood function as described in Section 2.

The `gstlal` pipeline natively determines the functions $p_0(x)$ and $p_1(x)$ for its detection statistic x . For this analysis a threshold of $x_{\min} = 5$ was applied, which is sufficiently low that the trigger density is dominated by terrestrial triggers near threshold. There were $M = 15848$ triggers observed above this threshold in the 17 days of observation time analyzed by `gstlal`.

For `pycbc`, the quantity x' is the re-weighted SNR detection statistic.¹ We set a threshold $x'_{\min} = 8$, above

¹ When quoting pipeline-specific values we distinguish `pycbc` quantities with a prime.

Figure 1. Inferred terrestrial (p_0 ; blue) and astrophysical (p_1 ; green) trigger densities for the `pycbc` pipeline as described in Section 1.

which $M' = 270$ triggers remain in the search. We use a histogram of triggers collected from time-shifted data to estimate the terrestrial trigger density, $p_0(x')$, and a histogram of the recovered triggers from the injection sets described in Section 2.2 of the Letter to estimate the astrophysical trigger density, $p_1(x')$. These estimates are shown in Figure 1. The uncertainty in the distribution of triggers from this estimation procedure is much smaller than the uncertainty in overall rate from the finite number statistics (see, for example, Figure 5). The empirical estimate is necessary to properly account for the interaction of the various single- and double-interferometer thresholds in the `pycbc` search (Abbott et al. 2016c). At high SNR, where these thresholds are irrelevant, the astrophysical triggers follow an approximately flat-space volumetric density (see Section 3) of

$$p_1(x') \simeq \frac{3x_{\min}^3}{x'^4}, \quad (1)$$

but they deviate from this at smaller SNR due to threshold effects in the search.

For the `pycbc` pipeline, a detection statistic $x' \geq 10.1$ corresponds to an estimated search false alarm rate (FAR) of one per century.

2. DERIVATION OF POISSON MIXTURE MODEL LIKELIHOOD

In this section we derive the likelihood function in Eq. (3) of the Letter. Consider first a search of the type described in Section 1 over N_T intervals of time of width δ_i , $\{i = 1, \dots, N_T\}$. Triggers above some fixed threshold occur with an instantaneous rate in time and detection statistic x given by the sum of the terrestrial

and astrophysical rates:

$$\frac{dN}{dt dx}(t, x) = R_0(t)p_0(x; t) + R_1(t)V(t)p_1(x; t), \quad (2)$$

where $R_0(t)$ is the instantaneous rate (number per unit time) of terrestrial triggers, $R_1(t)$ is the instantaneous rate density (number per unit time per unit comoving volume) of astrophysical triggers, p_0 is the instantaneous density in detection statistic of terrestrial triggers, p_1 is the instantaneous density in detection statistic of astrophysical triggers, and $V(t)$ is the instantaneous sensitive comoving redshifted volume (Abbott et al. 2016a, see also Eq. (15) of the Letter) of the detectors to the assumed source population. The astrophysical rate R_1 is to any reasonable approximation constant over our observations so we will drop the time dependence of this term from here on.² Note that R_0 and R_1 have different units in this expression; the former is a rate (per time), while the latter is a *rate density* (per time-volume). The density p_1 is independent of source parameters as described in Section 3. Let

$$\frac{dN}{dt} \equiv \int dx \frac{dN}{dt dx} = R_0(t) + R_1 V(t). \quad (3)$$

If the search intervals δ_i are sufficiently short, they will contain at most one trigger and the time-dependent terms in Eq. (2) will be approximately constant. Then the likelihood for a set of times and detection statistics of triggers, $\{(t_j, x_j) | j = 1, \dots, M\}$, is a product over intervals containing a trigger (indexed by j) and intervals that do not contain a trigger (indexed by k) of the corresponding Poisson likelihoods

$$\mathcal{L} = \left\{ \prod_{j=1}^M \frac{dN}{dt dx}(t_j, x_j) \exp \left[-\delta_j \frac{dN}{dt}(t_j) \right] \right\} \times \left\{ \prod_{k=1}^{N_T-M} \exp \left[-\delta_k \frac{dN}{dt}(t_k) \right] \right\} \quad (4)$$

