14 assigned to Roche-Ventana on behalf of his employer. He will receive no personal  
15 remuneration.

16

17

1 **Abstract**

2

3 Digital microscopy produces high resolution digital images of pathology slides. Since  
4 no acceptable and effective control of color reproduction exists in this domain, there  
5 is significant variability in color reproduction of whole slide images. Guidance from  
6 international bodies and regulators highlights the need for color standardization.

7

8 To address this issue, we systematically measured and analyzed the spectra of  
9 histopathological stains. This information was used to design a unique color calibration  
10 slide utilizing real stains and a tissue-like substrate which can be stained to produce  
11 the same spectral response as tissue. By closely mimicking the colors in stained  
12 tissue, our target can provide more accurate color representation than film-based  
13 targets, whilst avoiding the known limitations of using actual tissue. The application of  
14 the color calibration slide in the clinical setting was assessed by conducting a pilot  
15 user-evaluation experiment with promising results.

16

17 With the imminent integration of digital pathology into the routine work of the diagnostic  
18 pathologist, it is hoped that this color calibration slide will help provide a universal color  
19 standard for digital microscopy thereby ensuring better and safer healthcare delivery.

1 **Introduction**

2 **Background**

3 Histochemical and immunohistochemical staining of tissue sections on glass slides  
4 are the foundation on which diagnoses in pathology is based - an estimated 300 million  
5 slides are stained in the US every year <sup>1</sup>. These techniques rely on the selective  
6 staining of tissue components which enables pathologists to be able to identify  
7 structures to form interpretations and make diagnoses. The most commonly used stain  
8 for morphological assessment is hematoxylin and eosin (H&E); a pink and purple stain.

9

10 Color consistency is not a major concern with the analogue optical microscope as it  
11 uses light to view the tissue directly and the known variation in slide staining has been  
12 accepted for many decades <sup>2,3</sup>. Despite these known inconsistencies, there is  
13 significant empirical evidence that pathologists can make successful diagnoses from  
14 slides with a wide variety of staining variation and using a range of optical  
15 microscopes, yet, the common laboratory practice of re-cutting and re-staining referred  
16 or 'foreign' slides suggests that pathologists prefer working with familiar colors when  
17 possible.

18

19 However, unlike light microscopy, digital microscopes and whole slide imaging (WSI)  
20 systems as used in digital pathology present issues with regards to color  
21 standardization since the pathologist does not observe the tissue directly. Moreover,  
22 the digitization process itself involves many stages (Figure 1), each of which  
23 substantially affects slide color <sup>4</sup>.

The big effect of varying the scanner and viewer independently on the color of H&E slides can be seen in Figure 2. Previous work by our group<sup>2</sup> has shown that there is up to 8% variation in H&E ratio when scanning the same slide on the same scanner on a different day, consistent with a significant visually noticeable difference in color.

[Figure 2 should go approximately here]

Such a wide variation in image appearance has caused concern regarding the ability of the digital image to facilitate accurate interpretation. A review of the issues surrounding color consistency in digital pathology was discussed at the International Color Consortium (ICC) Conference on Color in Medical Imaging <sup>5</sup>, which highlighted that many of the issues were based around the absence of an established ‘gold standard’ for slide color. To try and resolve this issue, an ICC group on color in medical imaging <sup>5,6</sup> was formed. Recent guidance has also been published by the US Food and Drug Administration (FDA) <sup>7</sup>, stipulating requirements to ensure that digital microscope images are displayed in a consistent and reliable fashion.

**Color Calibration**

Color calibration is a technique which seeks to match an array of perceived colors between two or more devices. End-to-end calibration describes the process of controlling color from source to output through each step of the imaging pathway.

In the print industry, end-to-end color calibration has been established for many

1 decades <sup>8</sup>. It is routinely used, for example, to ensure that the printed pages of a  
2 magazine match the original image. Color calibration works by imaging a set of colored  
3 patches of a known (measured) color. These colored patches are carefully selected to  
4 be representative of the colors encountered by the device being calibrated.

5

6 Calibrating a digital camera is challenging since the set of colors encountered when  
7 taking photographs varies widely and the importance of color regulation varies  
8 between colors. The Macbeth color checker <sup>9,10</sup> (Figure 3) addresses this issue  
9 through the inclusion of “memory colors” to ensure accurate reproduction of those  
10 critical colors. In a similar method to the print industry, photographers take a photo of  
11 the Macbeth color chart and the colors derived from each of the patches in the photo  
12 are compared to the ‘known’ values for those patches. These differences can then be  
13 used to derive a color profile which compensates for the color differences of that  
14 particular device.

15

16 [Figure 3 should go approximately here]

17

18 In radiology, where most images are greyscale rather than color, the need for end-to-  
19 end calibration of grey levels is recognized as essential to ensure diagnostic  
20 consistency of a system. Therefore, image calibration has been incorporated into  
21 Digital Imaging and Communications in Medicine (DICOM) Grayscale Standard  
22 Display Function (GSDF) requirements for radiological images <sup>11</sup> and has become a  
23 standard part of all radiology imaging workflows. Digitization of radiology, nearly 20  
24 years ago, faced many of the same challenges, so it is important to ensure that lessons  
25 are learnt from these experiences <sup>12</sup> as digital pathology is integrated into clinical

1 practice.

