### 37 Summary

38 The availability of global microbial diversity data, collected using standardized metabarcoding

techniques, makes microorganisms promising models for investigating the role of regional and

40 local factors in driving biodiversity.

41 We modelled the global diversity of symbiotic arbuscular mycorrhizal (AM) fungi using

42 currently available data on AM fungal molecular diversity (SSU-rRNA gene sequences) in field

43 samples. To differentiate between regional and local effects, we estimated species pools (sets of

44 potentially suitable taxa) for each site, which are expected to reflect regional processes. We then

45 calculated community completeness, an index showing the fraction of the species pool present,

46 which is expected to reflect local processes.

47 We found significant spatial variation, globally in species pool size, as well as in local and dark

48 diversity (absent members of the species pool). Species pool size was larger close to areas

49 containing tropical grasslands during the last glacial maximum, which are possible centres of

50 diversification. Community completeness was larger in regions of high wilderness (remoteness

from human disturbance). Local diversity was correlated with wilderness and current

52 connectivity to mountain grasslands.

53 Applying the species pool concept to symbiotic fungi facilitated a better understanding of how

54 biodiversity can be jointly shaped by large-scale historical processes and recent human

55 disturbance.

### 60 Introduction

61 Global diversity patterns have frequently been described for macroorganisms, including vascular

62 plants and vertebrates (Gaston, 2000, Orme *et al.*, 2005, Kreft & Jetz, 2007). Yet, understanding

63 the relative roles of different processes in shaping diversity patterns is an ongoing challenge

64 (Pärtel *et al.*, 2016). Local diversity patterns in any group of taxa are expected to emerge as a

65 consequence of simultaneous, and potentially confounding, effects of regional (evolutionary changes, historical dispersal) and local processes (dispersal in contemporary landscapes, local 66 biotic and abiotic filters, natural and anthropogenic disturbances; Huston, 1994; Ricklefs, 2004, 67 2007; Zobel, 2016). Distinguishing between regional and local processes requires diversity data 68 that are comparable and replicated over large spatial scales. Molecular identification of microbial 69 taxa from environmental samples might provide data that are much closer to meeting this 70 requirement than traditional sampling of macroorganisms. However, macroecology of microbes 71 is a recent field (Hanson et al., 2012; Wardle & Lindahl, 2014) and descriptions of global 72 diversity patterns and their potential underlying drivers are largely lacking. 73

Identifying species pools – sets of potentially available species that are able to inhabit and 74 reproduce under particular habitat conditions in given sites (Cornell & Harrison, 2014) – is a 75 76 useful starting point for distinguishing regional and local processes acting on diversity. Species pools develop via speciation under particular habitat conditions, as well as via historical 77 78 migrations between regions with similar conditions (Zobel 2016; Pärtel et al. 2016). Hence, one may expect that species pools are shaped mainly by regional factors. Species pools can be 79 partitioned into locally present and locally absent fractions; the latter has been referred to as dark 80 diversity (Pärtel et al., 2011). From these two pieces of information, community completeness – 81 82 an index characterizing the share of the species pool present at a given site (Pärtel *et al.*, 2013) – can be calculated as the log-transformed ratio of local and dark diversity. Community 83 84 completeness indicates how easily potentially suitable species reach and establish in local 85 communities, but also how well local populations persist. Hence it can be expected that 86 community completeness is mainly driven by local factors.

There is only limited empirical support for the theoretical expectations stemming from the 87 88 species pool concept (see Lessard *et al.*, 2012 and Zobel, 2016 for review). Empirical species pool studies have hitherto addressed vertebrates, insects and plants, but large scale 89 generalizations have been limited due to the multitude of methods and scales used to assess 90 diversity and the hugely variable depth of diversity data from different parts of the globe. 91 92 Consequently, local diversity estimates used in large-scale comparisons have often been derived from coarse grid-based distributions, or even from distribution range maps, and have therefore 93 lacked information about actual diversity in local communities. A more suitable approach to 94

disentangling the relative roles of regional and local factors in driving large-scale patterns of

- 96 biodiversity is to use local community data that are collected in a comparable manner throughout
- 97 an area of interest and take proper account of species pools.

The paucity of current data also poses challenges for dark diversity estimation (Pärtel et al., 98 99 2016). For well-studied organisms, expert opinion has been used to estimate dark diversity, either by linking species to habitat types or giving indicator scores along the main environmental 100 gradients (de Bello et al., 2016). Current developments in mathematical dark diversity methods 101 based on species co-occurrences or species distribution modelling provide a promising 102 103 alternative (Lewis et al., 2016; Ronk et al., 2016). These techniques assume that co-occurring taxa share similar ecological preferences and possibly also joint biogeographic history. Such an 104 assumption is probably valid for stable ecosystems but should be applied with caution to 105 106 successional ecosystems where many species are not in equilibrium with environmental

107 conditions.

