Abstract. Animals and robots must constantly make sense of multiple streams of noisy information gathered from the environment, and combine them appropriately to make improved decisions. Recently, it has been proposed that animals might combine conflicting cues optimally using a ring attractor network architecture inspired by the head direction system in rats and augmented with a dynamic re-weighting mechanism. In this work we report that an older and simpler ring attractor network architecture, requiring no re-weighting property combines cues according to their certainty for small to moderate cue conflicts but converges on the most certain cue for larger conflicts. These results are consistent with observations in animal experiments that show sub-optimal cue integration and switching from cue integration to cue selection strategies. This work therefore demonstrates an alternative architecture for those seeking neural correlates of sensory integration in animals. In addition, performance is shown robust to noise and miniaturization and thus provides an efficient solution for artificial systems.

Keywords: ring attractor · cue integration · sensor fusion · optimal · Bayesian integration · head direction cells

1 Introduction

A fundamental principle underlying animal intelligence is the capacity to appropriately combine redundant sensory (e.g. vision, olfactory and haptic) of the same percept (e.g. location of a sensory source) to achieve a more accurate and robust estimate [1, 2]. For example, both mammals and insects constantly track their pose using head-direction cells which combine information from external cues (e.g. from surrounding visual features) with self-motion cues (from path integration) to maintain a precise estimate of their current orientation [3, 4] (Fig.1). Yet, as all sensory information is subject to errors which can change drastically depending on the situation (e.g. relying on visual cues in a darkened room) animals must employ an adaptive cue combination strategy reflecting the known errors (variance) in the different sensory signals to achieve the optimal estimate of the desired environmental property.

Fig. 1. The cue integration problem. (a) Example of an animal maintaining an estimate of its current pose (green area) using different cues of varying certainty (Self-motion, black area, and vision, red area). (b) When cues are represented by conflicting Gaussian functions, the width describes the uncertainty of each and the optimal solution is given by weighting each cue according to their known variance as described by Bayes' rule.

Bayes' theorem (1) provides a mathematical framework describing the optimal way in which information from different sources should be combined, and some studies argue that animals have Bayesian brains [2, 5–7]. According to Bayes' Rule, the posterior probability $P(x_{true}|x_{cue})$ (the probability of event x will happen when the cue about x is sensed) is proportional to the product of the prior probability $P(x_{true})$ (the probability of event x happening based on prior knowledge) and the likelihood function $P(x_{cue}|x_{true})$ (the probability of the cue when x truly happened, which represents the reliability of this cue). Assuming that the prior probability $P(x_{true})$ is uniform and the x_{cue} is corrupted by Gaussian noise with variance σ^2 , then the posterior probability is proportional to $1/\sigma^2$. Therefore, when there are n cues all concerning x event and corrupted by Gaussian noise with variance $\sigma_i^2, i = 1, 2, \dots, n$, the optimal way to reduce the uncertainty of estimating x (i.e., the maximum the posteriori probability) is averaging the cues weighted by their reciprocal variances $1/\sigma^2$, as indicated by (2), which is identical with results calculated by the MLE (maximum-likelihood estimate) [6, 8]. The theorem asserts that cues with lowest variance (e.g. more reliable) should be weighted more than those with high variance (i.e. less reliable) as demonstrated in Fig.1(b).

$$P(x_{true}|x_{cue}) = P(x_{cue}|x_{true}) P(x_{true}) / P(x_{cue}) \quad (1)$$

$$\hat{X} = \sum_i^n W_i X_i, W_i = (1/\sigma_i^2) / \left(\sum_j^n 1/\sigma_j^2 \right) \quad (2)$$

Artificial systems also rely on redundant sensory information to maintain pose estimates and thus must solve the same problem although in robotics the

problem is commonly known as sensor fusion. For example, a classical robot called Blanche optimally combines the result calculated by matching algorithm that registers the range data with the map and the measurement from mounted odometer to get a more precise self-location estimate [9]. Sensor fusion for mobile robot navigation is a long standing issue and many statistical methods based on maximum *a posteriori* and maximum-likelihood estimation have been applied to solve it [10]. Recent advances in deployment of robot systems such as cars with their suite of GPS, radar, cameras, and laser scanning sensors to estimate precise lane position, owe much to adoption of probabilistic integration of cues in line with the Bayesian formulation described above [11]. Yet, **such methods**, are generally computationally expensive and unsuitable for application on small, cheap robot platforms. Learning from biology may bring significant potential benefits for solving these problems in the artificial system [10, 12].