2

### 3 **Color calibration in pathology**

4

5 Color calibration in digital pathology is still in its infancy, with a widespread lack of  
6 awareness of the importance of consistent color reproduction, or even an assumption  
7 that all digital imaging devices reproduce color in essentially the same way. This is  
8 evident from the fact that there are very few studies in the literature evaluating the  
9 importance of color on diagnosis in digital microscopy <sup>13</sup>.

10

11 Recently, the FDA have released further recommendations <sup>7</sup> stating that whole slide  
12 imaging devices have their color consistency tested with a color calibration slide which  
13 would perform the same function as the Macbeth color chart in digital photography.  
14 This would involve scanning the color calibration slide on the scanner and comparing  
15 the measured color values of the patches with the known values to create a color  
16 profile which can be applied to WSI. The guidance also recommends that ideally, the  
17 color calibration device should have “similar spectral characteristics to stained tissue”<sup>7</sup>.

18

19 Recognizing the importance of color reproduction and in an effort to comply with  
20 international guidance, several digital pathology vendors and research groups have  
21 attempted to develop color calibration systems for pathology images. Silverstein et al  
22 developed ICC color calibration profiles for three displays focusing on the display end  
23 of the imaging workflow <sup>14</sup> using an on-screen color target. The resulting profiles can  
24 be used to compare display performance, but as they do not include measurement of  
25 the color variation introduced by the imaging device (WSI instrument or digital

1 microscope), they cannot provide end-to-end color calibration. Others have used color  
2 calibration targets which involves imaging the target with the imaging device, then  
3 using the resulting image to develop a color correction profile specific to that device  
4 <sup>15-18</sup>. Most of these targets are film-based and although they will almost certainly  
5 produce improvements in color consistency between scanners, it is likely that the  
6 colors involved (cyan, magenta and yellow film or gel dyes) have substantially different  
7 spectra from that of histopathology stains, exacerbated by film also being denser than  
8 tissue. The resulting targets are likely to suffer from 'metameric failure' as they will not  
9 replicate tissue and stain spectra under all conditions.

10

11 To address these limitations, tissue-based color targets have been proposed, such as  
12 a section of mouse embryo with standard staining, or cell cultures. Although such  
13 targets have the advantage of accurately representing the target material to be imaged  
14 and employ spectra appropriate for histochemical staining, producing useful color  
15 phantoms based on stained tissue is difficult due to the significant variation between  
16 samples.

17

18 This paper describes the development of a novel color calibration assessment slide  
19 for digital pathology which overcomes the limitations outlined above. The primary  
20 objective is to create a target slide that includes a reproducible set of colors that are  
21 spectrally similar to the colors produced in stained tissue samples. This will  
22 necessitate investigation into the range of colors in tissue slides from representative  
23 stained sections, as well as histochemical stain interaction within stained tissue  
24 samples.

25

1 **Materials and methods**

2

3 **Slide preparation and staining protocols**

4

5 At the start of the project a list of staining protocols was created to represent the gamut  
6 of colors used in histopathology and cytopathology practice. The list was generated  
7 by a consultant histopathologist (DT) within our institution.

8

9 A calendar year of histopathology laboratory staining activity was extracted from the  
10 laboratory information system of our institution and the list of staining protocols used  
11 was sorted by frequency. This provided information on a total of 258,793 stained  
12 slides, of which 79% were H&E, 13% were Hematoxylin-Diaminobenzidine stain (H-  
13 DAB), and the remaining 8% comprised 66 different histochemical stains. This practice  
14 is likely reflective of similar academic institutions within the UK. The stains were sorted  
15 by frequency and those accounting for the top 96% of all stains were included in the  
16 list to account for the majority. This was supplemented by the commonly used  
17 cytological stains, as well as some additional stains added to include less well-  
18 represented parts of the color spectrum (e.g. green and yellow).

19

20 Staining strategies were developed in order to capture the color spectrum of each  
21 constituent stain without interference from other colors. This involved staining mouse  
22 embryo tissue slides using a standard staining protocol (usually with multiple stains)  
23 as well as slides stained with each of the stains independently. For example, the H&E  
24 staining protocol involved three slides that were sectioned and stained with (i)  
25 hematoxylin and eosin, full protocol, (ii) hematoxylin only and (iii) eosin only. For the

1 Martius Scarlet Blue staining protocol, four slides were sectioned and stained with (i)  
2 Martius scarlet blue, full protocol, (ii) Martius yellow only, (iii) Crystal scarlet only and  
3 (iv) Aniline blue only. In total, 200 reference slides were stained to represent all the  
4 staining protocols. The specific protocols used for tissue processing, sectioning and  
5 staining are included in Appendix 1.

6

7 Stained sections were recut at varying thicknesses (2 to 12 microns) to investigate the  
8 impact of tissue thickness on color.

9

10 Slides were visually assessed for quality of staining. For protocols involving multiple  
11 stains the overall result was assessed to ensure that all components were correctly  
12 stained and well differentiated with regards to intensity of color, and differentiation of  
13 staining in different tissue components by the constituent dyes. Where single stains  
14 were applied to tissue the intensity of color was the only assessment available.

15

## 16 **Identification and measurement of colors**

17

18 Each of the tissue slides was imaged at 40X magnification and approximately 300-400  
19 spectral measurements were collected for each slide. To understand the range of  
20 independent colors in sets of measurements, we grouped measurements using a k-  
21 means clustering algorithm. This allowed us to identify measurements of contaminants  
22 such as dust in measurements of slides stained with a single stain and to identify  
23 measurements of regions with different proportions of stains. The location of each  
24 measurement on the slide was recorded so that we could later identify the region  
25 measured to determine whether the color was likely to be significant for a pathologist.