108 Perhaps surprisingly, suitable data for exploring global biodiversity patterns and processes may

- already be available in the form of microbial community data. Microbial diversity estimates are
- frequently derived using fairly standardized metabarcoding approaches and thus seem to more
- easily satisfy criteria of comparability than existing macro-organism data sets (Taberlet *et al.*,
- 112 2012; Ficetola *et al.*, 2015). Although microbes had until recently received little attention in
- 113 macroecology (Wardle & Lindahl, 2014), new information is accumulating rapidly (e.g. Põlme et
- al. 2013; Tedersoo *et al.*, 2014; Pärtel *et al.*, 2017; Maestre *et al.*, 2015; Louca *et al.*, 2016),
- providing suitable data for dark diversity calculations using species co-occurrences without
- relying on empirical expert opinion about habitat preferences.
- 117 A potentially suitable target for studying regional and local effects on diversity are the
- 118 microscopic arbuscular mycorrhizal (AM) fungi (subphylum Glomeromycotina; Spatafora et al.,
- 119 2016). AM fungi live in symbiosis with the roots of about 80% of terrestrial plant species (Smith
- 120 & Read, 2008) and provide nutrients (mainly P and N) to their host plants in exchange for plant-
- assimilated carbon. AM fungi alleviate plant abiotic stress and are able to increase plant
- resistance to pathogens (Smith & Read, 2008; Pozo *et al.*, 2015). There is accumulating
- information about the geographic distribution of these fungi (Öpik et al., 2010, 2013; Kivlin et
- *al.*, 2011; Yang *et al.*, 2012; Tedersoo *et al.*, 2014). Most recently, Davison *et al.* (2015)

analysed AM fungal diversity in plant roots based on systematic sampling of 67 sites globally
and found little endemism at the continental scale. At the same time, the diversity of AM fungal
communities varied in relation to environmental variables (precipitation, soil organic C content
and pH), and spatial distance. The species pool concept promises a more powerful approach for
disentangling possible large- and small-scale factors determining AM fungal diversity, such as
proximity to centres of evolutionary diversification and the effect of contemporary human
influence.

- 132 AM fungi have several advantages as a model group for studying global diversity patterns and
- underlying processes. Standardised methodologies for delineating AM fungal taxa (Öpik *et al.*,
- 134 2014; Öpik & Davison, 2016) and processing environmental samples exist and are widely used
- 135 (Hart *et al.*, 2015). DNA-based species delimitation is challenging due to the scarcity of
- 136 sequences from morphologically described species (Öpik & Davison, 2016), so phylogenetically-
- delimited sequence groups (phylogroups) are often used (groupings of taxa based on 97%
- similarity of the target gene sequence; Öpik *et al.*, 2010, 2014). Furthermore, the global diversity
- 139 of such approximately species-level phylogroups of AM fungi is fairly low (< 2000 groups
- 140 globally; Öpik *et al.*, 2014; Öpik & Davison, 2016).

As well as addressing theoretical challenges concerning the roles of regional and local factors in 141 driving observed diversity patterns, the study of global AM fungal diversity can provide 142 additional specific information about the role of historical factors in shaping the global 143 144 distribution patterns of these fungi. While Beck et al. (2012) emphasized the significance of integrating past environmental conditions into macroecological analyses, little is known about 145 the effect of historical factors on global microbial diversity. Davison *et al.* (2015) recorded only 146 a minor effect of continental paleogeographic history on AM fungal community composition. 147 148 The more recent past, however, might have left an important imprint. For example, during the Quaternary period, glacial periods have been more common than warmer conditions, such as the 149 current interglacial, and biodiversity might be better described by conditions during the most 150 recent glaciation (e.g., the Last Glacial Maximum or LGM) than by contemporary factors 151 (Weigelt et al., 2016). Biomes associated with large species pools might indicate regions where 152 AM fungi have diversified. 153

154 Here, we use the framework of the species pool concept to study the effects of regional and local drivers on the diversity of AM fungal communities. We used the MaarjAM database (Öpik et al., 155 156 2010) to compile data from all available studies addressing AM fungal molecular (SSU rRNA gene sequence) diversity in environmental samples. The specific objectives of the study were: (1) 157 to quantify and map global patterns in the species pools, local diversity, dark diversity and 158 community completeness of AM fungi; and (2) to link these AM fungal diversity measures to 159 160 various regional and local drivers, including latitude, current and past (LGM) biome distribution, current and past climate, wilderness index (remoteness from human influence) and local 161 vegetation type. Our results show that species pools, local diversity and dark diversity exhibited 162 significant spatial structure at the global scale. Species pool and dark diversity were related to 163 regional factors (LGM biome configuration and climate), community completeness to local 164 factors (wilderness), and local diversity was jointly associated with regional and local factors 165 (wilderness and current biome configuration). 166

167

### 168 Materials and Methods

169

We used the MaarjAM database (cf. Öpik et al., 2010; updated in November 2016) as a source of 170 AM fungal distribution data. MaarjAM is a curated repository containing AM fungal sequence-171 based records from published studies, each including information about Virtual Taxa (VT) in a 172 specific geographical location. VT are SSU rRNA gene sequence-based approximately species-173 level phylogroups of AM fungi, which are phylogenetically delimited on the basis of sequence 174 similarity and clade support (Öpik et al., 2010, 2014). A record in the MaarjAM database 175 represents the presence of a VT in a plant species at a site in the case of individual plant root-176 based records, or the presence of a VT at a site in the case of soil samples or mixed-root samples. 177 The database includes records from both Sanger and 454 sequencing platforms and incorporates 178 179 2-3 representative sequences per VT per site or per plant species per site from each study (see Öpik et al., 2010 for details). The MaarjAM database currently contains c. 24 000 SSU rRNA 180 gene sequence records associated with c. 400 VT. We associated all records of VT to unique 181 geographical coordinates (sites). We also used information about vegetation type recorded for 182

183 each site: woodland vegetation (forest, woodland, shrubland) or grassland (both natural and184 semi-natural). Records from disturbed successional habitats were excluded.

185 For further analysis, we selected only sites that were associated with at least 20 records, since

very low numbers of records might not allow precise extrapolations of local diversity. This

resulted in a total of 128 sites and 361 VT (Fig. 1a, Table S1).