(cf. Farr et al. (2015, Eq. (21)) or Loredo & Wasserman (1995, Eq. (2.8))).³ Now let the width of the observation intervals δ_i go to zero uniformly as the number of intervals goes to infinity. Then the products of exponentials in Eq. (4) become an exponential of an integral, and we have

$$\mathcal{L} = \prod_{j=1}^M \left[\frac{dN}{dt dx}(t_j, x_j) \right] \exp[-N], \quad (5)$$

² The astrophysical rate can, in principle, also depend on redshift, but in this paper we assume that the BBH coalescence rate is constant in the comoving frame.

³ There is a typo in Eq. (2.8) of Loredo & Wasserman (1995). The second term in the final bracket is missing a factor of δt .

where

$$N = \int dt \frac{dN}{dt} \quad (6)$$

is the expected number of triggers of both types in the total observation time T .

As discussed in Section 1, in our search we observe that R_0 remains approximately constant and that p_0 retains its shape over the observation time discussed here; this assumption is used in our search background estimation procedure (Abbott et al. 2016c). The astrophysical distribution of triggers is universal (Section 3) and also time-independent. Finally, the detector sensitivity is observed to be stable over our 16 days of coincident observations, so $V(t) \simeq \text{const}$ (Abbott et al. 2016b). We therefore choose to simply ignore the time dimension in our trigger set. This generates an estimate of the rate that is sub-optimal (i.e. has larger uncertainty) but consistent with using the full data set to the extent that the detector sensitivity varies in time; since this variation is small, the loss of information about the rate will be correspondingly small. We *do* capture any variation in the sensitivity with time in our Monte-Carlo procedure for estimating $\langle VT \rangle$ that is described in Section 2.2 of the Letter.

If we ignore the trigger time, then the appropriate likelihood to use is a marginalization of Eq. (5) over the t_j . Let

$$\begin{aligned} \bar{\mathcal{L}} &\equiv \int \left[\prod_j dt_j \right] \mathcal{L} \\ &= \prod_j [\Lambda_0 p_0(x_j) + \Lambda_1 p_1(x_j)] \exp[-\Lambda_0 - \Lambda_1], \end{aligned} \quad (7)$$

where

$$\Lambda_0 p_0(x) = \int dt R_0(t) p_0(x; t), \quad (8)$$

and

$$\Lambda_1 p_1(x) = \int dt R_1 V(t) p_1(x; t), \quad (9)$$

with

$$\int dx p_0(x) = \int dx p_1(x) = 1. \quad (10)$$

If we assume that R_1 is constant in (comoving) time, and measure $p_1(x)$ by accumulating recovered injections throughout the run as we have done, then this expression reduces to the likelihood in Eq. (3) of the Letter. A similar argument with an additional population of triggers produces Eq. (10) of the Letter.

2.1. The Expected Number of Background Triggers

The procedure for estimating $p_0(x)$ in the `pycbc` pipeline also provides an estimate of the mean number of background events per experiment Λ_0 (Abbott et al.

Figure 2. The two-dimensional posterior on terrestrial and astrophysical trigger expected counts (Λ_0 and Λ_1 in Eq. (5) of the Letter) for the `pycbc` search. Contours are drawn at the 10%, 20%, ..., 90%, and 99% credible levels. There is no meaningful correlation between the two variables. The Poisson uncertainty in the terrestrial count is $\sim \sqrt{270}$, or 16, which is also very nearly the Poisson uncertainty in the total count. Because this uncertainty is much larger than the astrophysical count, changes in the astrophysical count do not force the terrestrial count to adjust in a meaningful way and the variables are uncorrelated in the posterior.

2016c). The procedure for estimating p_0 used in the `gstlal` pipeline, however, does not naturally provide an estimate of Λ_0 ; instead `gstlal` estimates Λ_0 by fitting the observed number of triggers to a Poisson distribution. We have chosen to leave Λ_0 as a free parameter in our canonical analysis with a broad prior and infer it from the observed data, rather than using the `pycbc` background estimate to constrain the prior, which would result in a much narrower posterior on Λ_0 . This is equivalent to the `gstlal` procedure for Λ_0 estimation in the absence of signals; the presence of a small number of signals in our data here do not substantially change the Λ_0 estimate due to the overwhelming number of background triggers in the data set.