1 Figure 4 shows a typical tissue slide with the regions measured shown.

2

3 [Figure 4 should go approximately here]

4

5 Our measurement system comprised a digital microscope based on a commercial  
6 scanner which uses a custom Leica lens and white light LED illumination source <sup>19</sup>  
7 that was adapted to include a Hamamatsu C10082MD spectrophotometer <sup>20</sup>. The  
8 optics were adjusted so that the Hamamatsu aperture was aligned with the image  
9 plane of the digital microscope. The system was calibrated to align the measurement  
10 aperture to the high resolution (40X) image. We developed a software program in  
11 MATLAB R2015a <sup>21</sup> which allowed us to (a) scan a high resolution image, (b) analyze  
12 the high resolution image to select suitable measurement points and (c) make  
13 measurements and show the position and size of the measurement aperture in relation  
14 to the high resolution image.

15

16 The relative sensitivity across the measurement aperture was calculated by measuring  
17 a high-contrast edge in small intervals. This was repeated for horizontal and vertical  
18 edges. The high contrast edge was from a phantom slide which is used for geometric  
19 scanner calibration.

20

21 We calibrated our spectrophotometer using a set of neutral density filters and a  
22 Holmium slide for which measurements traceable to the National Physical Laboratory  
23 <sup>22</sup> have been provided. The result is shown in Supplementary Figures 1 and 2. For the  
24 range 400 – 700 nm, absorbance measurement error overall was less than 0.5%, with

1 repeatability error less than 0.2 %. The error in wavelength is less than 2nm for this  
2 spectral range.

3

4 Ethical approval for this work was obtained from Leeds West LREC 05-Q1205-22.

5

## 6 **Creation of a color calibration slide**

7

8 After obtaining results regarding histochemical stain interaction (see results section),  
9 we investigated of the ability of a number of materials to retain pathological stains.

10 After many unsuccessful attempts, an appropriate biopolymer was identified.

11

12 Sheets of the biopolymer were stained using three different intensities of hematoxylin  
13 and three different intensities of eosin, spanning the range of absorbance measured  
14 in stained tissue. This was determined by including the maximum intensity for each  
15 stain in the tissue slides and selecting two intermediate stain intensity patches with  
16 approximately even visual spread. These sets of sheets were cut into 3 strips and then  
17 laid on top of each other to produce different color combinations in each overlapping  
18 region. This produced 16 H&E color patches. Further sheets of biopolymer were  
19 stained with other histopathological stains, including: Silver stain, Picric Acid, Neutral  
20 Red, Crystal Scarlet, Tartrazine, Aniline Blue, Fuchsin, Periodic Acid Schiff, Orange G  
21 and Light Green.

22

23 A prototype slide was manufactured to include a range of 2mm color patches of stained  
24 biopolymer, with an extended H&E region and a number of patches including other

1 stains (Figure 5).

2

3 [Figure 5 should go approximately here]

4

## 5 **Pilot user-evaluation experiment**

6

7 This participant blinded, user-evaluation experiment took place in May and June 2015.

8

9 Six glass pathology slides with different specimens and tissue stains were selected for  
10 evaluation by author DT (Figure 6). The cases were chosen to represent the spectrum  
11 of stains, including cases where color is important in diagnosis, as well as those known  
12 from previous experience to represent diagnostic difficulty when viewed as a digital  
13 slide <sup>23,24</sup>. The slides were scanned using the same commercial scanner at x40  
14 magnification on the same day to produce 6 WSIs.

15

16 [Figure 6 should go approximately here]

17

18 An ICC color profile was created using our color calibration slide to calibrate each WSI.  
19 This involved measuring the colors (CIELAB) on the color calibration slide using a  
20 spectrophotometer and then scanning it to generate RGB values. Intermediate color  
21 values for the ICC Profile were interpolated from the 'known' values from the color  
22 calibration slide. Flare (where light from surrounding areas reduces image contrast)  
23 was estimated at 5% and a compensation applied.

24

1 Each color calibrated WSI was presented alongside its uncalibrated (i.e. original)  
2 counterpart on the experiment monitor. To blind the participants to the intervention,  
3 each image pair was assigned labels of 'Image A' and 'Image B'. 'Image A' remained  
4 on the left-hand side of the screen and 'Image B' on the right (Figure 7). The  
5 positioning of the calibrated or uncalibrated WSI (i.e. whether it was assigned to the  
6 'Image A' or 'Image B' position) was alternated per participant.

7

8 [Figure 7 should go approximately here]

9

10 All experiments took place in the same windowless room, using the same equipment  
11 (Figure 7). The WSIs were viewed using bespoke FFEI software on a Barco Coronis  
12 Fusion MDCC6130 monitor <sup>25</sup>. The monitor luminance was set to 400 cd/m<sup>2</sup> and was  
13 color calibrated using the X-Rite® i1 Display Pro colorimeter <sup>26</sup> which incorporated the  
14 ambient lighting of the room. The settings used for monitor calibration were: CIE  
15 Standard Luminant D65, native contrast ratio, gamma 2.2. The lighting was  
16 standardized at 7 lux, and placed behind the participant, facing the floor to avoid glare.  
17 The display calibration was checked and recorded prior to each experimental session  
18 using the X-Rite® i1 Display Pro software, which permitted a maximum error of 15  
19 DeltaE.