188 We calculated four related diversity measures: i) species pool size, ii) local diversity, iii) dark 189 diversity (the locally absent fraction of the species pool), and iv) community completeness (the 190 ratio of local and dark diversity). Natural logarithm transformation was used for all these measures to express relative differences. On a log scale, differences indicate how many times 191 192 diversity values differ, e.g. on a log scale the difference between 5 and 10 VT is equivalent to the 193 difference between 50 and 100 VT rather than the difference between 50 and 55 VT. It should be 194 noted that several of these diversity measures are inherently related (e.g. local and dark diversity are additive components of the species pool), and patterns from these measures are expected to 195 196 covary. At the same time, the pairs local - dark diversity, and species pool size - community completeness are mathematically independent (Pärtel et al. 2013). 197

In order to estimate species pool size (we use this term for the number of AM fungal VT in the 198 pool for simplicity), it is necessary to sum local diversity and dark diversity. Local diversity was 199 200 determined from observations at individual sites. The number of records per site ranged from 20 to 815 (mean 125). To account for differences in sampling intensity between sites, we used the 201 Shannon index-based effective number of species and extrapolation to an asymptote 202 implemented in the iNEXT software (Hsieh et al., 2016). The asymptotic diversity equates to 203 expected local diversity at full sample coverage sensu Hsieh et al. (2016). This technique made it 204 205 possible to maximise use of the information in the original data, which would have been lost with rarefying approaches whereby many observations are removed (Chao et al., 2016). 206 207 Supporting Information Figure S1 shows rarefaction and extrapolation curves for each site. On 208 average, extrapolated local diversity was 1.3 times larger than observed local diversity. The ratio 209 of extrapolated / observed local diversity was not related to sequencing platform and was not strongly spatially clustered (Fig S1b). 210

211 Dark diversity was estimated using species co-occurrence patterns (Lewis et al., 2016). This

approach defines taxa as belonging to dark diversity when they are absent from a site but

213 otherwise frequently co-occur with those species present at the site. Thus, species that are locally present are used as indicators for absent species: if there are frequent co-occurrences, it is 214 215 assumed that the species share similar ecological requirements. A co-occurrence index, also known as Beals index, was calculated for each VT in each site. Threshold values for assigning 216 VT to the dark diversity were determined on a VT-by-VT basis since the co-occurrence index 217 depends on species frequency (De Cáceres & Legendre, 2008). For each VT, we examined co-218 occurrence index values for all sites where it was present and recorded the minimum. Then, if the 219 VT was absent from a site, but its co-occurrence index exceeded the minimum observed in sites 220 where it was present, the VT was considered part of the dark diversity. See Lewis *et al.* (2016) 221 for methodological details and working examples. Community completeness was calculated as 222 the log-ratio of local and dark diversity (Pärtel *et al.*, 2013). Species pool size and community 223 completeness were calculated on the assumption that local and dark diversity estimates represent 224 distinct sets of taxa, i.e. without many overlapping taxa. 225

226

### 227 Geographical distribution

We predicted the global distribution of the four different diversity measures using Generalized 228 229 Additive Models (GAMs) and the spline-over-the-sphere algorithm in R package mgcv, with the method 'sos.smooth' and the default arguments except k=30 (Wood, 2003). This model can 230 predict smooth variation in diversity values over the globe without producing edges. For each 231 model, we recorded its estimated degrees of freedom (*edf*), F and P values, and amount of 232 variation described. We measured the predictive power of the model using cross-validation by 233 dividing locations into random 20% bins and estimating values for bins using the rest of the data 234 (Franklin, 2010). We then calculated the correlation between observed and predicted values. We 235 present only prediction maps when predicted values were significantly correlated with observed 236 values. As a measure of uncertainty in our predictions, we mapped the standard deviation of 100 237 238 global predictions using random subsets of 80% of sites.

239

#### 240 AM fungal diversity drivers

241 In order to relate diversity values to possible drivers, we obtained measures of the following

parameters for each site: (1) latitude, (2) current connectivity to biomes, (3) connectivity to

biomes during the LGM, (4) major bioclimatic variables describing current conditions and (5)

those during the LGM, (6) wilderness index (remoteness from human influence), and (7) local

245 vegetation type.

246 We measured latitude as distance from the equator (km). Although latitude is not a

247 biogeographic gradient *per se* and climate and biomes are expected to be more directly related to

- biodiversity, latitude has been often used in previous studies and we included it to permit
- 249 comparison.

250 We used the current biome vector map from Olson et al. (2001) and the LGM (ca 21,000 yrs 251 before present) biome vector map from Ray & Adams (2001). The current biome map defines 14 252 biomes, while the original LGM biome map defines 24 biomes. Therefore, we regrouped LGM biomes to match the current classifications (Supporting Information Table S2; Fig. 1b,c). To 253 254 calculate connectivity to biomes, we constructed a grid of points equally distributed across the globe by using centroids of the ISEA3H geodesic discrete global grid system (Sahr et al., 2003). 255 We used R package 'dggridR' to obtain 65,612 points. We determined biome identity for each 256 point and applied Hanski's connectivity index (Hanski, 1994; Moilanen & Nieminen, 2002): 257 Connectivity =  $\sum \exp(-d/a)$ ; where d is the distance from the site to all terrestrial points of a 258 biome. The parameter *a* defines the influence of distance in the exponential distribution and can 259 260 be seen as the average influence distance. We used a values 500, 1000 and 2000 km. To improve its distribution, connectivity was In-transformed for modelling. 261

For each site, we compiled 19 bioclimatic variables (Supporting Information Table S3) (Hijmans 262 263 et al., 2005) to describe both current conditions and the conditions predicted for the LGM according to the Community Climate System Model (Braconnot et al., 2007). The current 264 265 climate map had resolution of 5' and the LGM climate map had resolution of 10'. Precipitation 266 measures were In-transformed. We collapsed the 19 variables to 4 principal components using 267 correlation matrices. The four principal components described >90% of total variation. The first axis was strongly correlated with annual mean and winter temperature (r>0.9), the second axis 268 269 with precipitation during the dry period (r>0.9). The third axis was more related to precipitation 270 during the warm period (r>0.6), and the fourth axis to modern maximum temperature (r=0.5), or

diurnal temperature range during the LGM (r>0.6). See Supporting Information Table S3 for thefull correlation table.