Using a broad prior on Λ_0 is *conservative* in the sense that it will broaden the posterior on Λ_1 from which we infer rates. However, because there are so many more triggers in both searches of terrestrial origin than astrophysical there is little correlation between Λ_0 and Λ_1 , and so there is little difference between the posterior we obtain on Λ_1 and the posterior we would have obtained had we implemented the tight prior on Λ_0 . Figure 2 shows the two-dimensional posterior we obtain from Eq. (5) of the Letter on Λ_0 and Λ_1 .

We have checked that using a δ -function prior

$$p(\Lambda_0) = \delta(\Lambda_0 - 270) \quad (11)$$

Figure 3. The posterior on the population-based rate obtained from our canonical analysis (blue) and an analysis where the expected background count, Λ_0 , is fixed to the value measured by the `pycbc` pipeline, $\Lambda_0 = 270$ (green). There is no meaningful change in the rate posterior between the two analyses.

in the `pycbc` analysis that is the result of the pipeline Λ_0 estimate from `timeslides`⁴ (Abbott et al. 2016c) and using a looser prior that is the result of a `gstlal` estimate on a single set of time-slid data produces no meaningful change in our results. Figure 3 shows our canonical rate posterior inferred with the `pycbc` Λ_0 prior in Eq. (11) and our canonical broad prior.

3. UNIVERSAL ASTROPHYSICAL TRIGGER DISTRIBUTION

Both the `pycbc` and `gstlal` pipelines rely on the SNR as part of their detection statistic, x . The SNR of an astrophysical trigger is a function of the detector noise at the time of detection and the parameters of the trigger. Schutz (2011) and Chen & Holz (2014) demonstrate that the distribution of the expected SNR $\langle \rho \rangle$ in a simple model of a detection pipeline that simply thresholds on SNR, $\rho \geq \rho_{\text{th}}$, with sources in the local universe is *universal*, that is, independent of the source properties. It follows

$$p(\langle \rho \rangle) = \frac{3\rho_{\text{th}}^3}{\langle \rho \rangle^4}. \quad (12)$$

This result follows from the fact that the expected value of the SNR in a matched-filter search for compact binary coalescence (CBC) signals scales inversely with trans-

verse comoving distance (Hogg 1999):

$$\langle \rho \rangle = \frac{A(m_1, m_2, \vec{a}_1, \vec{a}_2, S(f), z) B(\text{angles})}{D_M}, \quad (13)$$

where A is an amplitude factor that depends on the intrinsic properties (source-frame masses and spins) of the source, the detector sensitivity expressed as a noise power spectral density $S(f)$ as a function of observer frequency and redshift z , and B is an angular factor depending on the location of the source in the sky and the relative orientations of binary orbit and detector. The redshift enters A only through shifting the source waveform to lower frequency at higher redshift, changing A because the sensitivity varies with observer frequency f . For the redshifts to which we are sensitive to BBH in this observation period this effect on A is small.

If we assume that the distribution of source parameters is constant over the range of distances to which we are sensitive, and ignore the small redshift-dependent sensitivity correction mentioned above, then the distribution of SNR will be governed entirely by the distribution of distances of the sources, which, in the local universe is approximately

$$p(D_M) \propto D_M^2, \quad (14)$$

yielding the distribution of SNR given in Eq. (12).

Both the `pycbc` and `gstlal` pipelines use goodness-of-fit statistics in addition to SNR and employ a more complicated system of thresholds than this simple model, but the empirical distribution of detection statistics remains, to an approximation suitable for our purposes, independent of the source parameters. Figure 4 shows the distribution of recovered detection statistics for the various injection campaigns with varying source distribution used to estimate sensitive time-volumes in the `pycbc` pipeline. In each injection campaign $\mathcal{O}(1000)$ signals were recovered. For loud signals, the detection statistic is proportional to SNR in this pipeline, and the distribution is not sensitive to the complicated thresholding in the pipeline, so we recover Eq. (12); for quiet signals the interaction of various single-detector thresholds in the pipeline causes the distribution to deviate from this analytic approximation, but it remains independent of the distribution of sources. Note that the *empirical* distribution of detection statistics, not the analytic one, forms the basis for p_1 , the foreground distribution used in this rate estimation work.