We therefore take a bio-inspired approach to firstly understand how animals resolve this task, which in turn may offer inspiration to engineers seeking efficient solutions. As a starting point, we use classic neural network architecture known as a ring attractor network. Ring attractors can be constructed such that the output activity resembles a Gaussian profile that is maintained even in the absence of sensory input. When new sensory input is presented, the activity profile will shift towards and stabilize at the new location. If this sensory input is driven by orientation cues such as path integration or visual features then the Gaussian mean will naturally track the animal orientation. Such networks have been proposed to underpin the head-direction cells in animals [13, 14]. Further when more than one input signal is presented ring attractors can be constructed such that the output settles on the weighted average of the combined cues as required for optimal cue integration [15]. In a recent review, Jeffery et al [16] proposed that ring-attractor networks may provide a general architecture for optimal cue integration. Their biomimetic model (constrained by physiological data from rats) used re-weighting mechanism to achieve optimal integration. **This re-weighting (ruled by Hebbian learning) is driven by the greater activation in the overlap zone of input cues, which strengthens the synapse within the overlapped area and then shifts the activation towards the in-between position of input cues.**

In this study, **we take a more bio-inspired approach that is unconstrained by the biology** and revisit the Touretsky [15] ring attractor network and assess its ability to combine conflicting cues of different strengths. Specifically we seek to assess how this network performs when given cues of different strengths and with different levels of conflict. Specifically, we wish to document if and when the network optimally integrates cues or if it adheres to a winner-takes-all solution, or switches strategy depending on the situation.

Our results suggest that a Touretsky ring attractor network can integrate cues in a manner approaching optimal (i.e, consistent with MLE) for small conflicts. For larger conflicts the network switches to WTA (winner-takes-all) mode, mirroring results of ethological experiments [17]. Performance is shown to be robust to noise and significant reduction in the network size, and thus provides a simple (no re-weighting mechanism required), compact ring attractor solution to

@MM - reviewer said we should specify the method, If it's just a kalman filter wouldn't this be computationally very cheap?

@MM - discuss more details of how the re-weighting works

@MM - this sentence is confusing, shall we just say that we revisit the RA which believed has WTA, but we found that it can do optimal integration and computationally simpler?

cue integration that can provide inspiration for those seeking similar integration networks in animals or act as a bio-inspired method for optimal sensor fusion in robots.

2 Models and Methods

2.1 Touretsky Ring Attractor Model

Artificial Neurons The network is constructed using two populations of CTRNN (continuous time recurrent neural network) neurons which are the simplest nonlinear and continuous dynamical neurons suitable for simulating the subset of real numbers as required for our ring attractor model [18]. The average membrane potential c_i of a CTRNN i^{th} neuron is updated by the differential equation (3), where τ is the positive time constant and I_i is the total number of inputs into the neuron which equals the weighted sum of other neurons' outputs O_j , $j = 1, 2, \dots, n$ and the external inputs, as shown in (4), where W_{ji} is the weight matrix representing the connection strength from j^{th} to i^{th} neuron, g is the activation function and X_i is the external input. To acquire the nonlinear property of the network, the activation function of g should be a nonlinear function. Here we simply applied a semi-linear threshold function with a threshold defined by θ as indicated in (5).