273 Wilderness can be defined as a continuous index quantifying remoteness and the level of

disturbance by modern technological society (Carver & Fritz, 2016). This synthetic variable was

first elaborated for Australia (Lesslie & Taylor, 1985), but later applied globally by UNEP-

276 WCMC (<u>http://www.unep-wcmc.org/resources-and-data/global-wilderness</u>). Available data have

a resolution of ca 1.4', and for each site we calculated the mean index value for radiuses of 5, 10

and 20 km. It should be noted that we had already excluded disturbed sites, so high wilderness

index values were indicative of low human impact in the vicinity of sample sites.

We obtained information from original publications about local vegetation type for each site from the Maarj*AM* database and classified each site broadly as grassland (both natural and seminatural) or woodland (forest and shrublands). Unfortunately, information about other potential local drivers (e.g. geological and soil characteristics, host plants) was not available for all studied sites.

We used an information theoretical approach and compared models using Akaike Information 285 Criterion corrected for sample size (AICc, Burnham & Anderson, 2002). We first standardized 286 287 all our variables to have equal inputs of mean  $\pm 1$  standard deviation using the R package 'arm' (Gelman 2008). This allows direct comparisons between model coefficients of both continuous 288 and binary variables. Then we modelled each of the driver types separately. If there were several 289 variables available for a driver type (e.g. connectivity to different biomes, wilderness within 290 different radiuses, Supporting Information Tables S4, S5) we selected the variable for which the 291 model resulted in the lowest AICc values. For latitude, principal components of climate and 292 293 wilderness, we investigated both linear and quadratic relationships, since unimodal patterns are theoretically possible, and selected the model with the lower AICc value. For connectivity to 294 295 biomes, we only considered linear models where diversity was positively related to connectivity.

In a second step, we examined 29 models: (1) the full model with seven variables, (2) seven

univariate models, addressing each driver type in isolation, (3) and all pairwise variable

combinations to examine pairs of regional and local drivers in combination. Model assumptions

were verified by plotting residuals versus fitted values and each independent variable. We

300 calculated the importance of each driver as the sum of Akaike weights from models where the

driver was included. Then we took the top-ranked models ( $\Delta AICc < 4$ ) and used full model

averaging to identify the most important variables (Grueber *et al.*, 2011). Several of the

independent variables were correlated (e.g. latitude with climate and biomes, or past and current

304 climate; see Supporting Information Table S6 for a correlation matrix). Model averaging,

however, is relatively insensitive to such correlations (Freckleton, 2011). Details of the top-

ranked model are given in Supporting Information Table S7, of model averaging in Table S8,

and a summary of all initial models can be found in Table S9. The R package 'MuMIn' was used

- 308 for multi-model inference (Bartón, 2016).

312 *AM fungal local diversity, species pool size, community completeness and dark diversity* 

Average richness was estimated to 60 VT per site (Shannon effective number of taxa), with

values ranging between 6 and 216. Species pool size per site was on average 132 VT (range: 46

to 285) and dark diversity was on average 71 VT (range: 29 to 145). Relationships between local

or dark diversity and species pool size are shown in Fig. 2. As expected, AM fungal local

317 diversity co-varied with AM fungal species pool size but variation in dark diversity introduced

considerable variation into this relationship. Local and dark diversity were negatively correlated,

although not tightly (Fig. 2c). Average community completeness was slightly negative (-0.37),

showing that dark diversity estimates often exceeded local diversity at sites. Variation in

321 community completeness was, however, large (range: -2.7 to 1.3).

322

## 323 *Global distribution of AM fungal diversity measures*

AM fungal species pool size and local and dark diversity were non-randomly distributed across

the globe. Spatial GAM models accounted for 34% of the variation in AM fungal species pool

size (Fig. 1e; edf=14.1, F=1.6, P<0.0001), 12% of the variation in AM fungal local diversity

- 327 (Fig. 1f; *edf*=4.8, *F*=0.4, *P*=0.016), and 45% of the variation in AM fungal dark diversity (Fig.
- 1g; *edf*=20.8, *F*=2.5, *P*<0.001). Large AM fungal species pools were found in southeastern

329 Africa and eastern South America. Small species pools occurred at higher latitudes of the Northern Hemisphere, especially in North America. Higher local AM fungal diversity values 330 331 were found in southern South America and southern Africa. North America was characterized by low values. Higher AM fungal dark diversity was found close to the equator, in eastern North 332 America, eastern Australia and New Zealand. Low dark diversity was found in northeastern 333 Asia, western North America and southern South America. Cross-validation revealed moderate 334 correlation between actual and predicted values for the species pool size (r=0.41, P<0.001) and 335 dark diversity (r=0.39, P<0.001), while the correlation between actual and predicted local 336 diversity was indicative of lower predictive power (r=0.20, P=0.025). All predictions for North 337 America (and for New Zealand's dark diversity) were associated with high uncertainty 338 (Supporting Information Fig. S2). 339

The spatial GAM for AM fungal community completeness was non-significant (*edf*=5.5, *F*=0.4, *P*=0.052) and cross-validation showed that actual and predicted values of AM fungal community completeness were not significantly related (r=0.08, P=0.367). Thus, community completeness had no identifiable geographical pattern and is more likely linked to local factors. Therefore, we cannot present a prediction map and present instead a map showing observed values for AM fungal community completeness (Fig. 1h); sites with low and high completeness are frequently found in close proximity.

