CORRESPONDING AUTHOR: Janet Franklin, Department of Botany and Plant Sciences, University of California – Riverside, 900 University Ave, Riverside CA 92521. Telephone: 951-827-7020; Email: janet.franklin@ucr.edu

KEYWORDS: Biogeography, Biogeographic legacies, Forest classification, Forest functional similarity, Pan-tropical, Phylogenetic community distance.

Knowledge about the biogeographic affinities of the world's tropical forests helps to better understand regional differences in forest structure, diversity, composition and dynamics. Such understanding will enable anticipation of region specific responses to global environmental change. Modern phylogenies, in combination with broad coverage of species inventory data, now allow for global biogeographic analyses that take species evolutionary distance into account. Here we present the first classification of the world's tropical forests based on their phylogenetic similarity. We identify five principal floristic regions and their floristic relationships: (1) Indo-Pacific, (2) Subtropical, (3) African, (4) American, and (5) Dry forests. Our results do not support the traditional Neo- versus Palaeo-tropical forest division, but instead separate the combined American and African forests from their Indo-Pacific counterparts. We also find indications for the existence of a global dry forest region, with representatives in America, Africa, Madagascar and India. Additionally, a northern hemisphere Subtropical forest region was identified with representatives in Asia and America, providing support for a link between Asian and American northern hemisphere forests.

Significance

Identifying and explaining regional differences in tropical forest dynamics, structure, diversity and composition is critical for anticipating region specific responses to global environmental change. Floristic classifications are of fundamental importance for these efforts. Here we provide the first global tropical forest classification that is explicitly based on community evolutionary similarity, resulting in the identification of five major tropical forest regions and their relationships: (1) Indo-Pacific, (2) Subtropical, (3) African, (4) American, and (5) Dry forests. African and American forests are grouped, reflecting their former western Gondwanan

connection, while Indo-Pacific forests range from eastern Africa and Madagascar to Australia and Pacific. The connection between northern hemisphere Asian and American forests is confirmed, while dry forests are identified as a single tropical biome.

\body

The biogeographic origin of species, in combination with dispersal limitation and environmental filtering, are the principal determinants of spatial variation in the species composition of tropical forests (1, 2). Despite evidence of long-distance dispersal (1, 3, 4, 5), tropical forests maintain conspicuous regional differences in species composition. For example, only ~4% of tropical tree species are shared among Africa, America and Asia (6). The lack of species overlap between continents makes global inference of relationships among tropical forests problematic because such classifications depend on comparison of amount of shared species. Therefore, pan-tropical biogeographic analyses have been based on comparison of compositional patterns at higher taxonomic levels, i.e. genus or family (6, 7, 8). However, such analyses treat taxa as independent units, while in reality taxa vary in their degree of phylogenetic relatedness and as a consequence their morphological and ecological similarity (1, 2). Taking phylogenetic relatedness in consideration enhances our ability to delimit phytogeographical boundaries that characterize functional and biogeographic affinities among forest regions (1, 2, 9, 10). Here we include phylogenetic relationships in a floristic analysis to provide such insight.

We compiled a standardized dataset of old-growth tropical forest inventories of angiosperm trees (trunk diameter ≥ 10 cm) for 406 1° latitude/longitude grid cells (hereafter referred to as locations) originally dominated by natural forests across the (sub-)tropics (**Table S1**). These locations represented all major tropical forest regions and had broad environmental amplitude, including low to high elevations and dry to wet forests (**Fig. 1, Fig. S1**). To determine

the phylogenetic distance between locations we constructed a dated phylogenetic tree that was resolved to genus level and contained all taxa used for our classification analyses (**File S1**). Location pair-wise phylogenetic distance matrices were constructed using 20 randomly drawn tree taxa per location. We used 20 taxa as this maximized the number of locations that could be included in the classification analyses while still providing a reliable classification result. In total, we generated 20 phylogenetic distance matrices, each with a different set of 20 randomly drawn taxa per location, which served as input for 20 cluster analyses (**Fig. S2**). The final classification of each location depended on the frequency with which it was classified in a particular cluster across all 20 cluster analyses (**Fig. S3**). Relationships between the clusters were represented by a majority rule consensus tree (**Fig. 1**).

Results & Discussion

Mean pairwise phylogenetic distance analysis, which emphasizes ancient lineages in phylogenetic community comparisons, detected almost no spatial patterns in community phylogenetic similarity across the tropics, indicating that all tropical forest locations consist of more or less the same set of ancient plant lineages. This is in accordance with recent findings that the whole present day tropics are dominated by similar high levels of Late-Cretaceous aged phylogenetic lineages (11). Only when we used mean nearest taxon distance, which emphasizes recent lineages in phylogenetic community comparisons, did we detect clear spatial patterns across the tropics. Therefore, current day biogeographic patterns in the tropics seem to mainly reflect Cenozoic speciation events when Gondwanan breakup was already well on its way.

Using the mean nearest taxon distance, our phylogenetic cluster analyses showed that the world's tropical forests are divided into two major floristic regions: a combined American-African versus Indo-Pacific region (**Fig. 1**). This division contradicts previous hypotheses about

major global realms, which either recognized Neo- versus Palaeo-tropical regions or several separate continental regions (4, 12, 13, 14). However, Gentry (7) already noted the high generic level similarity of tropical American and African forests. He attributed this to Cretaceous and Cenozoic plate tectonic history (4, 15). Subsequent studies have shown that despite the severing of direct land connections between the African and South American plates ca. 96 Mya, long distance dispersal continued throughout the Late Cretaceous and Early Tertiary across the widening Atlantic Ocean (4, 5). The combined effect of shared origin with trans-Atlantic migration may explain the detected connection between South American and African forests.