20

21 A Leica DMR microscope <sup>19</sup> was used during the experiment. This was fitted with a 10  
22 x 25mm eyepiece and 2.5, 5, 10, 20, 40x dry objectives. Polarizer and filter settings  
23 were standardized, but participants could adjust the focus, interpupillary distance and  
24 substage condenser position. The daylight filter was applied and the rheostat was  
25 standardized at 7 where possible, as the light yellowed at lower light levels. However,

1 participants could adjust this if they found it uncomfortable. A script was used  
2 throughout each experimental session.

3

4 We invited all (approximately 40) consultant histopathologists employed at Leeds  
5 Teaching Hospitals NHS Trust at the time of the experiment, to take part. Informed,  
6 written consent was obtained. Participants compared glass slides using the optical  
7 microscope with the corresponding WSI, calibrated and uncalibrated, of the same  
8 tissue specimen. Details of the questions asked are outlined in Figure 8.

9

10 [Figure 8 should go approximately here]

11

12 When the glass slides were not being used, they were kept in an opaque envelope to  
13 help prevent fading.

14

15 Data were analyzed using SPSS v21 (IBM). Significance level was set at 0.05.  
16 Wilcoxon Signed Rank test was used to compare data and Kendall's Tau-b correlates  
17 are presented.

18

## 19 **Results**

### 20 **Stain interactions**

21

22 We examined the spectral measurements of the slides involved in each staining  
23 protocol, as described above. An example of the data obtained from the H&E staining  
24 protocol can be seen in Figure 9. By measuring the spectral absorbance of samples

1 with different staining levels separately and then in combination we conclude that the  
2 total spectral absorbance of hematoxylin, eosin and H&E is dependent only on the  
3 amount of stain present and therefore follows Beer-Lambert's law. As such, we are  
4 able to assume that the spectral absorbance is linearly proportional to the amount of  
5 staining. It is also apparent from the spectral data in Figure 9 that there is no interaction  
6 between hematoxylin and eosin stains and that they combine in a simple linear way.  
7 This knowledge enabled the layering of biopolymer, independently stained with eosin  
8 and hematoxylin, on top of one another, to create a representative gamut for H&E  
9 stained slides.

10

11 [Figure 9 should go approximately here]

12

13 All other stain combinations acted similarly to H&E in that they obey Beer-Lambert's  
14 Law and so were combined through simple addition. The only exception was HDAB,  
15 which has different spectral properties due to selective light scatter and therefore does  
16 not follow Beer-Lambert Law. However, in reality, our samples demonstrated that  
17 HDAB can be simulated to a similar accuracy achieved by other stains by including a  
18 number of patches stained with different intensities of DAB. Figure 10 shows the result  
19 of spectrophotometric analysis of HDAB absorbance and its modelling using  
20 combinations of H and DAB.

21

22 [Figure 10 should go approximately here]

23

24 Comparison of different thickness sections from 2 to 12 microns, showed that the  
25 shape of the spectrum is the same for the different thicknesses of material (see

1 Supplementary Figure 3).

2

### 3 **Theoretical performance assessment**

4

5 It is well known that when calibrating devices, the calibration target should include  
6 colors with similar spectra to those that the device has been designed to capture.

7 Since our calibration slide uses the same set of stains as are used to stain tissue we  
8 hypothesize that their spectra are likely to be very similar. To confirm this assumption,  
9 we compared spectral measurements of hematoxylin- and eosin-stained biopolymer  
10 patches with measurements from mouse embryo slides stained with hematoxylin and  
11 eosin single stains (Figure 11a). Typical spectral data for hematoxylin and eosin  
12 (normalized by peak absorbance) are shown in Figure 11b. These and similar  
13 comparisons with the other stains used on the slide demonstrate that the spectra of  
14 stained tissue and the stained biopolymer patches used on our color calibration slide  
15 are very similar.

16

17 [Figure 11a&b should go approximately here]

18

19 For comparison, we examined the spectra from a photographic film color calibration  
20 slide (HutchColor HCT Ektachrome™ 35mm) which is one method that has been  
21 proposed for digital microscope calibration. These spectra, which arise from the set of  
22 three dyes used in the photographic process, are substantially different in shape from  
23 the spectra of pathology stains. This can be seen from the comparison in Figure 12  
24 which shows the spectrum of a photographic film patch and a tissue color  
25 measurement. In our scanner, these two spectra produce the same scanner RGB

1 values but are visibly different, with a color difference of 5 CIEDE2000. This color  
2 difference is essentially a systematic error which cannot be removed by the calibration  
3 process.

4

5 [Figure 12 should go approximately here]

6

7 A comparison between color measurements of the photographic film calibration slide  
8 and color measurements of H&E-stained pathology slides is shown in Figure 13. This  
9 shows that the entire gamut for eosin and much of that for hematoxylin lies outside  
10 that of the photographic film color gamut and consequently photographic film color  
11 calibration slides are unable to predict any of the eosin colors. As there is no way to  
12 estimate colors outside the gamut of a calibration target, some form of extrapolation  
13 is necessary; this is likely to be very large as it essentially involves guessing these  
14 colors and values greater than 10 CIEDE2000 units are not uncommon in these  
15 situations.

16

17 [Figure 13 should go approximately here]

18

19 Although it is not possible to estimate precisely the difference in calibration accuracy  
20 between these two methods, our experience shows that the errors for a photographic  
21 film calibration target are likely to be several times larger than for our calibration slide.