$$\tau \frac{dc_i}{dt} = -c_i + I_i \quad (3)$$

$$I_i = \sum_{j=1}^n W_{ji} O_j + X_i = \sum_{j=1}^n W_{ji} g(c_j) + X_i \quad (4)$$

$$g(c) = \max(0, \theta + c) \quad (5)$$

Network Geometry We implemented a variant of the classic ring attractor network [13] (Fig.2(a)) which replaces the inhibitory interneurons with a single global inhibitory (uniform inhibitory) neuron making the network easier to tune while giving the same performance [15]. Each excitatory neuron in the network has recurrent excitatory connections to all other neurons in the ring with weights decreasing with distance which is crucial for generating the bell-shape activation profile in stable state, as revealed in (6), where d_{ij} is the distance between the i^{th} and j^{th} neuron. Our network poses a single dynamic inhibitory neuron that sums inputs from the excitatory neurons and then proportionally inhibits the entire network. Note, for ease of understanding the recurrent connections from a single excitatory cell are shown in Fig.2 (a) but in reality each neuron has the same set of recurrent connections.

$$W_{ji}^{E \rightarrow E} = e^{\frac{-d_{ji}^2}{2\sigma^2}} \quad (6)$$

Fig.2 (b) shows the process by which the network combines input from multiple cues. We simulate cues of different strengths using Gaussian functions (see equation (7) where K is the scale factor, μ defines the peak position of the Gaussian curve (estimation of the certain property based on the cue) and σ^2 is the variance of the Gaussian function determining the reliability of the signal). To have a corresponding connection with the integration neurons in the attractor, the cues are represented by the activation profile of N neurons with their preference p_i , and so the Gaussian curve is sampled by N points at intervals. This input is then passed to the integration population which is shown in unwrapped form in Fig.2 (b), and with the recurrent connections omitted for ease of reading. The integration population (and also population representing cue 1 and cue 2) has N neurons labeled with their preferences (for example, if these neurons represent the heading directions of the animal, the preferences will be the preferred directions evenly distributed around the entire 360° of possible directions). The inhibitory population has a single dynamic postulated inhibition neuron summing the activations from all integration neurons and which recurrently inhibits all integration neurons. Therefore, in accordance with equations (3) - (5), the average membrane potential of the output neurons (neurons in integration population) is computed by equation (8), where $X1$ and $X2$ represent the activation vectors of cue 1 and cue 2 respectively and u is the membrane potential of the uniform inhibitory neuron (calculated by equation (9)). Note that in order to maintain the nonlinear property and simultaneously guarantee the positive output of the model, we tuned the total input I to c and u using function g according to [15].

Note that in this paper, as an example, we use the ring attractor to represent the heading direction system so all the values have the unit-degree. But generally the unit could be other meanings when this model is applied to other specific contexts.

$$F(i) = \frac{K}{\sqrt{2\pi\sigma}} e^{-\frac{(p_i - \mu)^2}{2\sigma^2}} + \xi N(0, 1), i = 1, 2, \dots, N \quad (7)$$

$$\tau \frac{dc_i}{dt} = -c_i + g \left(\sum_{j=1}^n W_{ji}^{E \rightarrow E} c_j + X1_i + X2_i + W^{I \rightarrow E} u \right) \quad (8)$$

$$\tau \frac{du}{dt} = -u + g \left(W^{I \rightarrow I} u + W^{E \rightarrow I} \sum_{k=1}^n c_k \right) \quad (9)$$

3 Results

Fig.3 (a) shows the response of our ring attractor network configured with 100 neurons when stimulated with two conflicting cues (65° apart) with different variances ($\sigma_{cue1} = 40^\circ, \sigma_{cue2} = 35^\circ$) shown by red and black lines. The response of the network (green line) approaches the MLE, i.e., the optimal integration