To quantify the deviations from universality, we have performed two-sample Kolmogorov-Smirnov (KS) tests between all six pairings of the sets of detections statistics recovered in the injection campaigns described in Sections 2 and 3 of the Letter and featured in Figure 4. The most extreme KS p -value occurred with the comparison between the injection set with BBH masses drawn flat in

⁴ While the statistical uncertainty on the pipeline Λ_0 estimate is not precisely zero, $\sigma_{\Lambda_0}/\Lambda_0 \lesssim 10^{-3}$, it is so small that a δ -function prior is appropriate.

Figure 4. The distribution of detection statistics in the `pycbc` pipeline for the signals recovered in the injection campaigns used to estimate sensitive time-volumes for various BBH population assumptions (see Sections 2 and 3 of the Letter). The solid line gives the analytic approximation to the distribution from Eq. (12), which agrees well with the recovered statistics for loud signals; for quieter signals the interaction of various thresholds in the pipeline causes the distribution to deviate from the analytic approximation, but it remains independent of the source distribution.

$\log m$ and the one with masses drawn from a power law (both described in Section 3 of the Letter); this test gave a p -value of 0.013. Given that we have performed six identical comparisons we cannot reject the null hypothesis that the empirical distributions used for rate estimation from the `pycbc` pipeline are identical even at the relatively weak significance $\alpha = 0.05$. Certainly any differences in detection statistic distribution attributable to the BBH population are far too small to matter with the few astrophysical signals in our data set (compared with $\mathcal{O}(1000)$ recovered injections in each campaign).

Because the distribution of detection statistics is, to a very good approximation, *universal*, we cannot learn anything about the source population from the detection statistic alone; we must instead resort to parameter estimation (PE) followup (Veitch et al. 2015; Abbott et al. 2016e) of triggers to determine their parameters. The parameters of the waveform template that produced the trigger can be used to guess the parameters of the source that generated that trigger, but the bias and uncertainty in this estimate are very large compared to the PE estimate. We therefore ignore the parameters of the waveform template that generated the trigger in the assignment of triggers to BBH classes.

4. COUNT POSTERIOR

We impose a prior on the Λ parameters of:

$$p(\Lambda_1, \Lambda_0) \propto \frac{1}{\sqrt{\Lambda_1}} \frac{1}{\sqrt{\Lambda_0}}. \quad (15)$$

The posterior on expected counts is proportional to the product of the likelihood from Eq. (3) of the Letter and the prior from Eq. (15):

$$p(\Lambda_1, \Lambda_0 | \{x_j | j = 1, \dots, M\}) \propto \left\{ \prod_{j=1}^M [\Lambda_1 p_1(x_j) + \Lambda_0 p_0(x_j)] \right\} \times \exp[-\Lambda_1 - \Lambda_0] \frac{1}{\sqrt{\Lambda_1 \Lambda_0}}. \quad (16)$$

For estimation of the Poisson rate parameter in a simple Poisson model, the Jeffreys prior is $1/\sqrt{\Lambda}$. With this prior, the posterior mean on Λ is $N + 1/2$ for N observed counts. With a prior proportional to $1/\Lambda$ the mean is N for $N > 0$, but the posterior is improper when $N = 0$. For a flat prior, the mean is $N + 1$. Though the behaviour of the mean is not identical with our mixture model posterior, it is similar; because we find $\langle \Lambda_1 \rangle \gg 1/2$, the choice of prior among these three reasonable options has little influence on our results here.

For the `pycbc` data set we find the posterior median and 90% credible range $\Lambda_1 = 3.2_{-2.4}^{+4.9}$ above our threshold. For the `gstlal` set we find the posterior median and 90% credible range $\Lambda_1 = 4.8_{-3.8}^{+7.9}$. Though we have only one event (GW150914) at exceptionally high significance, and one other at marginal significance (LVT151012), the counting analysis shows these to be consistent with the possible presence of several more events of astrophysical origin at lower detection statistic in both pipelines.