22

### 23 **Pilot user-evaluation experiment**

24

1 Twelve participants took part in the pilot user-evaluation experiment who performed  
2 72 trials in total (6 slides per participant). The mean working experience in pathology  
3 for the cohort was 21.5 years. Most pathologists self-reported to have seen 100-1000  
4 WSIs prior to the experiment. Participants' opinion of digital pathology varied; when  
5 asked to rate how positively they felt about digital pathology on a scale of 0-10 (0 =  
6 very negative; 10 = very positive), the median score was 8 (IQR 3.25).

7

8 The monitor color calibration check using the X-Rite® i1 Display Pro had an average  
9 of 2.6 DeltaE across all experimental sessions.

10

11 The calibrated WSIs were reported to be closer in appearance to the optical  
12 microscope in 56% of trials (40/72) (Figure 14). On average over the 6 slides, seven  
13 pathologists (58%) thought that the color calibrated WSIs was more similar to the  
14 microscope.

15

16 [Figure 14 should go approximately here]

17

18 Regarding pathologist preference, 64% of trials (46/72) were in favor of the calibrated  
19 slide (Figure 14). On average over the six slides, nine pathologists (75%) favored the  
20 color calibrated WSIs.

21

22 The calibrated slide had no effect on diagnostic confidence in 53% of trials (38/72),  
23 but 38% of trials (27/72) found the calibrated slide improved diagnostic confidence.  
24 On average over the 6 slides, all pathologists reported that the calibrated slide  
25 increased or had no effect on diagnostic confidence. Overall, calibrated WSIs had a

1 higher median diagnostic confidence score as compared to the median diagnostic  
2 confidence score for the uncalibrated WSIs (Figure 15). Increased diagnostic  
3 confidence with the calibrated slides was correlated with preference for color  
4 calibration ( $r=0.499$ ).

5

6 [Figure 15 should go approximately here]

7

8 There was no statistical difference between each of the six cases for all three main  
9 outcomes; similarity to microscope, pathologist preference or diagnostic confidence.  
10 Similarly, there was no difference in scores for each main outcome when the six cases  
11 were categorized into H&E slides and non-H&E slides (Figure 16).

12

13 [Figure 16 should go approximately here]

14

## 15 **Discussion and Conclusion**

16

17 Accurate color reproduction is an essential next step in digital pathology. It will enable  
18 the adoption of image analysis/ computer aided diagnosis, increased confidence in the  
19 suitability of whole slide imaging for clinical use (both by clinicians and regulators),  
20 and possibly improve quality or speed of diagnosis. To date, no practical and robust  
21 method for color calibration in digital pathology exists.

22

23 There are several repositories for stain measurement data such as Color Index  
24 International (<http://www.color-index.com/>) and Stains File (<http://www.stainsfile.info/>)  
25 which provide details of the stains as measured in isolation. However, we believe we

1 have produced the first systematic evaluation of the way in which stains interact with  
2 tissue samples and with each other.

3

4 We can confirm that the spectral absorbance of histochemical stains is linearly  
5 proportional to the amount of staining and therefore we can use a few differing  
6 concentrations of H&E stain in our calibration device to create a full gamut that is very  
7 like the gamut of hematoxylin and eosin from stained tissue in clinical practice.  
8 Moreover, since stains interact through simple addition, sheets of stained biopolymer  
9 can be layered without impacting on the spectral properties. This detailed knowledge  
10 of stain spectra has enabled creation of a color calibration slide that has similar  
11 spectral characteristics to stained tissue.

12

13 We have also been able to demonstrate that film-based color calibration slides have  
14 differing spectral characteristics to stained tissue with typical metameric error of 5  
15 CIEDE2000 units. Additionally, there is color error of approximately 10 CIEDE2000  
16 when correcting for colors that lie outside the film color calibration slide color gamut,  
17 which includes the entire gamut for eosin. Therefore, the use of film-based color  
18 calibration targets for digital microscopy would result in substantial color error despite  
19 correction.

20

21 We observed that an increase in the tissue thickness did not change the shape of the  
22 spectrum. This is an important finding as the accuracy of the color calibration derived  
23 from our color calibration slide is maintained despite variation in tissue section  
24 thickness.

25

1 Our findings from our clinical pilot indicate that calibration with the color calibration  
2 slide made the WSI closer in appearance to the microscope in over 50% of trials, which  
3 was a weaker effect than hypothesized. A possible reason for this may be that since  
4 pathologists are used to seeing uncalibrated WSIs (and several participants had seen  
5 large numbers of uncalibrated slides previously), they are 'self-calibrating' to this  
6 standard and thus simply recalling the colors that they are used to seeing <sup>27</sup>. This was  
7 illustrated very well by one participant: *'I am used to the (uncalibrated image), so to  
8 me it looks closer to the microscope'*. This reconfirms the need for color  
9 standardization to prevent pathologist adjustment to varying color profiles.

10

11 Color calibration did not affect similarity to the microscope, as strongly as preference.  
12 These results question the underlying assumption that 'the ideal' color for WSIs is the  
13 glass slide as viewed under the optical microscope. Perhaps there are more essential  
14 key factors when optimizing WSI color that have not yet been determined, for instance  
15 flare, illumination or color temperature.

16

17 Although the findings suggest that color calibration may improve diagnostic  
18 confidence, it should be emphasized that this study was not designed as a diagnostic  
19 accuracy study; the cases did not represent diagnostic subtleties and moreover, the  
20 diagnoses were provided to participants. This will inevitably have biased the results in  
21 favor of calibration having no effect on diagnostic confidence, so the true effect of  
22 calibration on diagnosis may be more pronounced than observed in this small study.  
23 It is also important to note, that diagnostic confidence may not be an accurate  
24 surrogate marker of diagnostic accuracy <sup>28,29</sup> and so follow on work should focus on a  
25 bigger study formally evaluating the effect of color calibration on diagnosis.