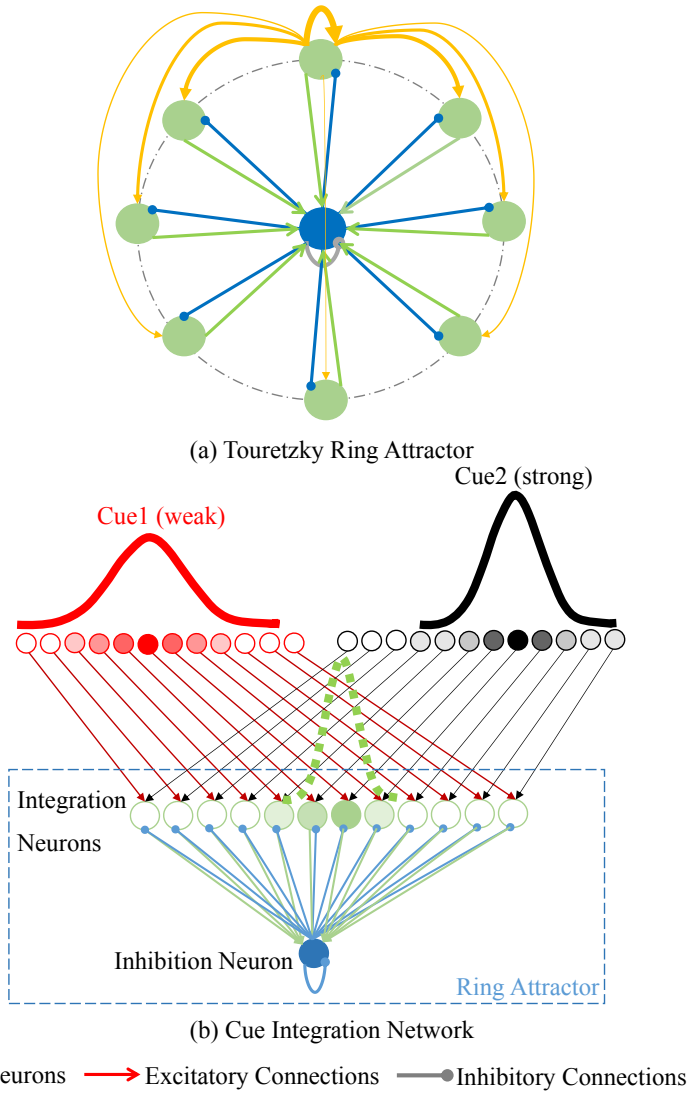

Fig. 2. The implemented Touretzky ring attractor network. (a) Excitatory neurons are shown by green circles, and the global inhibitory neuron depicted by the blue circle. The recurrent excitatory interneurons are shown by orange arrows with connection strength decreasing with distance between neurons. Excitatory and inhibitory connections between the global inhibitory neuron are also shown in blue and green respectively. (b) The full integration network shown in unwrapped form (minus recurrent connections for ease of reading) with example inputs and optimal output overlaid.

(blue dashed line) rather than following the WTA (winner-takes-all) solution. Fig.3 (b) shows that the network response is robust to noise with each cue

corrupted by Gaussian white noise ((7) with $\xi = 0.01$). Finally, inspired by recent anatomical results showing that insects encode their heading direction using populations of only 8 directional neurons in each hemisphere of the central complex [19, 20] we reduced the number of neurons in our integration network from 100 to 8. Fig.3 (c) demonstrates that the cue integration properties of the network remained stable despite the obvious loss of resolution in the Gaussian functions.