The thresholds applied to the `pycbc` and `gstlal` triggers for this analysis are *not* equivalent to each other in terms of either SNR or false alarm rate; instead, both thresholds have been chosen so that the rate of triggers of terrestrial origin ($\Lambda_0 p_0$) dominates near threshold. Since the threshold is set at *different* values for each pipeline, we do not expect the counts to be the same between pipelines.

The estimated astrophysical and terrestrial trigger rate densities (Eq. (1) of the Letter) for `pycbc` are plotted in Figure 5. We select triggers from a subset of the search parameter space (i.e. our bank of template waveforms) that contains GW150914 as well as the mass range considered for possible alternative populations of BBH binaries in Section 3 of the Letter. There are $M' = 270$ two-detector coincident triggers in this range in the `pycbc` search (Abbott et al. 2016e). Figure 5 also shows an estimate of the density of triggers that comprise our data set which agrees well with our inference of the trigger rate.

Figure 5. The inferred number density of astrophysical (green), terrestrial (blue), and all (red) triggers as a function of x' for the `pycbc` search (cf. Eq. (1) of the Letter), using the models for each population described in Section 2.1 of the Letter. The solid lines give the posterior median and the shaded regions give the symmetric 90% credible interval from the posterior in Eq. (5) of the Letter. We also show a binned estimate of the trigger number density from the search (black); bars indicate the 68% confidence Poisson uncertainty on the number of triggers in the vertical-direction and bin width in the horizontal-direction.

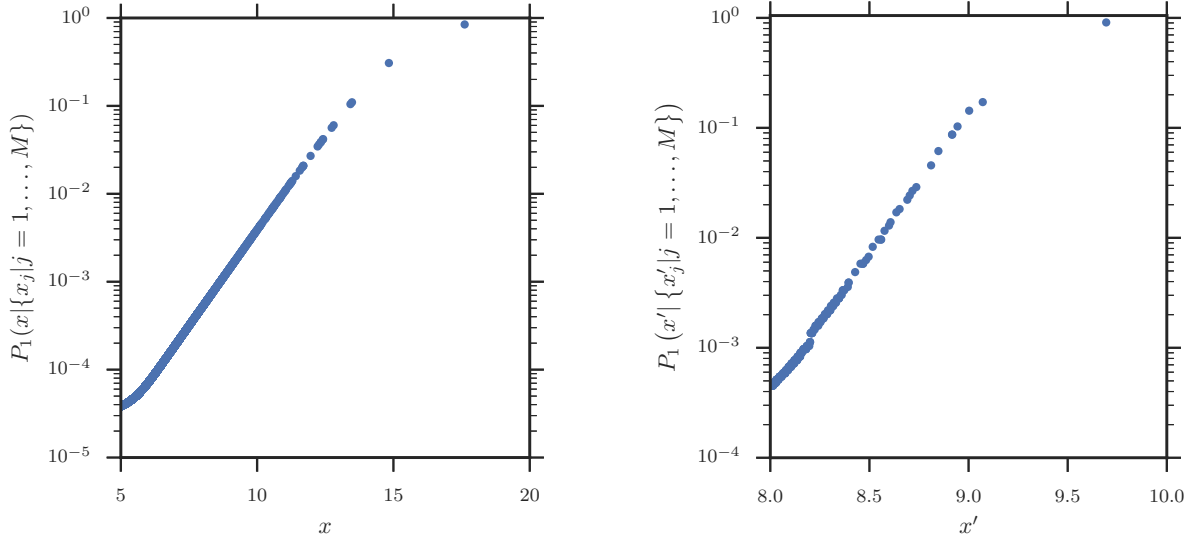

Figure 6. The posterior probability that coincident triggers in our analysis come from an astrophysical source (see Eq. (7) of the Letter), taking into account the astrophysical and terrestrial expected counts estimated in Section 2.1 of the Letter. Left: the `gstlal` triggers with $x > 5$; right: `pycbc` triggers with $x' > 8$. GW150914 is not shown in the plot because its probability of astrophysical origin is effectively 100%. The only two triggers with $P_1 \geq 50\%$ are GW150914 and LVT151012. For GW150914, we find $P_1 = 1$ to very high precision; for LVT151012, the `gstlal` pipeline finds $P_1 = 0.84$ and the `pycbc` pipeline finds $P_1 = 0.91$.