347

### 348 *Relationships with tested regional and local drivers*

349 According to driver importance and model averaging, AM fungal species pool size was best described by connectivity to Last Glacial Maximum (LGM) tropical grasslands and savannas 350 351 (Fig. 3a,b). No other driver had comparable importance or significance (Table S8). For AM fungal local diversity, wilderness around the sample site and current connectivity to mountain 352 353 grasslands had higher importance (Fig. 3c). Wilderness was significant in model averaging (Fig. 354 3d, Table S8), but current connectivity to mountain grasslands was not (P=0.184, but still significant in the univariate model, Table S8, coef.= 0.23, P=0.009). No clearly important driver 355 of AM fungal dark diversity emerged (Fig. 3e). In the averaged model, AM dark diversity was 356 significantly related to current temperature (PC1, Fig 3f, Table S8). Sites with higher annual or 357 winter temperatures exhibited significantly higher dark diversity estimates. 358

The degree of wilderness in the surrounding area was important in describing AM fungal community completeness (Fig. 3g) and in the averaged model the relationship was close to significant (P=0.08, Table S8). Wilderness significantly explained community completeness in the model where it was the sole explanatory variable (Fig 3h, Table S9). In bivariate plots, local diversity and community completeness formed triangular-shaped relationships with wilderness (Fig 3e,h): both high and low values of diversity or community completeness were recorded at low wilderness, while only high values were recorded at high wilderness.

366

## 367 Discussion

Here we show that application of the species pool concept to AM fungi can reveal previously 368 undescribed global biodiversity patterns and disentangle the effects of potential underlying 369 370 drivers. Our results support theoretical expectations that the species pool size is linked to 371 regional (and historical) factors, community completeness is linked to local (and contemporary) factors, and local diversity is a result of both. Using a global data set, we found that the species 372 pool, local diversity and dark diversity of AM fungi showed nonrandom global patterns, with 373 distinct regions of high and low magnitude. By contrast, community completeness did not show 374 375 significant global structure. AM fungal species pool size was larger in regions that were well connected to tropical grasslands during the Last Glacial Maximum (LGM) c. 21,000 y ago. 376 Community completeness was higher at sites with lower human impact in the vicinity (larger 377 wilderness). Local diversity was associated jointly with wilderness around the study site and 378 current connectivity to mountain grasslands. Dark diversity was higher (i.e. a greater number of 379 potentially suitable taxa were absent) in currently warm conditions. 380

381

### 382 Species pool size is related to historical biome distribution

The largest AM fungal species pools were identified in eastern and southern Africa and to a certain extent in eastern South America. These areas are dominated by tropical grasslands, which, together with sparse dry forests, form a distinct and diverse system called the tropical grassy biome (Parr *et al.*, 2014). We found that AM fungal species pool size was primarily associated with the connectivity to areas of tropical grasslands during the LGM (Ray & Adams, 2001). During the LGM, tropical grasslands covered ca 21 million km<sup>2</sup> (currently ca 20 million km<sup>2</sup>), of which 7 million km<sup>2</sup> have remained tropical grassland throughout the past 21000 years and constitute refugia. In fact, parts of the same areas have probably been covered by grasslands since the Miocene (Micheels, 2007). Given that glacial conditions have been more common than interglacials during the Quaternary (Weigelt *et al.*, 2016), biome distribution during the LGM is representative of the predominant environmental configuration through much of recent evolutionary time.

The phylogenetic analysis by Davison et al. (2015) suggested that the diversification of the 395 majority of current AM fungal VT occurred approximately within the period of 4-30 million 396 years ago, a timing that is corroborated by other molecular clock estimates for particular AM 397 fungal speciation events (reviewed by Öpik & Davison, 2016). This coincides with the 398 appearance and expansion of grasslands (Strömberg, 2011; Strömberg et al., 2013; Parr et al., 399 2014). High diversity of macroorganisms in particular habitats has often been associated with 400 401 high availability of that habitats area in space and through time (Mittelbach *et al.*, 2007). It is possible that developing grasslands created new and spatially (and temporally) very abundant (or 402 'voluminous', since roots occupy the three-dimensional space) habitat for AM fungi. Although 403 404 the relative area of grasslands in global vegetation has never been very high, these habitats may 405 be particularly relevant for AM fungi due to the high density and large total abundance of host plant roots. For instance, contemporary grasslands contribute about 68% of the global fine root 406 407 surface area and 78% of global fine root length (Jackson *et al.*, 1997). The difference between forests and grasslands is also evident at small scales: average live fine root length is 4.1 km/m<sup>2</sup> in 408 409 tropical evergreen forests but 60.4 km/m<sup>2</sup> in tropical grasslands (Jackson *et al.*, 1997). The appearance of this vast new grassland habitat may have led to higher diversification rates of AM 410 fungi due to spatial effects (e.g. isolation by distance in a complex three-dimensional habitat), 411

new niches due to the proliferation and spread of grassland plant species, or other mechanisms.