Within the American-African cluster, the first split separated the African from the American regions (**Fig. 1**), suggestive of the west Gondwanan breakup associated with the formation of the Atlantic Ocean and the, over time, increasing difficulty for plants to disperse across the Atlantic (1, 15). Interestingly, the African region showed the highest consistency in clustering of all five identified floristic regions. On average, locations belonging to the African region were assigned to this cluster in 91.4% of cases, versus consistency values of 79.5%, 63.7%, 79.5% and 70.3% for the Indo-Pacific, Subtropical, American and Dry forest regions, respectively. This clustering consistency indicates high floristic similarity across tropical Africa, which is in accord with the relatively low beta diversity observed for these forests (6).

Postulated repeated cycles of contraction and expansion of the tropical African forests from a few small forest refugia in combination with large scale species shifts during the Pleistocene glaciations may explain the relatively high compositional homogeneity of the forests within the African region (16, 17).

The tropical American forests were further divided into moist and dry forests (**Fig. 1; Fig S1**), indicating that this division is primarily environmental (18). The American floristic region

comprises humid forests, including the lowland forests of Central America, the Amazon basin, the Guianas, and the northern half of the Atlantic Forest. The Dry forest region encompasses the Caatinga and Cerrado regions as well as other dry forests throughout the Americas, but interestingly, and contrary to the non-phylogenetic pan-tropical analysis by Dexter et al. (8), also includes dry forests of Africa, Madagascar and India. Further research is needed to confirm whether this indicates the existence of a global dry forest region with a shared biogeographic origin, or whether selection for drought- and fire-resistance has favored the dominance of similar plant lineages in tropical dry forests around the world (8, 18, 19).

The Indo-Pacific floristic region occupies the humid areas of Eastern Africa, Madagascar, India, Southeast Asia, Australia and the Pacific islands (**Fig. 1**). With the exception of SE Asia which is of Laurasian origin, this floristic region combines all areas that once comprised eastern Gondwana (4, 15). Given the diverse geologic history of Asia and the Indo-Pacific (20), it is surprising to find a similar forest type covering most of the region. Nevertheless, there is strong evidence of significant plant migration within this region that likely had a homogenizing effect, notably the biotic exchange between India and Southeast Asia starting from ca. 45 Mya (21), and between Southeast Asia and Australia, New Guinea and the Pacific islands that commenced ca. 15 Mya (4). Presence of Indo-Pacific forests in eastern continental Africa may either reflect eastern Gondwanan origin, or dispersal within the Indo-Pacific region.

We also identified a group of locations in Asia and America that occupies cooler climates and higher elevations relative to the other identified forest clusters (**Fig 1; Fig. S1**), and which we therefore termed Subtropical region. This Subtropical floristic region confirms the floristic link between Asia and North America, reflecting a shared Boreotropical affinity (22). Within Asia, the Subtropical region is mostly restricted to the subtropics, with the exception of high elevation

forests of Java. In the Americas, by contrast, this floristic region extends from the subtropics deep into the tropics, probably because the cooler montane climate of the Central American highlands and South American Andes has facilitated the southward migration of cold-adapted plant lineages. The absence of continuous, North-South oriented mountain chains in Asia may have limited the dispersal of such lineages into lower latitudes.

Conclusion

We provide the first phylogenetic distance based biogeographic classification of the world's tropical forests, using the most extensive sampling scheme for the tropics currently in existence. Our results uncover novel floristic patterns which will help in the development of region specific models for forest structure, diversity and dynamics as well as possible responses of tropical forest regions to global environmental change. Our results may necessitate reconsideration of established biogeographic ideas. For example, Madagascar and New Guinea have often been considered two separate major tropical regions, ecologically and biogeographically distinct from tropical America, Africa and Southeast Asia (23, 24). However, despite their highly endemic species compositions, we show that they are both part of the widespread Indo-Pacific floristic region. Finally, our analysis can serve as a model for classifying regional floras.

Materials & Methods

Tree inventory data set

Individual angiosperm trees (diameter at breast height ≥ 10 cm) from old-growth forest inventories throughout the (sub-)tropics (between -35°S and 35°N latitudes) were pooled within their respective one degree latitude/longitude grid cells (henceforth called locations). These locations represented all major tropical forest regions and had broad environmental amplitude,

including low to high elevations and dry to wet forests (**Fig. S1**). Monocots and Cactaceae were excluded because these were not consistently surveyed in all data sets. This dataset originally included 439 locations, containing 925,009 individual trees belonging to 15,012 taxa. Species names were standardized using 'The Plant List' (www.theplantlist.org), 'Taxonomic Name Resolution Service' (trns.iplantcollaborative.org/TNRSapp.html) and 'The Asian Plant Synonym Lookup' (phylodiversity.net/fslk/synonym_lookup.htm). On average, 1.4% of individual stems per location remained unidentified. These unidentified individuals were excluded from further analyses.

Community phylogenetic tree

The APG-III classification (25) served as the family-level backbone of our community phylogenetic tree. Recent updates in APG-IV (26) are mostly of nomenclatural nature and did not affect our analyses. This tree was further resolved up to genus level using the species level phylogeny (32,223 species included) published by Zanne et al. (27), which covered most genera in our dataset (**File S1**). Genera present in our dataset, but not in Zanne et al. (27), were placed at the base of their respective families. Genera that had disjunct species occurrences in the phylogeny of Zanne et al. (27) were placed at the most basal node connecting the disjunct species. This phylogeny was subsequently dated using the BLADJ function in PHYLOCOM v4.2 (28), using taxon ages given in Magallon et al. (29) for the age file.

Phylogenetic distance analysis

Phylogenetic distance between all pairs of locations was calculated using the options COMDIST and COMDISTNT in PHYLOCOM v4.2 (28). COMDIST uses the mean pairwise phylogenetic distance (MPPD); for each taxon in a location, it finds the average phylogenetic distance to all taxa in the other location, and calculates the mean. COMDISTNT uses the mean nearest taxon

distance (MNTD); for each taxon in location 1, it finds the nearest phylogenetic neighbor in location 2, records this and calculates the mean. Both functions return a symmetrical matrix of locations versus locations with their pairwise phylogenetic distances. Principal Coordinate (PCO) analyses (in Multi Variate Statistical Package v3.13, Kovach Computing Services) on resulting location versus location matrices showed that the MPPD matrices had almost no explanatory power (generally the first five PCO axes explained less than 5% of data variance), meaning that detected patterns were mostly random. The MNTD matrices, however, explained considerable amounts of data variance in the first five axes of the PCO. Therefore, we used only MNTD for further analysis.