Based on the probability of astrophysical origin inferred for LVT151012 from the two-component mixture model in Eq. (16) and shown in Figure 6, we introduce a third class of signals and use a three-component mixture model with expected counts Λ_0 (terrestrial), Λ_1 (GW150914-like), and Λ_2 (LVT151012-like) to infer rates in Sections 2.1 of the Letter and 2.2 of the Letter.

We use the Stan and `emcee` Markov-Chain Monte

Carlo samplers (Foreman-Mackey et al. 2013; Stan Development Team 2015b,a) to draw samples from the posterior in Eq. (5) of the Letter for the two pipelines. We have assessed the convergence and mixing of our chains using empirical estimates of the autocorrelation length in each parameter (Sokal 1996), the Gelman-Rubin R convergence statistic (Gelman & Rubin 1992), and through visual inspection of chain plots. By all mea-

tures, the chains appear well-converged to the posterior distribution.

Table 1 contains the full results on expected counts and associated sensitive time-volumes for both pipelines.

Table 1. Expected counts and sensitive time-volumes to BBH mergers estimated under various assumptions. See Sections 2.1 of the Letter, 2.2 of the Letter, 3 of the Letter and 4.

	Λ		$\langle VT \rangle / \text{Gpc}^3 \text{ yr}$

Flat in log mass	$3.2^{+4.9}_{-2.4}$	$4.8^{+7.9}_{-3.8}$	$0.050^{+0.032}_{-0.019}$	$0.080^{+0.051}_{-0.031}$
Power Law (-2.35)			$0.0154^{+0.0098}_{-0.0060}$	$0.024^{+0.015}_{-0.009}$

5. CALIBRATION UNCERTAINTY

The LIGO detectors are subject to uncertainty in their calibration, in both the measured amplitude and phase of the gravitational-wave strain. Abbott et al. (2016b) discusses the methods used to calibrate the strain output of the detector during the 16 days of coincident observations discussed here. Abbott et al. (2016b) estimates that the reported strain is accurate to within 10% in amplitude and 10 degrees in phase between 20 Hz and 1 kHz throughout the observations.

The SNRs reported by our searches are quadratically sensitive to calibration errors because they are maximized over arrival time, waveform phase, and a template bank of waveforms (Allen 1996; Brown & LIGO Scientific Collaboration 2004). Abbott et al. (2016c) demonstrates that the other search pipeline outputs are also not affected to a significant degree by the calibration uncertainty present during our observing run. Therefore, we ignore effects of calibration on the pipeline detection statistics x and x' we use here to estimate rates from the pycbc and gstlal pipelines.

The amplitude calibration uncertainty in the detector results at leading order in a corresponding uncertainty between the luminosity distances of sources measured from real detector outputs (Abbott et al. 2016e) and the luminosity distances used to produce injected waveforms used to estimate sensitive time-volumes in this work. A 10% uncertainty in d_L at these redshifts corresponds to an approximately 30% uncertainty in volume. We model this uncertainty by treating $\langle VT \rangle$ as a parameter in our

analysis, and imposing a log-normal prior:

$$p(\log \langle VT \rangle) \propto N\left(\log \mu, \frac{\sigma}{\mu}\right), \quad (17)$$

where μ is the Monte-Carlo estimate of sensitive time-volume produced from the injection campaigns described in Section 2.2 of the Letter and

$$\sigma^2 = \sigma_{\text{cal}}^2 + \sigma_{\text{stat}}^2, \quad (18)$$

with $\sigma_{\text{cal}} = 0.3\mu$ and σ_{stat} is the estimate of the Monte-Carlo uncertainty from the finite number of recovered injections reported above. In all cases $\sigma_{\text{cal}} \gg \sigma_{\text{stat}}$.