1

2 The link between pathologist preference and diagnostic confidence is a further area of  
3 interest. This study demonstrated a positive correlation between preference for, and  
4 diagnostic confidence with, the calibrated WSI. Whether this reflects a true benefit in  
5 the fitness-for-purpose of the image is not known. There may of course be other  
6 benefits with increased preference for an image aside from diagnostic accuracy,  
7 extending to user fatigue or speed of diagnosis. This is clearly a question for another  
8 follow-on study.

9

10 As previously mentioned, there is little published work in this area, with only a couple  
11 of studies having investigated the clinical effect of color calibration <sup>28,30</sup>. Krupsinki et al  
12 <sup>28</sup> concluded that monitor color calibration did not affect diagnostic accuracy, but did  
13 statistically increase average interpretation speed by 22 percent when viewing breast  
14 biopsy regions of interest . Hanna et al 2014 <sup>30</sup> found that pathologists preferred using  
15 an uncalibrated monitor and the group did not demonstrate an effect of color  
16 calibration on diagnosis. Our results did not agree with the findings of Hanna et al and  
17 this discrepancy may emphasize that (i) the effect of memory on color preference and  
18 (ii) the need for end-to-end color calibration using a color calibration slide, rather than  
19 monitor calibration alone, which does not correct for color changes introduced through  
20 the scanning process.

21

22 The main strengths of the research we present here is the high degree of  
23 methodological rigor requiring expertise in pathology, color science, imaging and  
24 cognitive psychology, as well as the large number of samples used to create the color  
25 calibration target.

1

2 Despite this, there are inevitable limitations which require discussion. Firstly, the  
3 choice of stains included reflects UK histopathology and cytopathology practice, which  
4 we have assumed to be broadly representative of worldwide pathology practice.  
5 However, we recognize that there may be significant international variability in both  
6 the stains used and the exact chemical composition of the dyes. We have made an  
7 attempted to account for this through analysis of Meyer's and Harris hematoxylin, but  
8 it is likely that there will be further, unaccounted variation. Additionally, whilst the color  
9 calibration target can be used to calibrate any digital slide scanner, further  
10 development will likely be needed to manufacture this device on a large scale. Also,  
11 although slides stained with HDAB showed relatively low color error, ideally further  
12 work should be done and additional patches should be included to eliminate any errors  
13 due to metamerism. Finally, the limited exploratory nature of the clinical pilot limits the  
14 applicability of the results, both relating to the small number of slides assessed, as  
15 well as the small sample size – a larger study focused on the diagnostic impact of  
16 color calibration is required to draw firm conclusions.

17

18 A prototype color calibration slide was tested by members of the International Color  
19 Consortium Medical Imaging Working Group<sup>6</sup> and a production version is expected to  
20 available commercially within the next year from FFEI Limited and industrial partners.

21

22 We are confident that, when refined, this approach will:

- 23 1. Provide a solid basis for end-to-end color calibration assessment for digital  
24 pathology,
- 25 2. Facilitate interoperability between digital microscope systems and between

- 1 pathology labs image transfer,
- 2 3. Increase reproducibility of automated image analysis in whole slide imaging,
- 3 4. Improve clinical efficiency and accuracy of digital microscopy and whole slide
- 4 imaging, and
- 5 5. Facilitate work towards truly quantitative immunohistochemistry.

**Fig 1 [COLOR]: Examples of color variation**

The top row shows a WSI scanned on one scanner but viewed in two different software viewers. The image on the bottom row shows the results of the same glass slide scanned on scanners from two different manufacturers. A marked difference in the color of both eosin and hematoxylin is seen in both cases. These differences illustrate the effect of uncontrolled color variation in the image capture and image display components of the workflow. Fig 2 is reproduced with permission from Dr Yukako Yagi, MGH.

**Fig 4 [COLOR]: Illustration of measurement method.** The glass slide (left) was loaded onto the measurement apparatus. In the example shown, the glass slide contains an H&E stained section of mouse embryo. A low resolution whole slide image (“overview image”) was taken (middle). This image was used to guide measurements, indicated by the green stars on the tissue. The measurement aperture, illustrated on the right, was small enough to allow measurement of microscopic areas of tissue. Measurements were taken across the entire sample to generate measurements which are representative of all the colors and intensities present on the slide.

3 **Fig 9 [COLOR]: Spectral results of tissue stained with hematoxylin only, eosin**  
4 **only and H&E**