Correcting for taxon richness bias in MNTD

Taxon richness differed considerably between locations, varying between 4 and 1466. MNTD may be sensitive to such differences in taxon richness because the chance of finding a close relative between two locations may increase when their taxon richness increases. Applying MNTD to determine phylogenetic distance between locations with differing taxon numbers could therefore result in taxon-rich locations being grouped together in the cluster analysis simply because they are more taxon-rich. To determine the impact of this effect, we created five 'location by taxon' matrices, each with a lower number of taxa per location (320, 160, 80, 40, and 20 taxa per location, respectively), using the 41 locations containing more than 320 taxa. For each location, taxa were ranked according to abundance, so that the 'location by taxon' matrix based on, for example, 320 taxa consisted only of the 320 most abundant taxa per location. Where tied abundances exceeded the predefined number of taxa, we randomly selected the appropriate number of taxa from among those with tied minimum abundance. We then calculated the MNTD matrices for each of these five 'location by taxon' matrices and found

that with increasing taxon richness of locations, MNTD (as averaged over all locations) decreased with increasing taxon richness per location following a power function ($y = 310.4x^{-0.194}$ [Fig. S4]), demonstrating that MNTD is indeed sensitive to taxon richness.

Determining the optimal number of taxa per location for further analysis

To avoid taxon richness bias when using MNTD, locations had to be compared based on similar numbers of taxa. Minimum variance clustering, based on the five 'location by taxon' matrices described earlier, consistently recovered the same major clusters in the same configuration (African and American locations clustered on one main branch and Asian locations clustered on the other), although the relationships between locations within these main clusters could vary (Fig. S5). Only in the 20 taxon analysis, was one American location (location no. 165 from the Brazilian Atlantic Forest) placed in the Asian cluster. The amount of variance captured in the first five axes of a Principal Coordinate (PCO) analysis (using the same MNTD distance matrices) declined by only ~20%, from 83.3% to 60.7%, between the 320 and 20 taxa analysis, respectively. We decided to use 20 taxa per location in the final analyses (Table S1) because of this limited loss of information in the PCO and similarity of cluster results. In addition, we were able to use most of our locations (406 of the initial 439), including locations on remote islands and extreme habitats that would have been excluded if we had set the minimum number of taxa too high.

Forest classification analyses

For the final analyses we produced 20 location by taxon data sets. In these data sets, each location was represented by 20 randomly drawn taxa (from that location). Random draws were irrespective of taxon abundance as abundance is a spatially and temporally labile taxon trait that likely reflects contemporary environmental conditions rather than historical biogeographic

signal. For each of these 20 location by taxon data sets we calculated the corresponding symmetrical location by location matrices with their pairwise phylogenetic distances (MNTD). These matrices were then used as input for cluster analyses.

Locations were grouped in clusters using the Ward's minimum variance method (30), using Multi Variate Statistical Package v. 3.13. This is a centroid-based clustering technique that identifies cluster centers (centroids) by minimizing the overall squared distances of the objects (in this case locations) to the centroids at each cluster level. This clustering technique identified spatially clearly defined location groupings (**Fig. S2**). The optimal number of clusters for defining floristic regions across the tropics was determined by calculating the cophenetic correlation coefficient at each cluster level, starting at the first split (K2) in the dendrogram. The cophenetic correlation coefficient calculates the correlation between the distance of the clusters as calculated by the clustering algorithm and the distance based on observed MNTD values between clusters. The higher the cophenetic correlation, the better the cluster result reflects the patterns present in the original distance matrix. We applied this method to each of our 20 data sets, calculated the average cophenetic correlation coefficient for each cluster level, and found a steep increase in cophenetic correlation up to K5, after which it slowly declined (**Fig. S6**). Therefore we chose K5 as the optimum level for defining our main floristic regions across the tropics.

For each location, at cluster level K5, we determined the cluster in which it was classified for each of the 20 cluster analyses that we performed. The location was then assigned to the cluster in which it had the highest proportion of observations. A 'Single Proportion Test' (31), which calculates the probability of an observed (sample) proportion (in the range 0-1) against a hypothetical proportion, was then used to determine if the observed proportions were

significantly higher than expected by random (Paleontological Statistics [PAST] v3.08). For example, for K5, the expected random proportion of locations per cluster is 0.2. For a sample size of 20, a proportion has to be at least 0.38 to be significantly higher ($p < 0.05$) than the random expectation. The resulting classification success rates of locations for K5 are shown in **Figure S3 and Table S1**. The final classification (K5) of the clusters was based on the majority consensus rule (**Fig. 1**).

FIGURE LEGENDS

Figure 1. Classification maps of the world's tropical forests, showing from two (a) to five (d) clusters. Cluster result represents a majority rule consensus tree, with percentage of times that each grouping was observed in the 20 separate cluster analyses shown in (d). Only locations that could be classified with certainty ($p < 0.05$) are shown ($n = 392$).