To assess the performance of the network across likely scenarios we performed two more experiments using the noise free network with 100 neurons. Firstly, we assessed the performance of the network when presented with cues that were increasingly disparate. Cue 1 ($\mu_{cue1} = 0^\circ, \sigma_{cue1} = 40^\circ$) was presented at the same position throughout the tests, while Cue 2 was presented at increasingly distant positions (μ_{cue2} is from 0° to 180° in 5° steps). We performed this analysis under three conditions: (a) cues with identical variance ($\sigma_{cue1} = \sigma_{cue2} = 40^\circ$); (b) cues with slight differences in variance ($\sigma_{cue1} = 40^\circ, \sigma_{cue2} = 35^\circ$); and (c) cues with significantly different variance ($\sigma_{cue1} = 40^\circ, \sigma_{cue2} = 20^\circ$). Fig.4 shows the peak response of the network (green line) overlaid on the MLE (blue line) and WTA (red line) solutions. With cues of equal variance (Fig.4 (a)) the network response approaches (though never very precisely matches) the MLE solution but changes to WTA-like responses when cue-conflict exceeded approximately 100° . With small differences in variance (Fig.4(c)), the network again weights cue in an approximately optimal manner but shifts to a WTA response at higher values ($> 110^\circ$). In contrast when more significant differences in variance were presented (Fig.4 (d)), the network changes from the MLE to WTA response at much smaller conflicts ($> 60^\circ$). **Fig.4 (b) shows the outputs of ring attractor with re-weighting mechanism when conflict of the original heading direction firing with the light(visual stimulus) increasing (green line) and the data of biological experiments (black line), the whole tendency are very similar with our model's performance though it is not accurately identical due to the parameters setting.**

Secondly we assessed the performance of the network to combine cues when the certainty of one cue was altered while the other was held constant. Specifically, cue 1 and cue 2 were presented 90° apart. While cue 2 variance was held at 40° , the variance of cue 1 was increased from 5° to 200° . Fig.5 shows the peak position of the activation profile of the network changes from a WTA state for uncertainty of cue 1 below 15° and above 160° but performs a weighted average when uncertainty of cue 1 in the range from 20° to 155° . Although not acting in a truly optimal manner the switch from WTA to weighted-average and back again follows the general profile of the MLE prediction.

4 Discussion

In this work, we re-visited the classic ring-attractor network described by Touretsky [15] to assess if it could be configured for optimal cue integration, and if so

@MM : I have changed Fig4 by adding the re-weighting and biological data, and for the limited space, I deleted the schematic to indicate conflict between two cues is increasing. Also have added the statement that our model's performance matches the data of re-weighting and biological data

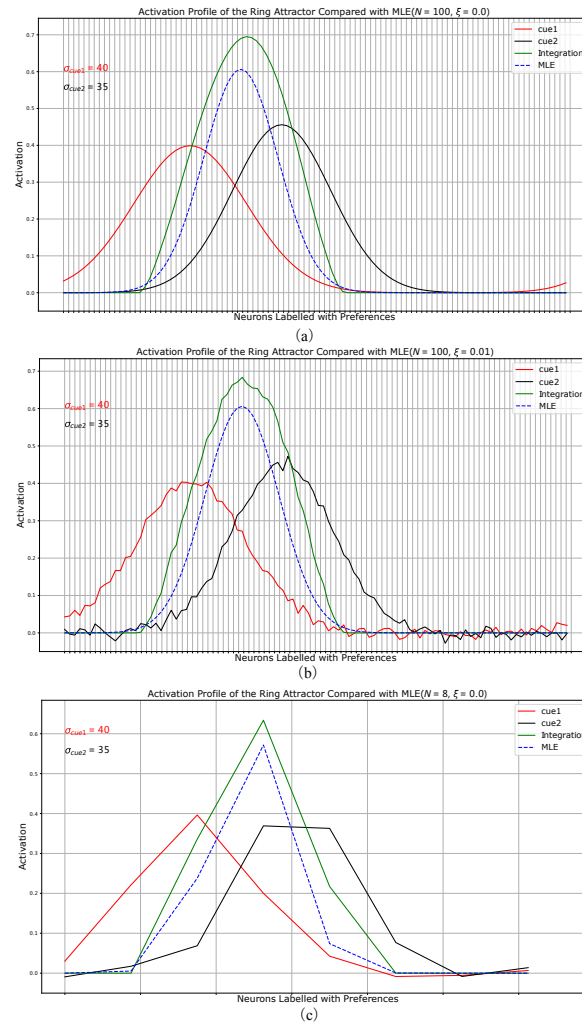

Fig. 3. Integration of conflicting cues by a ring attractor network. Activation profiles of cues are shown by the red and black curves, the output profile of RA (the ring attractor) by the green line, and the MLE by the blue dashed line. (a) shows the results for a noise-free network with 100 neurons, (b) shows the results of the same network with added white noise, and (c) show the results when the number of neurons is reduced to 8.