413

## 414 Local diversity is linked both to regional and local factors

In contrast to species pool size, local diversity was most strongly associated with wilderness
around study sites. Wilderness is a synthetic measure that is inversely related to human impact
(Carver & Fritz, 2016). It incorporates remoteness from modern human infrastructure such as

418 roads, buildings etc., and a lack of strong human influence such as high-input urban and agricultural areas. In this study, we *a priori* omitted sites that were heavily disturbed, but the 419 420 wilderness index was calculated within radiuses of 5-20 kilometers around study sites. Thus, our measure of wilderness probably reflected human influence on habitat patches neighbouring the 421 422 local sites under investigation. In this context, the results indicate that human influence can harm meta-community systems and cause loss of taxa in unaffected patches (Lekberg *et al.*, 2007). 423 424 Recent overviews show a significant decline in global wilderness (Watson et al., 2016), which may constitute a threat to local AM fungal diversity. Connectivity to current mountain grasslands 425 also had a positive effect on local diversity. The most plausible explanation for this is that it also 426 reflects relatively low human impact in mountainous areas (Sandel & Svenning, 2013). 427

428

### 429 *Higher dark diversity is recorded in warmer climates*

430 High dark diversity of AM fungi was found at lower latitudes: Central America, Sub-Saharan Africa, eastern Asia and eastern Australia. Modelling also identified current annual temperature 431 as the best predictor of dark diversity. Why a greater share of otherwise suitable taxa should be 432 absent in warm areas is not easy to explain, but indicates either more restricted dispersal or more 433 434 frequent local extinctions. The sites with high dark diversity were often (sub)tropical moist or dry forests, and dark diversity was higher in woodlands compared to grasslands (although this 435 model had low weight compared with the climate model). Woody vegetation in general hinders 436 wind dispersal of plants (Nathan et al., 2008) and the same might be true for AM fungi. Indeed, 437 forests exhibited higher spatial turnover of AM fungal communities compared to grasslands in a 438 recent global survey of AM fungal communities, and there was also a trend of decreasing forest 439 440 beta diversity along a latitudinal gradient (Davison *et al.*, 2015). It is conceivable that high spatial heterogeneity in (sub)tropical forests might explain why sampling sites towards the 441 equator lacked a larger number of suitable taxa and dark diversity was consequently higher. 442 443 However, to properly test this hypothesis we require further empirical studies of spatial structure 444 in AM fungal communities, in particular those inhabiting warmer biomes, such as tropical and subtropical habitats. 445

## 447 Community completeness as an indicator of local processes

Community completeness of AM fungi varied among study sites but did not exhibit geographic 448 structure. In contrast to species pool size and to a certain extent also to local diversity, variation 449 in community completeness is not expected to contain the footprint of biogeographic history; 450 451 rather it is expected to reflect local factors, such as barriers to dispersal, biotic interactions, or disturbances (Pärtel et al., 2013; Ronk et al., 2015). In our models the best descriptor of AM 452 fungal community completeness was the degree of wilderness around study sites: completeness 453 was high when wilderness was high nearby. Indeed, an adverse impact of intensive land use on 454 AM fungi has been noted in earlier studies (Lopez-Garcia et al., 2013; Moora et al., 2014). 455 However, further specific case studies are needed to disentangle the types of interaction and 456 disturbance that might be responsible for low completeness of AM fungal communities in 457 particular sites. There is evidence that AM fungal taxa with specific traits (ruderal, measured as 458 459 ease of sporulation) are more common in anthropogenic habitats (Ohsowski et al., 2014), 460 possibly caused by differences in tolerance to anthropogenic disturbance (Hart & Reader, 2004; Säle et al. 2015). Alternatively, low wilderness may have a cascading effect through loss of 461 functioning meta-communities within highly human-modified areas. 462

463

# 464 *Methodological assumptions and potential limitations*

465 Our findings rest on several methodological assumptions. To identify AM fungi we used phylogroups, in the form of 18S rRNA gene-defined VT, and not traditional taxonomically-466 467 defined species. VT are known to merge closely related morphospecies in some, but not all lineages of AM fungi, and across most of the Glomeromycotina phylogeny there is limited 468 469 information about species boundaries with which to assess the exact taxonomic rank of VT (Öpik et al. 2014; Thiéry et al. 2016). Nonetheless, the rank of VT has been shown to capture 470 471 ecologically-relevant responses to environmental gradients (Powell et al. 2011), suggesting that 472 VT-based estimates of local diversity are meaningful even if precise species boundaries are 473 unknown. For dark diversity estimates obtained using co-occurrence techniques, we assume that VT have similar ecological properties in distant parts of the globe. We are unaware of published 474 evidence with which to assess this assumption. However, we excluded all successional sites 475 where taxa might not be in equilibrium with their environment. We also assume that our local 476

477 and dark diversity measures can be used in parallel. Theoretically, our estimates of extrapolated local and dark diversity might include taxa present at sites but not recorded. In this case, the 478 479 species pool size would be overestimated and community completeness would be underestimated. However, we do not expect over- or underestimation to be large. Present but 480 481 unrecorded species are likely to occur at low abundance, and such species would contribute relatively little to local diversity estimates since the Shannon index counts taxa in proportion to 482 483 their abundance (Chao et al., 2016). However, we excluded sites for which we expected the sampling effort to be seriously limited. Furthermore, rare taxa often have too few co-occurrences 484 to be included in dark diversity calculations (Ronk *et al.*, 2016). Using observed rather than 485 extrapolated diversity decreased average species pools from 132 to 112 and increased average 486 community completeness from -0.76 to -0.37. Observed and extrapolated estimates of the species 487 pool size and community completeness were strongly correlated (r=0.89, r=0.97, respectively). 488 We anticipate that the accumulation of highly standardised local sampling data using high-489 throughput methods will further avoid uncertainty related to sampling adequacy and estimation 490 of local and dark diversity. 491

492

### 493 Conclusions

Community theory predicts that regional drivers are primarily responsible for shaping species 494 pool size, local drivers shape community completeness, and local diversity contains the footprint 495 of both regional and local drivers (Pärtel et al., 2013; Cornell & Harrison, 2014; Zobel, 2016). 496 Nevertheless, comprehensive empirical support for these predictions has been scarce. This study 497 of global diversity patterns in AM fungi provides one of the first large-scale, empirical 498 499 confirmations of the theory. Furthermore, this study found that the historical distribution of biomes during the LGM was the most important tested regional driver, whereas the degree of 500 501 wilderness in the vicinity of a study site constituted the most important tested local driver of AM 502 fungal diversity patterns.