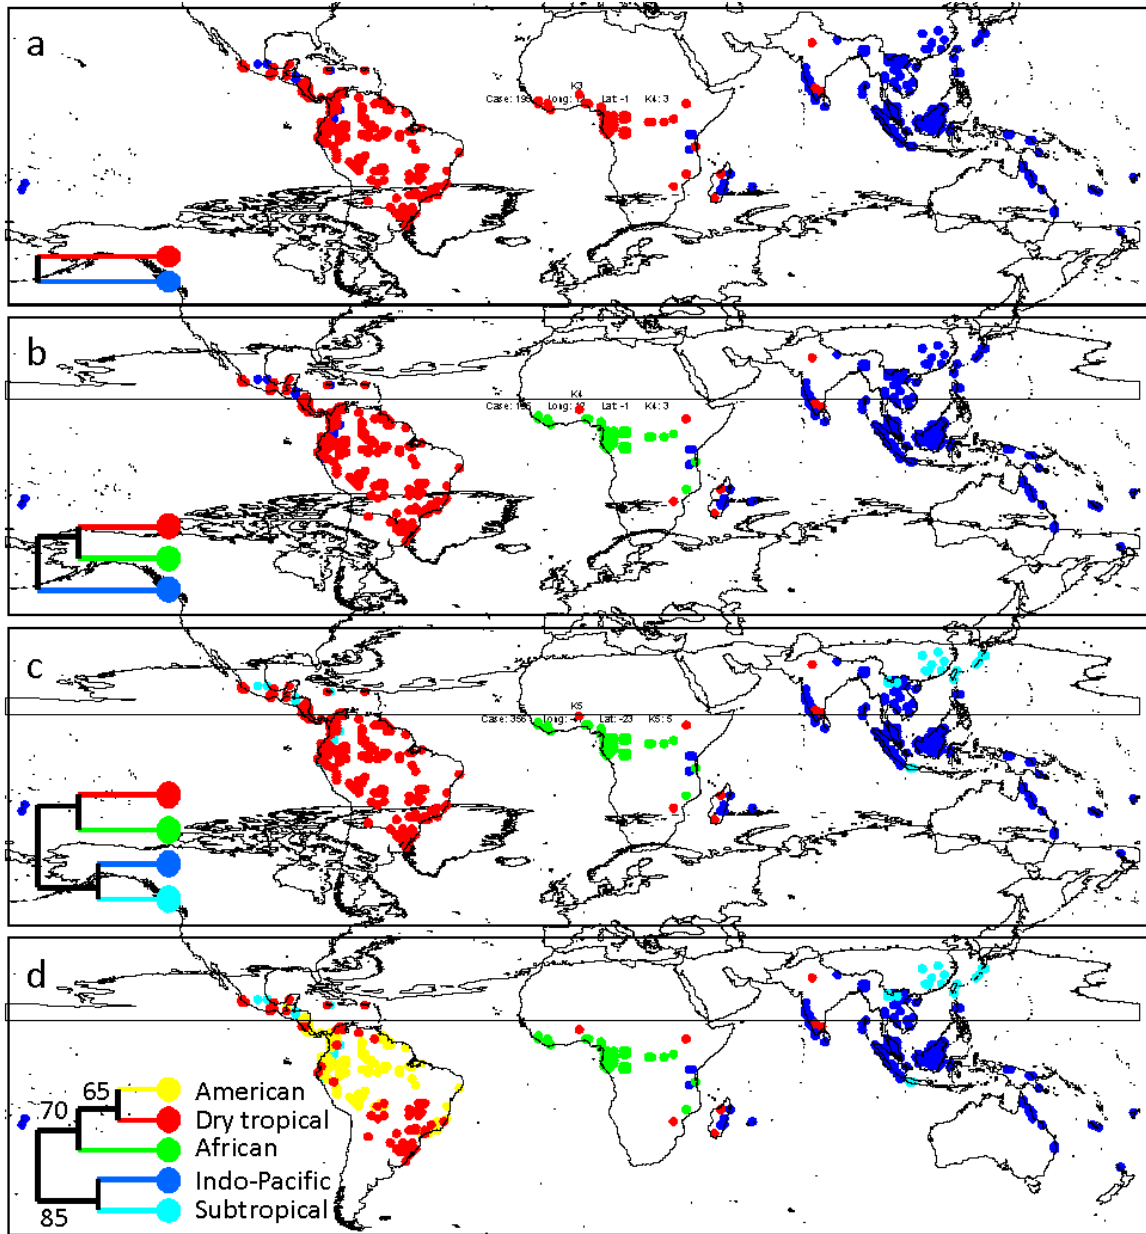

Figure 1

SUPPLEMENTARY INFORMATION

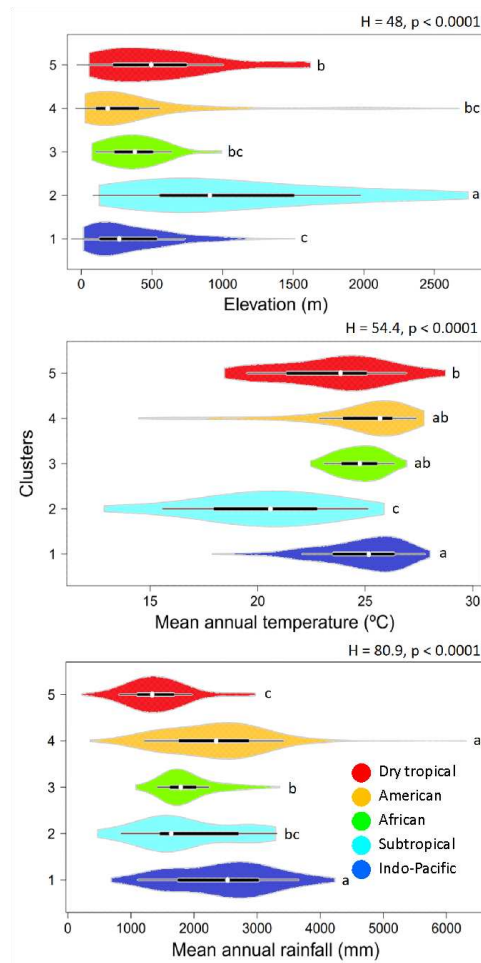

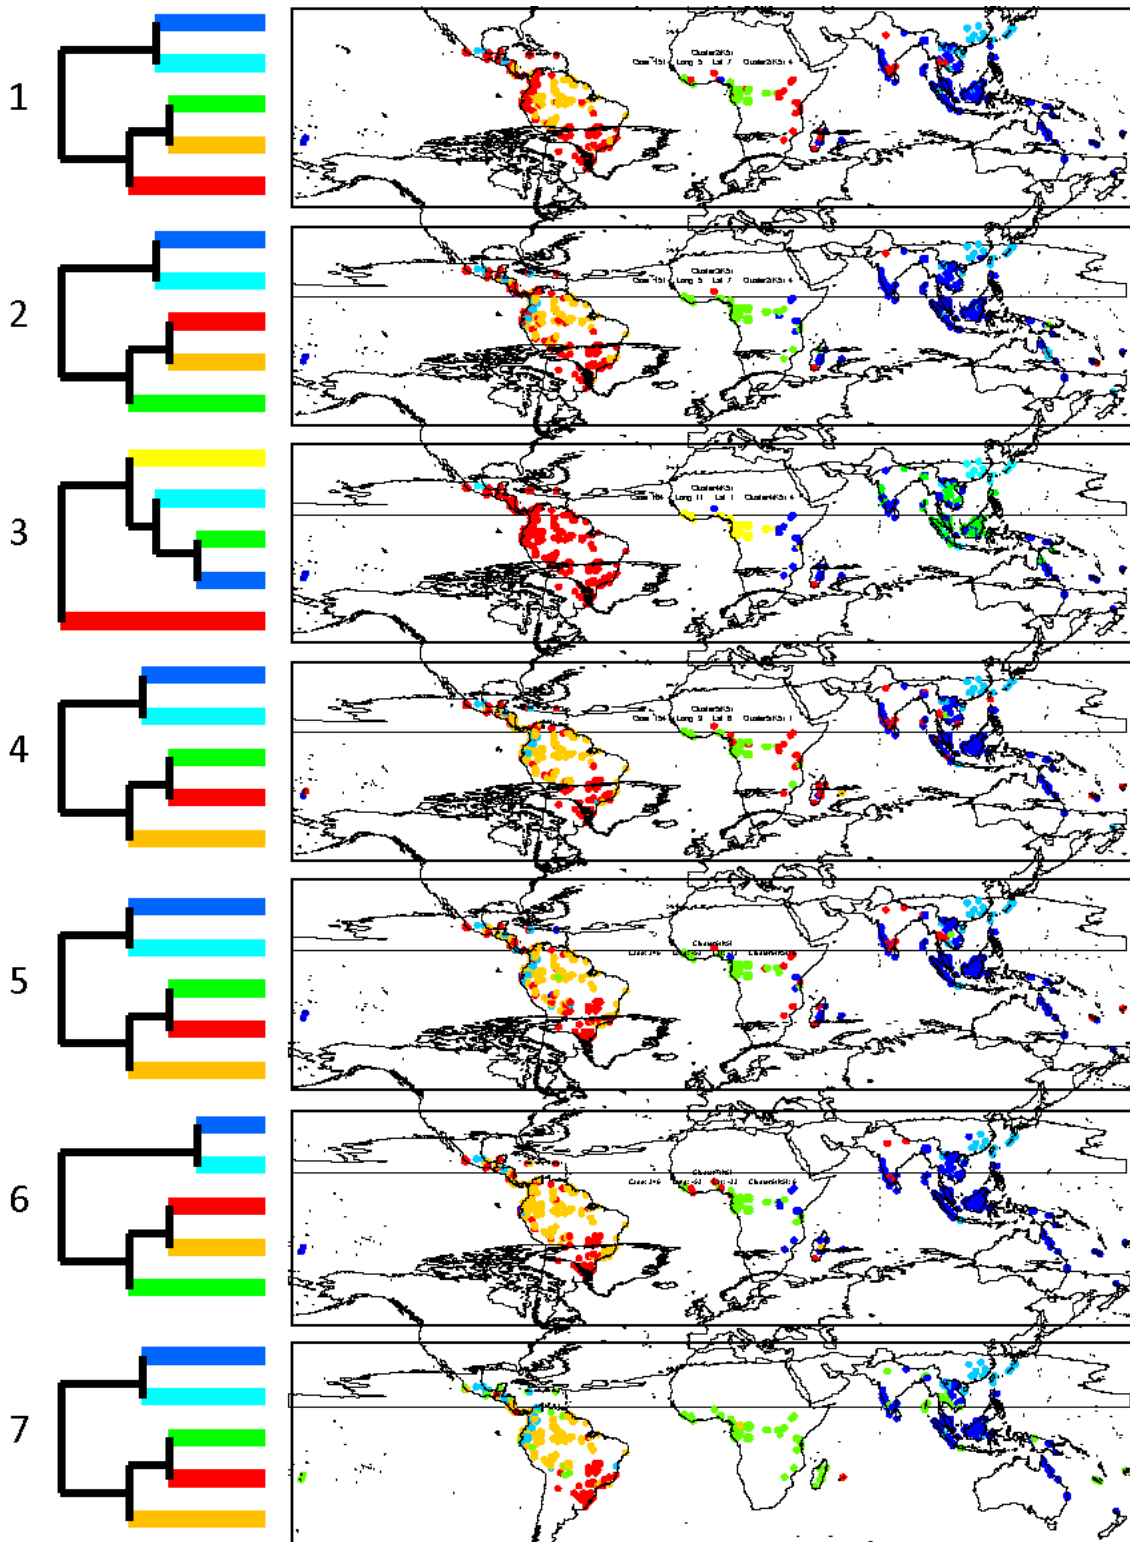

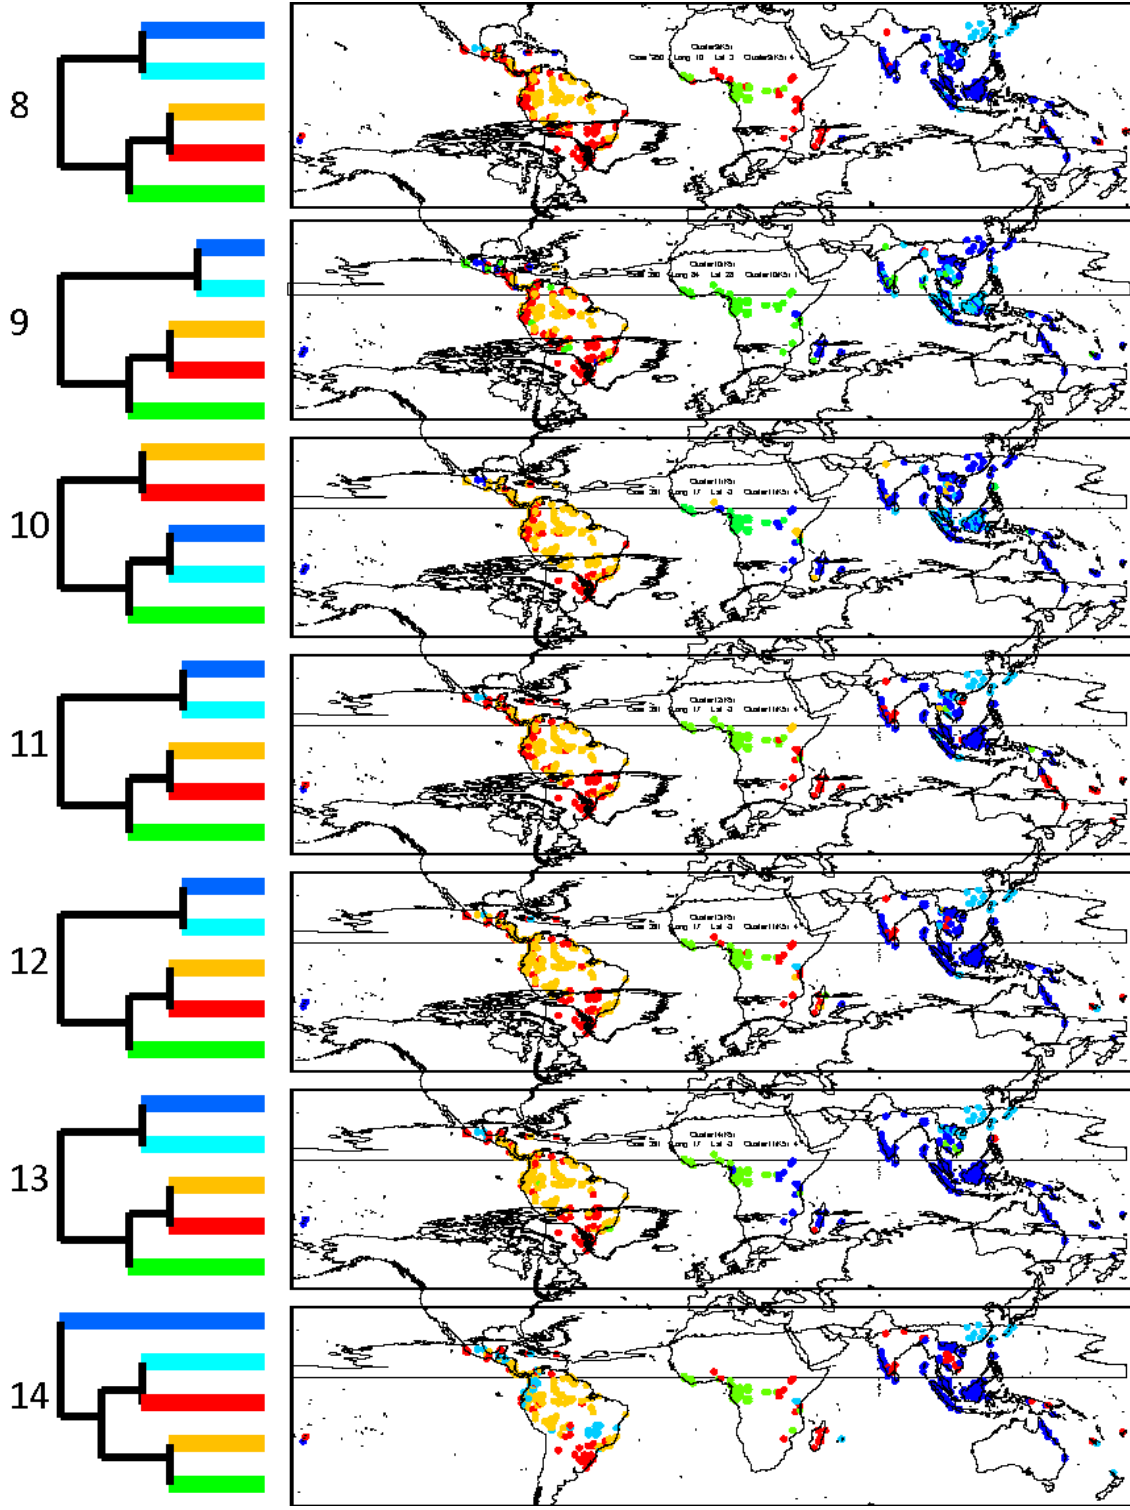

Figure S1. Elevation and climatic variables (temperature and rainfall) of each of the five floristic clusters. Each violin plot indicates the probability density of the data at different values, the median (white dots), 1st and 3rd quartiles (black thick lines) and range. Climate data were taken from WorldClim (32). Overall differences between clusters were tested with Kruskal-Wallis (H) test. The differences between pairs of clusters were assessed with Mann-Whitney tests with Bonferroni corrected p values (indicated with different letters in each plot). Sample sizes: Indo-Pacific 138; Subtropical 34; African 46; American 105; Dry forest 69.