Since the likelihood in Eqs. (3) of the Letter or (10) of the Letter does not constrain $\langle VT \rangle$ independently of R , sampling over $\langle VT \rangle$ at the same time as Λ and R has the effect of convolving the log-normal distribution of $\langle VT \rangle$ with the posterior on Λ in the inference of R . In spite of the 30% relative uncertainty in $\langle VT \rangle$ from calibration uncertainty, the counting uncertainty on R from the small number of detected events dominates the width of the posterior on R .

6. ANALYTIC SENSITIVITY ESTIMATE

As a rough check on our $\langle VT \rangle$ estimates and the integrand $d\langle VT \rangle/dz$, we find that the following approximate, analytic procedure also produces a good approximation to the pycbc Monte-Carlo estimate in Table 1.

1. Generate inspiral–merger–ringdown waveforms in a single detector at various redshifts from the source distribution $s(\theta)$ with random orientations and sky positions.

Figure 7. The rate at which sensitive time-volume accumulates with redshift. Curves labeled by component masses in M_{\odot} are computed using the approximate prescription described in Section 6, assuming sources with fixed masses in the comoving frame and without spin; the GW150914 and LVT151012 curves are determined from the Monte-Carlo injection campaign described in Section 2.2 of the Letter.

2. Using the high-sensitivity early Advanced LIGO noise power spectral density from [Abbott et al. \(2016f\)](#), compute the SNR in a single detector.
3. Consider a signal found if the SNR is greater than 8.

Employed with the source distributions described above, this approximate procedure yields $\langle VT \rangle_1 \simeq 0.107 \text{ Gpc}^3 \text{ yr}$ and $\langle VT \rangle_2 \simeq 0.0225 \text{ Gpc}^3 \text{ yr}$ for the sensitivity to the two classes of merging BBH system. Figure 7 shows the sensitive time-volume integrand,

$$\frac{d\langle VT \rangle}{dz} \equiv T \frac{1}{1+z} \frac{dV_c}{dz} \int d\theta s(\theta) f(z, \theta) \quad (19)$$

estimated from this procedure for systems with various parameters superimposed on the Monte-Carlo estimates from the injection campaign described above.

The authors gratefully acknowledge the support of the United States National Science Foundation (NSF) for the construction and operation of the LIGO Laboratory and Advanced LIGO as well as the Science and Technology Facilities Council (STFC) of the United Kingdom, the Max-Planck-Society (MPS), and the State of Niedersachsen/Germany for support of the construction of Advanced LIGO and construction and operation of the GEO600 detector. Additional support for Advanced LIGO was provided by the Australian Research Council. The authors gratefully acknowledge the Italian Istituto Nazionale di Fisica Nucleare (INFN), the French Centre National de la Recherche Scientifique (CNRS) and the Foundation for Fundamental Research on Matter supported by the Netherlands Organisation for Scientific Research, for the construction and operation of the Virgo detector and the creation and support of the EGO consortium. The authors also gratefully acknowledge research support from these agencies as well as by the Council of Scientific and Industrial Research of India, Department of Science and Technology, India, Science & Engineering Research Board (SERB), India, Ministry of Human Resource Development, India, the Spanish Ministerio de Economía y Competitividad, the Conselleria d’Economia i Competitivitat and Conselleria d’Educació, Cultura i Universitats of the Govern de les Illes Balears, the National Science Centre of Poland, the European Commission, the Royal Society, the Scottish Funding Council, the Scottish Universities Physics Alliance, the Hungarian Scientific Research Fund (OTKA), the Lyon Institute of Origins (LIO), the National Research Foundation of Korea, Industry Canada and the Province of Ontario through the Ministry of Economic Development and Innovation, the Natural Science and Engineering Research Council Canada, Canadian Institute for Advanced Research, the Brazilian Ministry of Science, Technology, and Innovation, Russian Foundation for Basic Research, the Leverhulme Trust, the Research Corporation, Ministry of Science and Technology (MOST), Taiwan and the Kavli Foundation. The authors gratefully acknowledge the support of the NSF, STFC, MPS, INFN, CNRS and the State of Niedersachsen/Germany for provision of computational resources. This article has been assigned the document number [LIGO-P1500217](#).