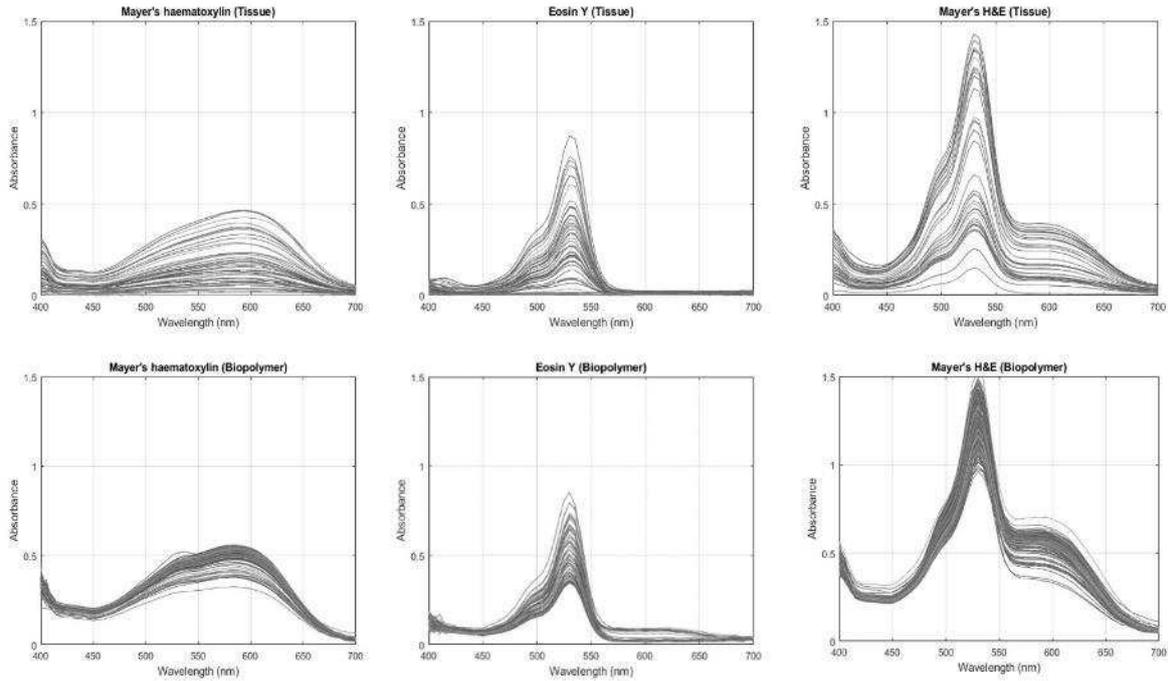

5 The left graph shows the spectra for tissue stained with hematoxylin only. The middle  
6 graph shows the spectra for tissue stained with eosin only. The right graph shows  
7 spectra for tissue stained with H&E. The total spectral absorbance of hematoxylin,  
8 eosin and H&E is dependent only on the amount of stain present and therefore H&E  
9 follows Beer-Lambert's law. Hence we can assume that the spectral absorbance is  
10 linearly proportional to the amount of staining. It is also apparent that there is no  
11 interaction between hematoxylin and eosin stains and that they combine in a simple  
12 linear way; the hematoxylin and eosin peaks are discernible from the H&E spectra.

14

1

2

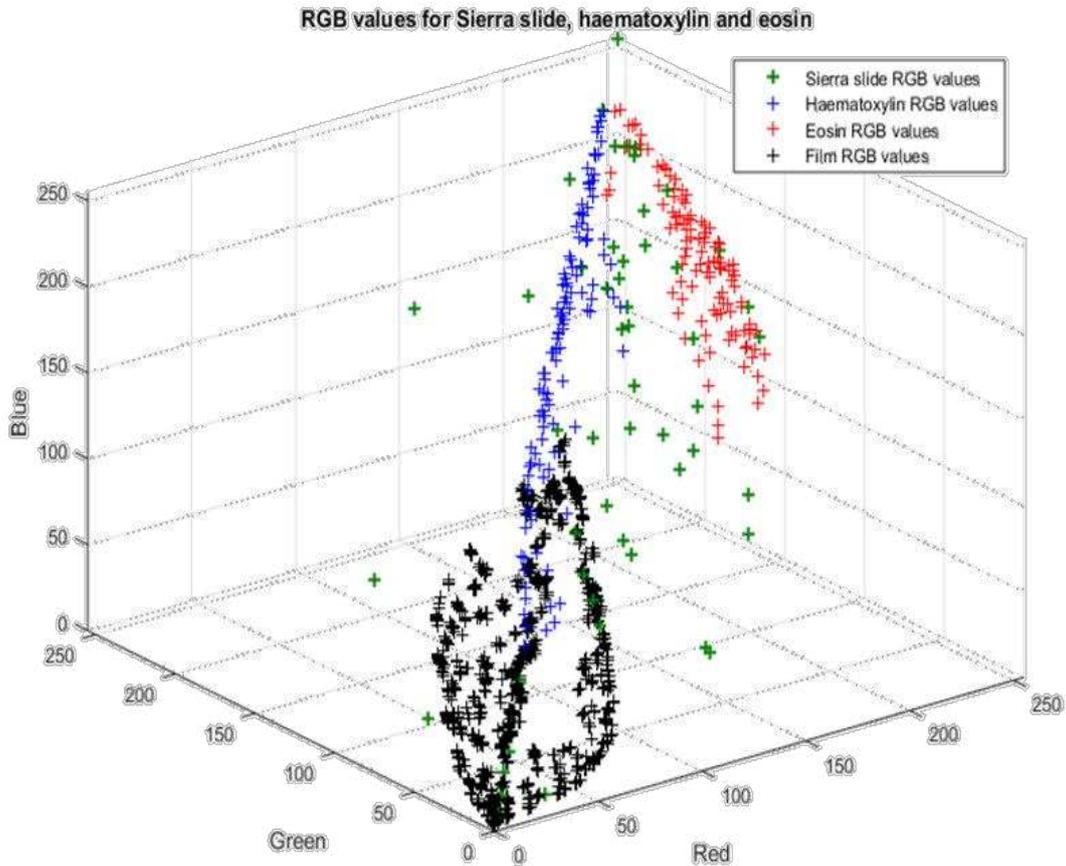

3 **Fig 11b: A direct comparison of typical absorbance spectra, in biopolymer and**  
4 **in tissue.** The graph on the left is for tissue and biopolymer stained with hematoxylin  
5 only and the graph on the right is for tissue and biopolymer stained with eosin only,  
6 with striking similarity in each. These spectra are normalized by peak absorbance.