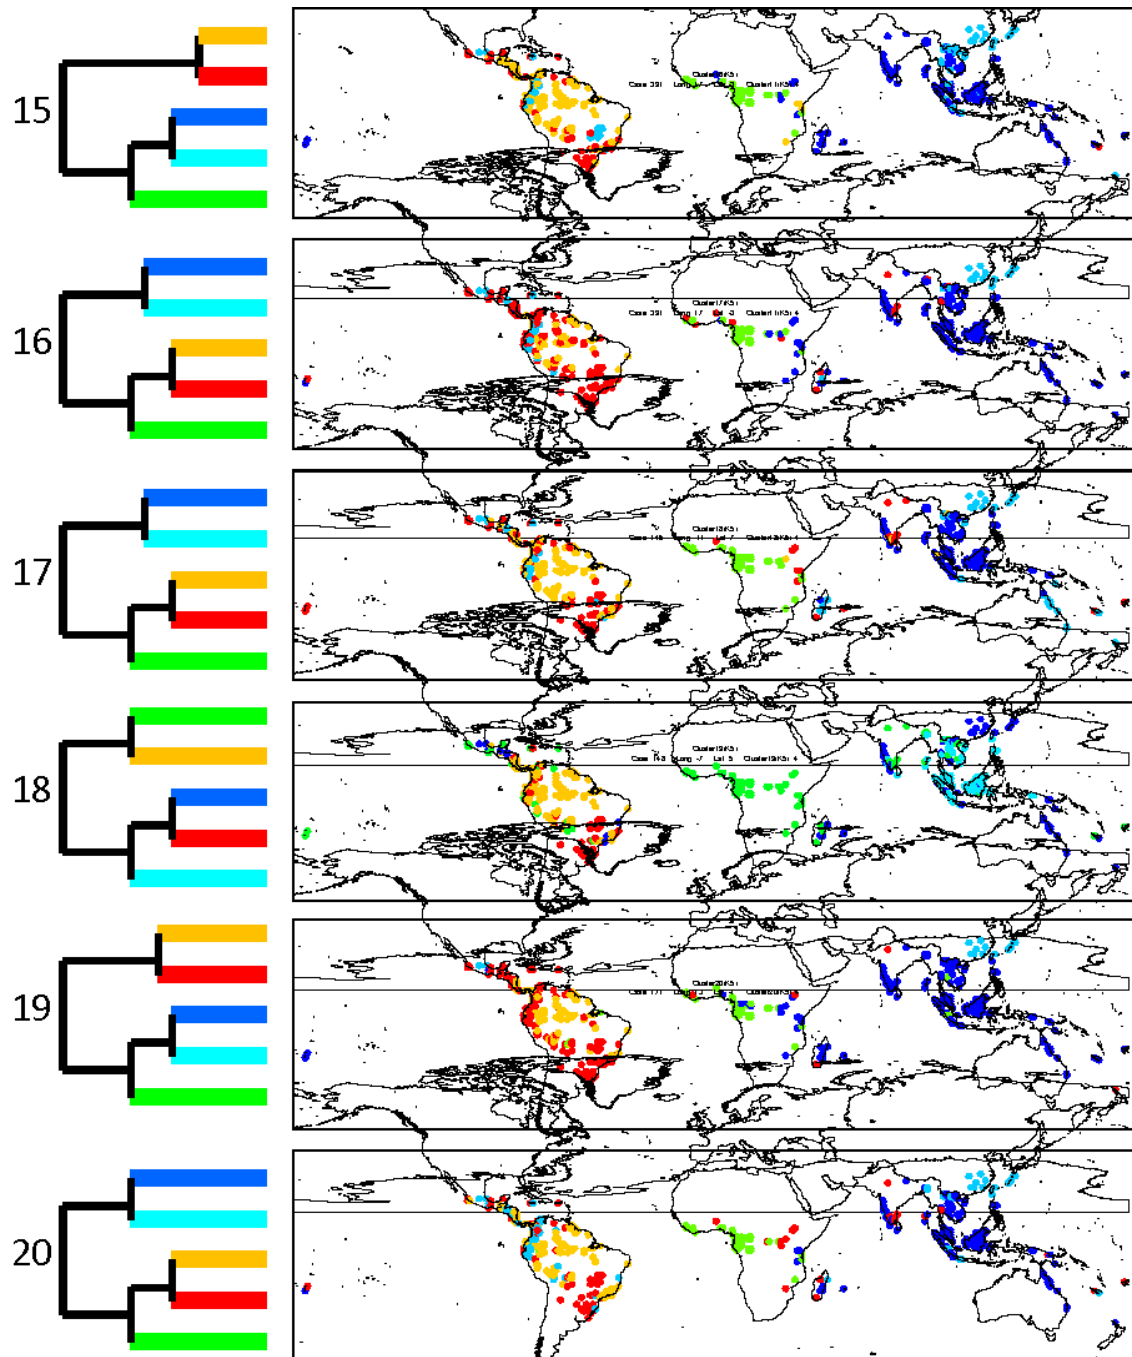

Figure S2. Clustering results for the 20 datasets based on Mean Nearest Taxon Distance. Each data set is based on a random draw of 20 taxa for each location ($n = 406$).