Tropical grasslands and savannas harbored the largest species pool of AM fungal species and may thus represent evolutionary hotspots and important refugia. Remoteness from human influence was associated with higher local diversity and greater completeness of AM fungal communities. This is a warning signal that anthropogenic factors have shaped and will continue to shape AM fungal communities to a significant extent. Although human impact on microbial
communities has been reported elsewhere, our study provides the first evidence of potential
global impacts.

510

511

### 512 Acknowledgements

513 We thank the New Phytologist Trust for funding the 16<sup>th</sup> New Phytologist Workshop on "Dark 514 diversity of co-occurring arbuscular mycorrhizal fungi and host plants", held in Tartu, Estonia in

January 2016. This paper is an outcome of that workshop. We are grateful to Ingolf Kühn,

516 Thomas D. Bruns, Jason Pither and two anonymous referees who provided valuable comments

517 on earlier versions of this work. This research has been supported by the Estonian Ministry of

Education and Research (IUT20-28, IUT20-29), and by the European Union through the

519 European Regional Development Fund (Centre of Excellence EcolChange). MCR acknowledges

support from the German Federal Ministry of Education and Research (BMBF) within the

521 Collaborative Project "Bridging in Biodiversity Science (BIBS)" (01LC1501A). TH

acknowledges support from NERC standard research grant NE/M004864/1. YL is grateful to

523 MPG Ranch for funding.

### 524 Author Contribution

525 All authors discussed the topic during the 16<sup>th</sup> New Phytologist Workshop and following e-mail

526 exchanges. MÖ coordinated the workshop and the collaboration network. MP performed

analyses. MZ coordinated writing of the paper. All authors discussed results and contributed towriting.

718 Figure legends:

- Fig.1. (a) Sampling locations of AM fungal communities from the MaarjAM database. We
- excluded sites where the number of recorded sequences was <20. Locations are slightly jittered
- to show overlapping points. (b, c) Current (Olson et al., 2001) and Last Glacial Maximum
- 722 (LGM, ca 21000 yrs before present; Ray & Adams, 2001) distribution of biomes: 1: Tropical &
- 723 Subtropical Moist Broadleaf Forests; 2: Tropical & Subtropical Dry Broadleaf Forests; 3:
- 724 Tropical & Subtropical Coniferous Forests; 4: Temperate Broadleaf & Mixed Forests; 5:
- 725 Temperate Conifer Forests; 6: Boreal Forests/Taiga; 7: Tropical & Subtropical Grasslands,
- 726 Savannas & Shrublands; 8: Temperate Grasslands, Savannas & Shrublands; 9: Flooded
- 727 Grasslands & Savannas; 10: Montane Grasslands & Shrublands; 11: Tundra; 12: Mediterranean
- Forests, Woodlands & Scrub; 13: Deserts & Xeric Shrublands; 14: Mangroves; 15: Not
- vegetated. (d) Wilderness (the degree to which a place is remote from and undisturbed by the
- influences of modern technological society; UNEP-WCMC). (e, f, g) Global smoothed maps of
- AM fungal species pool size (GAM,  $R^2 = 0.34$ ), local diversity ( $R^2 = 0.12$ ) and dark diversity ( $R^2$
- = 0.45). (h) Distribution of AM fungal community completeness across study sites. A smoothed
- prediction of is not presented because the predictive power of the corresponding model was low.
- 734 Locations are slightly jittered to distinguish immediately neighbouring points. Colours indicate
- 735 quantiles (e h).

Fig. 2. Relationships between AM fungal local (a, c), dark diversity (b, c), and species pool size 736 737 (a, b) at 128 sites worldwide. Local diversity was estimated as the asymptotic Shannon indexbased effective number of taxa using coverage-based rarefaction and extrapolation from site 738 records. Dark diversity was estimated based on VT co-occurrences globally (absent VT which 739 generally co-occur with locally present VT and therefore likely fit local ecological conditions). 740 741 AM fungal species pool (the theoretical set of VT that can inhabit a study site) is calculated by summing AM fungal local and dark diversity. Lines indicate the 1:1 relationship, i.e. the upper 742 limit that local or dark diversity can have. Semi-transparent symbols are used to show 743 overlapping values. The two outliers with large species pools originate from tropical rainforest in 744 French Guiana, and temperate beech forest in Georgia. Local and dark diversity are negatively 745 correlated (c, Spearman r = -0.45, P<0.001). Local vegetation type is shown (grasslands or 746 747 woodlands).