whether this might give inspiration for those seeking such networks in animals or provide a biologically-inspired solution for robotics.

to state that our model is identical to the Touretsky's, but we reminded the application of cues integration

We report that our implementation of the classic ring attractor although is identical to the Touretsky model, but we show that it can perform optimal-like cue integration when presented with conflicting cues. The network output is also

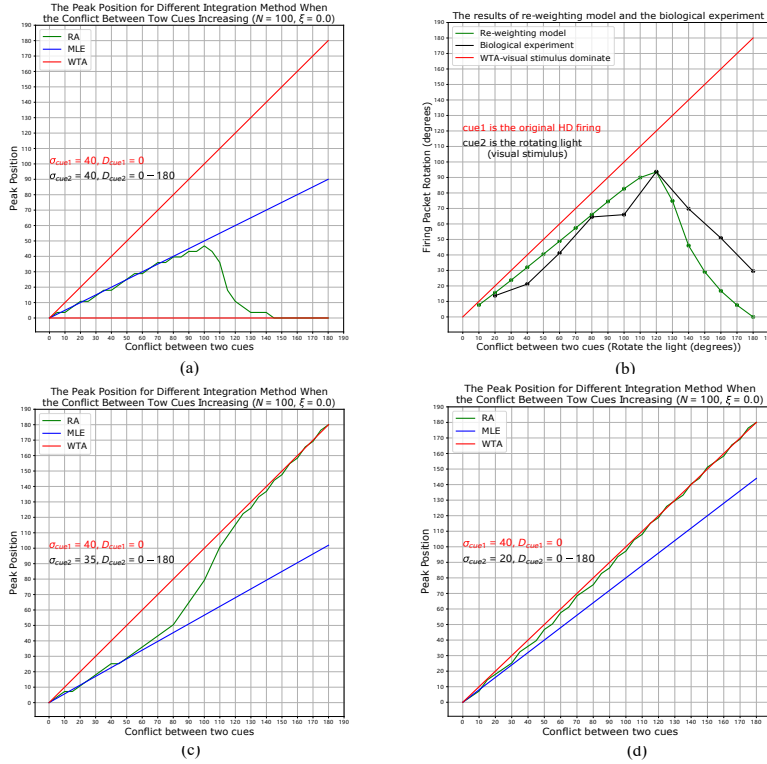

Fig. 4. Network performance with increasing cue conflict. Cue 1 was presented in the same location while cue 2 was presented at increasing distances. For (a),(c) and (d), the response of the RA (ring attractor) is shown by the green line, the WTA prediction by the red line, and the MLE by the blue line. (a) Cues of equal variance, (b) the results of re-weighting model (green line) [21] and biological experiment (black line) [17], (c) Cue 1 has slightly more variance than Cue 1, (d) Cue 1 has significantly more variance than cue 1. Raw data of (b) are provided by Hector Page and Kate Jeffery.

shown to be robust to noise on the sensory input and reduction in size to the 8 neurons that encode direction in insects. Our sweep tests showed that both the variance and distance between conflicting cues strongly affect the network properties. With equal or small differences in variance of cues the network performs a weighted average for small cue conflicts, but switches to a WTA response for larger conflicts. For larger differences the network switches to WTA responses at much smaller conflicts. This changing of response is akin to meta-Bayesian decision making where it is highly sub-optimal to integrate two hugely conflicting cues e.g. one should not go West, when one cue states North and the other South. Instead one should choose the best single option, but how does the agent know when to apply each strategy? We show that the [15] ring attractor network inherently possesses this capacity.