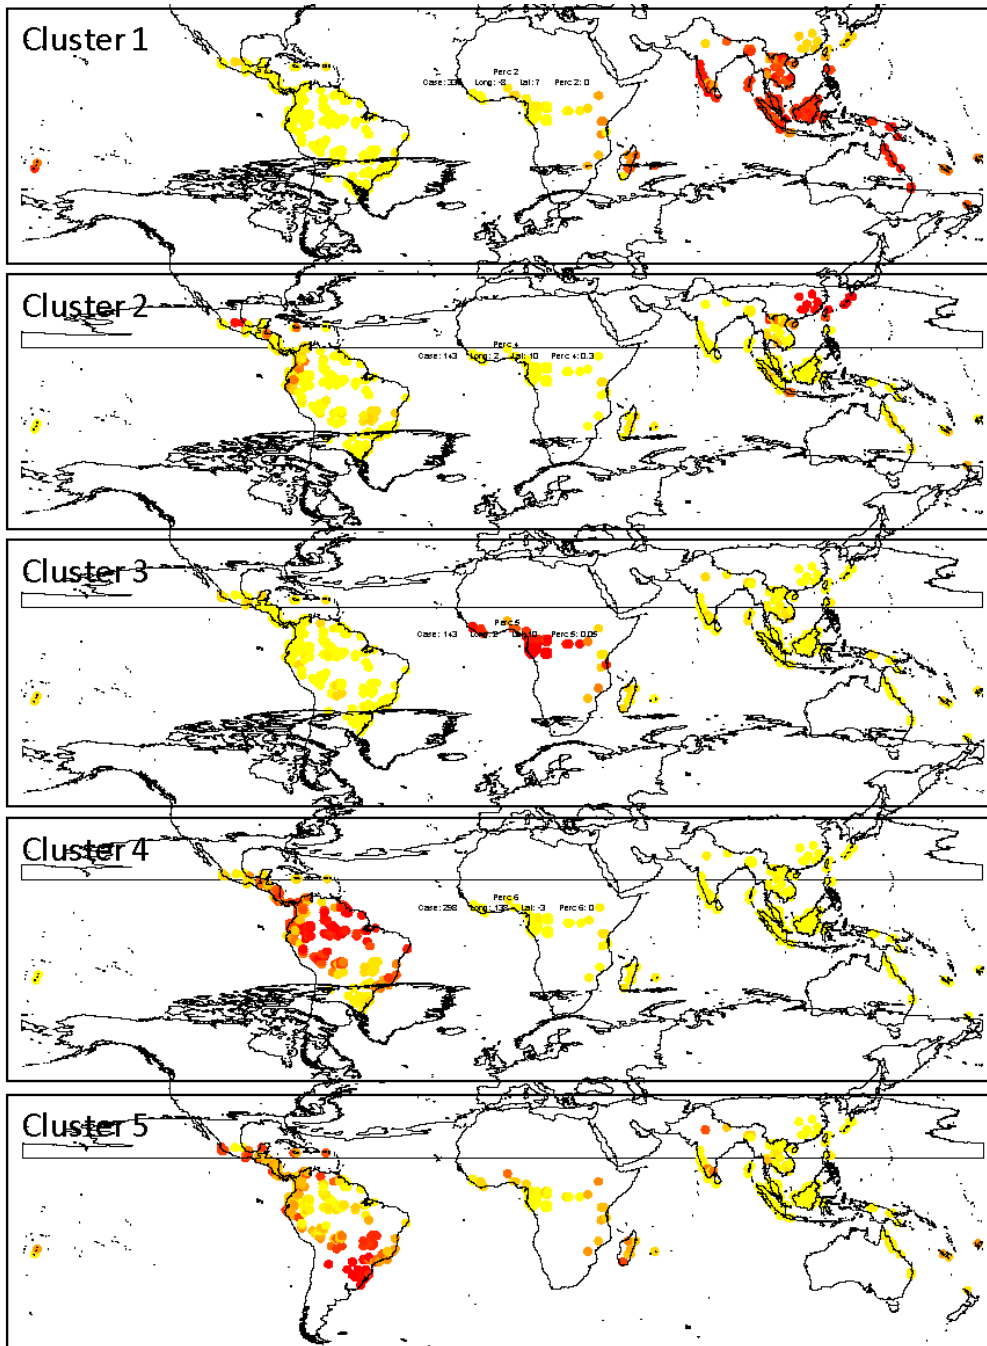

Figure S3. The classification frequency of each location in one of the five identified clusters, based on the 20 classifications shown in Extended Data Figure 4. Colours range from yellow (zero) to red (one). Cluster numbers correspond to those indicated in Extended Data Table 1.

Figure S4. Relationship between 'Mean Nearest Taxon Distance' (MNTD) and taxa richness of locations (black dots), based on 41 locations which had more than 320 taxa. With increasing taxa richness of locations, MNTD decreased following a power-function ($y = 310.4x^{-0.194}$). Standard deviation (white dots) was not influenced by taxa richness.

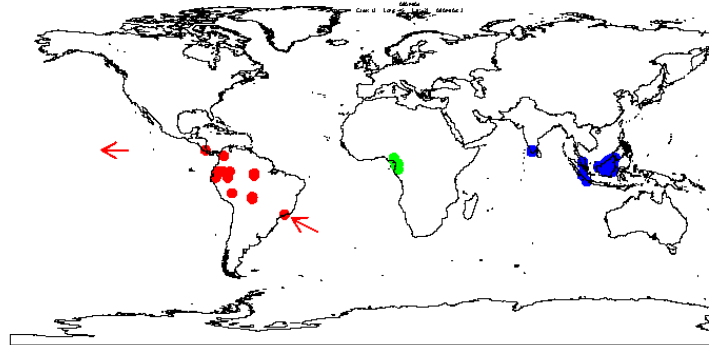

Figure S5. Cluster results for 41 locations (indicated in lower right map) using decreasing numbers of taxa per location (320, 160, 80, 40 and 20 from top to bottom). All analyses recovered the same three main groups of locations in the same configuration (African and American versus Asian locations), although one American location (indicated with red arrow) was grouped with the Asian cluster in the 20 taxon analysis.

Figure S6. Standardized cophenetic correlation coefficients for cluster levels K2 to K7 (mean with confidence interval of 20 cluster analyses). Cophenetic correlation coefficients show how well the distance data in the original data matrix fits the cluster dendrogram, i.e. the higher the value, the better the fit. Cophenetic correlation increased to cluster level 5 (K5).

Table S1. *The 406 locations with 20 or more species that were used in this study (contributor abbreviations given at end of table). Cluster assignment is given along with cluster success (percentage of times that each location was assigned to the same cluster based on 20 cluster analyses, each time with a different random set of 20 species per location). Environmental conditions represent the average for each location (1 x 1 degree latitude/longitude grid cell).*