- 748 Fig.3. Importance of potential drivers (sum of Akaike weights in models where the driver was
- included) determining AM fungal species pool size, local and dark diversity, and community 749
- 750 completeness (a, c, e, g). Details on the best supported models are presented in Table S7. Scatter
- plots show relationships with the most significant drivers from model averaging (Table S8). 751
- 752 Species pool size is related to the connectivity of LGM tropical grasslands (b, bivariate
- relationship: R2=0.17, P=<0.001), local diversity is related to wilderness in the vicinity (d, 753
- 754 R2=0.08, P=0.002), dark diversity is related to current temperature (f, R2=0.14, P<0.001),
- community completeness is related to wilderness in the vicinity (h, R2=0.07, P=0.004). Species 755
- pool size, local and dark diversity are ln-transformed, completeness is the logratio of local vs. 756
- a. . and ch dark diversity. Connectivity, wilderness and climate PC1 have relative values without units. 757

- 759 Table S1. Summary of data used in analyses. Geographical coordinates, local vegetation type, number of
- 760 records (representative sequences from a sampling unit), number of Virtual Taxa (VT), primers and
- 761 sequencing platform used, and sources.

Fig. S1. (a) Shannon index based effective number of species for sites with varying numbers of records
(number of representative sequences from a sampling unit in a site). Red lines show rarefaction and
blue lines extrapolations. We used estimated local diversity extrapolated to the asymptote, i.e. full

- sample coverage *sensu* Hsieh *et al.* (2016). (b) Increase due to extrapolation (extrapolated / observed
- 768 local diversity) and sequencing platform within study sites. Locations are slightly jittered to show
- overlapping points.
- Table S2. Homogenization of biome classifications between current and Last Glacial Maximum (LGM)
- 771 maps.

ID	Current	LGM
1	Tropical & Subtropical Moist Broadleaf Forests	Tropical rainforest
2	Tropical & Subtropical Dry Broadleaf Forests	Tropical woodland Monsoon or dry forest Tropical thorn scrub and scrub woodland
3	Tropical & Subtropical Coniferous Forests	Montane tropical forest
4	Temperate Broadleaf & Mixed Forests	Broadleaved temperate evergreen forest
5	Temperate Conifer Forests	
6	Boreal Forests/Taiga	Open boreal woodlands Main Taiga
7	Tropical & Subtropical Grasslands, Savannas & Shrublands	Tropical grassland Savanna
8	Temperate Grasslands, Savannas & Shrublands	Temperate steppe grassland Forest steppe Dry steppe
9	Flooded Grasslands & Savannas	
10	Montane Grasslands & Shrublands	Alpine tundra Montane Mosaic Subalpine parkland
11	Tundra	Tundra Steppe-tundra Polar and alpine desert
12	Mediterranean Forests, Woodlands & Scrub	Semi-arid temperate woodland or scrub
13	Deserts & Xeric Shrublands	Tropical semi-desert Tropical extreme desert Temperate desert Temperate semi-desert
14	Mangroves	
15	Not vegetated	Not vegetated

Table S3. Correlation matrix of Bioclimatic PCA from current and Last Glacial Maximum predictions

(LGM). Very high correlations r>0.9 are indicated by coloured backgrounds.

7	7	8	

779	Table S4. Correlation between connec	tivity of biomes usi	ing different distan	ces of influence (500, 1000

- and 2000 km). We show only connectivity of biomes that had high importance: cur.10 current
- 781 mountain grasslands and shrublands, Igm.7 Last Glacial Maximum tropical grasslands and savannas.
- 782 [Uploaded as a separate file]

784

- Table S5. Correlation between wilderness measures using different radiuses (5, 10 and 20 km) around
  study sites.
- 787 [Uploaded as a separate file]

- 789 Table S6. Correlations between independent variables used in models: absolute latitude (abs.lat),
- connectivity to current and Last Glacial Maximum (LGM) biomes (cur# and lgm#, respectively: see
- 791 numerical codes of biomes in Fig 1 or Table S1), four current and LGM climate principal components
- 792 (PC#, PC#lgm, see Table S2 for numerical codes), wilderness and local vegetation type (grassland vs.
- woodland). For connectivity of biomes we included only the mean distance of influence 1000 km; other
- 794 distances were highly correlated (see Table S4). For Wilderness we included here only radius of 10 km;
- 795 other radiuses gave highly correlated values (see Table S5).
- 796 [Uploaded as a separate file]
- 797
- 798

- Table S7. Top-ranked models (delta AICc < 4). All variables were standardized with 2 sd values.
- 800 Polynomial fits are indicted by "+". See model averaging and details about variables in Table S8.

# Table S8. Averaged models (full average) from top-ranked models (delta AICc<4, see Table S7). All

variables were standardized with 2 sd values. Variables with P<0.1 are marked by bold font.

805

806

- Table S9. Details all models tested. Four dependent diversity measures (AM fungal species pool size,
- 810 local diversity, dark diversity, and community completeness) are related to seven driver types: absolute
- 811 latitude, connectivity to current and LGM biomes (see biome numbers from Tables S1, three distance of
- 812 influence are used, 500 km, 1000 km and 2000 km, models with coefficient >0 are given since the
- 813 negative connectivity has no biological meaning here), current and LGM climate (four principal
- components, PC1...PC4), wilderness index (mean value in radiuses 5 km 10 km and 20 km) and local
- 815 vegetation type (grassland vs. woodland). For latitude, climate and wilderness both linear and
- 816 polynomial models have been considered. Coefficients are comparable since all variables were
- 817 standardized with 2 sd.

819

820	Fig. S2. Uncertainty maps	or predictions of AN	I fungal species pool size	, local and dark diversity. Global
-----	---------------------------	----------------------	----------------------------	------------------------------------

- 821 predictions were made using random 80% subsets of the full data. This was repeated 100 times and
- 822 uncertainty was calculated as the standard deviation of estimates derived from the different iterations.