7

13 **Fig 12. A comparison of film spectra and stained tissue.** These patches have the  
14 same RGB values (48,43,69) but have a CIEDE2000 color difference of 5.3. This is  
15 systematic error and cannot be removed through the calibration process.

1

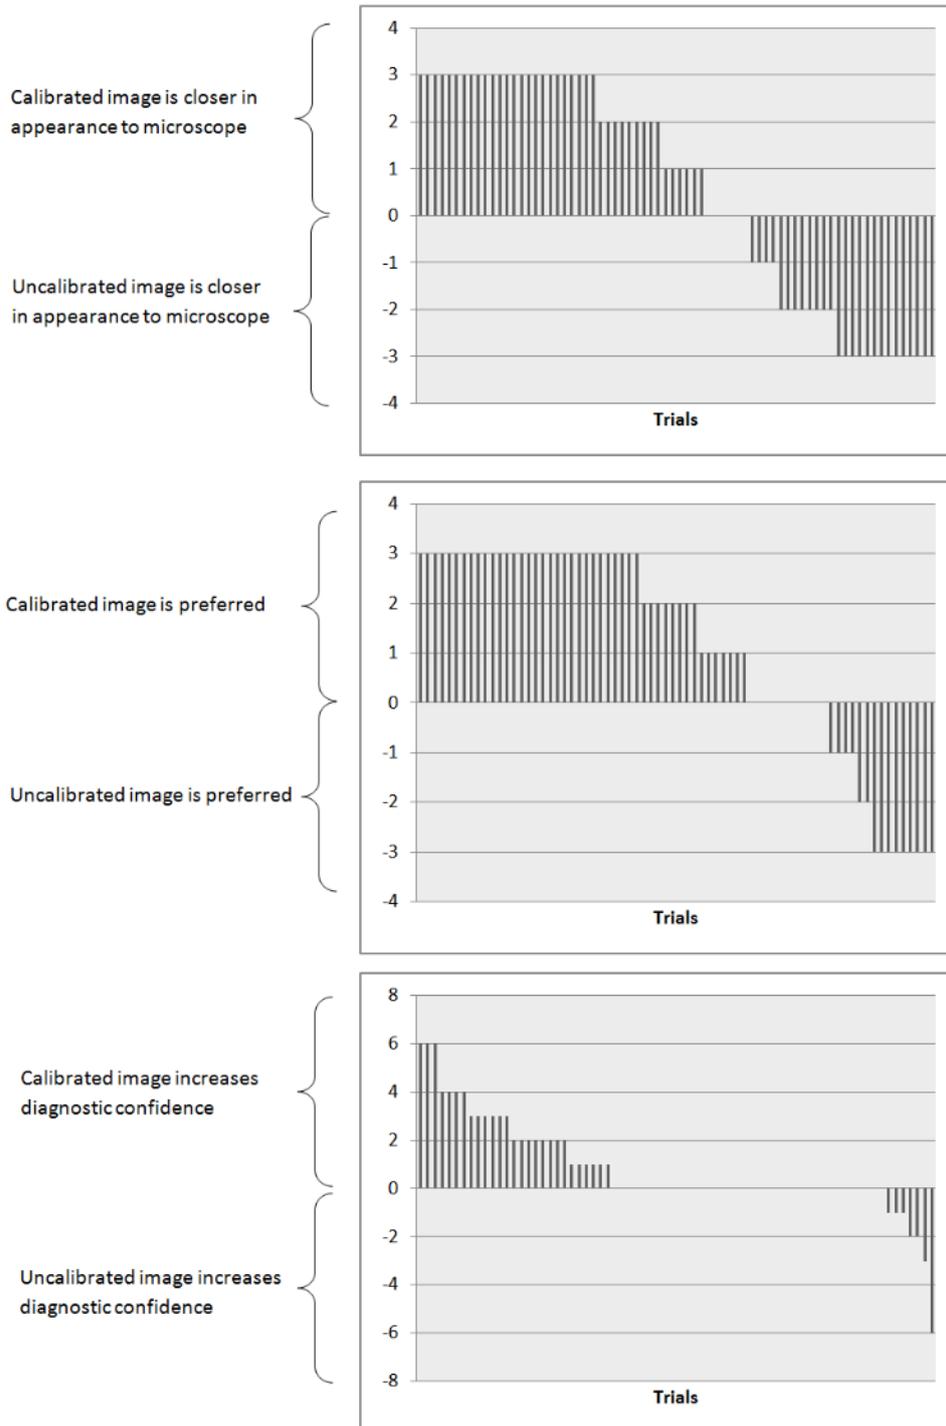

2

3 **Fig 13. [COLOR] A comparison of RGB values for film (black), hematoxylin-**  
4 **stained tissue (blue), eosin-stained tissue (red) and the color calibration slide**  
5 **(green).** The eosin RGB values do not overlap with the film RGB values and therefore  
6 film-based targets cannot accurately capture the color of eosin. Therefore, the use of  
7 film-based targets would result in color variation between images despite calibration.  
8 The spectra of the novel color calibration slide overlaps with the eosin and hematoxylin  
9 RGB values and therefore color calibration using the novel color calibration slide  
10 enables more accurate color calibration.