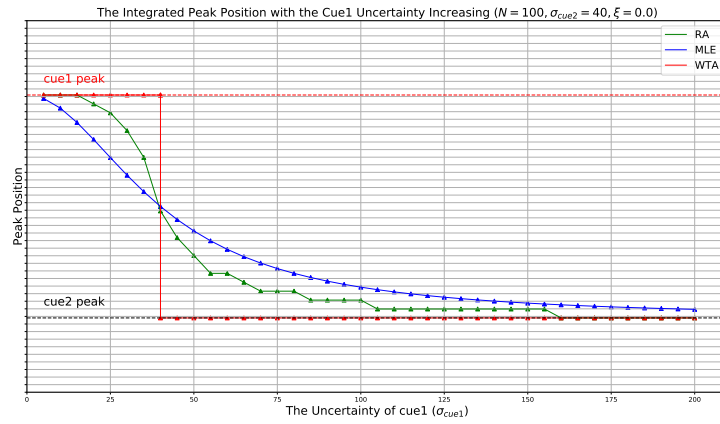

Fig. 5. Network performance with changes in variance difference. Cue 1 and cue 2 were presented at the same location 90° apart. The variance of cue 2 was kept at 40° while cue 1 changed from 5° to 200° in intervals of 5° . The position the peaks of activation profile of cues 1 and 2 are shown by the dashed red and black lines respectively; the WTA response by the solid red line; the MLE by the blue line; and the RA (ring attractor) output by the green line.

Over two decades ago the ring attractor network was cited as a possible solution underpinning the head direction cells in mammals that integrate directional cues from different sensory modalities to maintain an accurate read-out of their current orientation [13]. Recent models of the head direction cells of mammals have moved away from the original ring attractor architecture because the physiology not mirroring the excitatory interconnections required by the original model [21, 22], and the belief that ring attractors will tend to a WTA outcome over the weighted-average observed in behavioral experiments [16]. Through augmentation of these models with a re-weighting mechanism (Hebbian learning) [21] it has been proposed that this network architecture may be a ubiquitous neural circuit underlying optimal cue integration across many functions [16]. Here we provide evidence that the original ring attractor network can also perform weighted cue integration (closely matching the performance of the re-weighting network [21] Fig.4 (b)), or cue selection in a manner closely approximating data from rats [17] (Fig.4 (b)). **Since no one has tried to use pure ring attractor to do cues integration, let alone the analysis of its properties of combining different cues, hence it is a interesting and meaningful reminding to show the ability and property of ring attractor for future researching.**

@MM - again stress our specific contribution?

Direction cells have recently been revealed in insects (*Drosophila*) with so-called E-PG neurons forming a bump of activity that moves in response to both rotation of vision cues and self-motion and combines in both cue selection or cue integration like a averaged weighted [4]. These E-PG neurons have also been shown to have ring attractor dynamics [23]. Biomimetic (highly constrained by the anatomy of the animal) have successfully recreated the activation phenomena

of behavioral experiments [24, 25] but have not, as yet, been extended to the broader cue integration problem discussed here and in [16]. We note that [24] showed that fixed connection weights are sufficient to track the self-motion and visual cues well with the dynamic re-weighting with slower learning rates giving improved performance describing a trade-off between computational complexity and required robustness.

By analyzing the Touretzky ring attractor network, we show that it can still be considered a biologically plausible mechanism to achieve cue integration of the animals. Although not well suited to describe the head-direction system of mammals due to physiological constraints, it is an open question whether other areas of animal brains that perform cue integration can use this ring attractor model. For instance, the lateral accessory lobe (LAL) of insects brain, which is a converging point of sensory information and has inputs from sensory lobes, mushroom body and the central complex [26, 27] provides a candidate to search for such network architectures. To date, we know little about how different cues (like vision memory from mushroom body and path integration from central complex) might be integrated in this area and wherein ring attractors may also play crucial roles. As a bio-inspired neural network, the ring attractor is a compact but efficient model to solve the similar problems in sensor fusion and its anti-noise and stable performance with only 8 neurons endow it the advantage of implementation on robots with limited computation resources.
