Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

3 ABSTRACT
4
5
6

7 Atomically thin black phosphorus (BP) has attracted considerable interest due to its unique properties, such as
8 an infrared band gap that depends on the number of layers and excellent electronic transport characteristics.

9
10 This material is known to be sensitive to light and oxygen and degrades in air unless protected with an
11 encapsulation barrier, limiting its exploitation in electrical devices. We present a new scalable technique for
12 nano-patterning few layer thick BP crystals by direct electron beam exposure of encapsulated crystals
13 achieving a spatial resolution down to 6 nm. By encapsulating the BP with single layer graphene or hexagonal
14 boron nitride (hBN), we show that a focused electron probe can be used to produce controllable local oxidation
15 of BP through nanometre size defects created in the encapsulation layer by the electron impact. We have tested
16 the approach in the scanning transmission electron microscope (STEM) and using industry standard electron
17 beam lithography (EBL). Etched regions of the BP are stabilized by a thin passivation layer and demonstrate
18 typical insulating behavior as measured at 300 K and 4.3 K. This new scalable approach to nano-patterning of
19 thin air sensitive crystals has the potential to facilitate their wider use for a variety of sensing and electronics
20 applications.

INTRODUCTION

The successful isolation of few-layer black phosphorus (BP) has generated remarkable excitement in a very short time.¹⁻³ Such isolation is possible due to its highly anisotropic crystal structure where corrugated layers of phosphorous atoms are bonded by weak van-der-Waals interactions and can be easily separated. Using a similar strategy to that of graphene, atomically thin layers of BP can be extracted from the bulk by mechanical exfoliation⁴⁻⁶ and by liquid phase exfoliation⁷⁻⁹. As it is made progressively thinner, the direct band gap in BP varies from ~0.3 eV in bulk to ~1.5 eV for a monolayer.^{4, 10-14} Crystals only a few nanometers thick demonstrate high carrier mobility (reported hole mobility of 5200 cm²V⁻¹s at room temperature and 45000 cm²V⁻¹s below 20K)¹⁵) and high on-off ratios in field-effect devices (up to 10⁵)^{5, 16-17} offering potential for applications in high-speed optoelectronic devices.^{2, 5, 17-20} Black phosphorous is a complementary addition to the 2D materials library, providing a variable band gap between those of graphene (no band gap) and semiconducting 2D-dichalcogenides (which lie between 1.3-2 eV). Nonetheless, the exploitation of BPs electronic properties is hampered by the materials strong susceptibility to oxidation²¹ in the presence of air. This degradation is amplified by humidity, exposure to light and elevated temperatures^{6, 22-25} leading to a drastic deterioration of BPs electronic and optical properties.²⁴⁻²⁵ The observed degradation rate increases for thinner BP flakes,²⁶ with monolayers visibly degrading over the course of a few minutes and even relatively thick (10 nm) crystals degrading to form droplet-like oxidation bubbles within 24 hours in air.^{4, 6, 24-25, 27} The etching process in thicker flakes (>50 nm) is observed to self-terminate after a few days due to the accumulation of oxidized phosphorus (P_xO_y) forming a protective layer on the surface of the flake²⁸.

Reduced degradation of BP has been achieved using a number of different methods including deliberate generation of a protective surface oxide layer through plasma etching²⁹, coating with alumina,^{25, 30-31} polymers^{6, 30} and ionic liquids³²⁻³³ but perhaps most promising method for electronic device applications is the encapsulation with 2D materials such as graphene³⁴ or hBN.^{16, 34-36} These materials provide an ultrathin, chemically robust and impermeable barrier to anything larger than a single proton.³⁷ Precise patterning of BP nanoribbons has been proposed as a route to tuning the band gap and electronic properties by controlling orientation, width and edge terminations.³⁸⁻⁴² Drndić et al⁴³⁻⁴⁴ have reported nanoscale sculpting of many-layer

1
2
3 (17 nm thick) BP nanoribbons using direct write electron beam ablation in the STEM. Unfortunately the
4
5 theoretically predicted transport properties could not be verified experimentally and the ribbon would have
6
7 been susceptible to atmospheric degradation on removal from the high vacuum of the STEM.⁴³ Additionally, it
8
9 is important to consider the potential effect of electron beam irradiation on the BP structure, both in the context
10
11 of STEM patterning and for the more scalable approach of EBL processing.
12
13
14

15 Here, we develop a scalable protocol to controllably sculpt BP devices using EBL and graphene or hBN
16
17 encapsulation. We demonstrate that introducing atomic scale defects in the encapsulation layer with a focused
18
19 electron beam allows air species to come into contact with selected areas of the embedded BP crystal and
20
21 generate a few-nanometer oxide region around the perforation point. We induce such local oxidation
22
23 controllably within both STEM and EBL instruments and use electron diffraction, energy dispersive X-ray
24
25 spectroscopy (EDXS) and electron energy loss spectroscopy (EELS) to study the atomic and chemical
26
27 structure of the etched locations. After prolonged exposure to ambient conditions, the patterns have a smallest
28
29 feature size of 6 nm (STEM) and 10 nm (EBL). Such resolution is extremely difficult to achieve using other
30
31 traditional masking and etching techniques used in semiconductor fabrication due to the necessity of using
32
33 polymer resists. We further show that oxidized lines as narrow as 10 nm demonstrate clear insulating behavior
34
35 with a breakdown voltage well above that of vacuum even at room temperature.

3 RESULTS/DISCUSSION
4

5 The experimental BP samples were mechanically exfoliated from bulk crystals in a clean argon glovebox to
6 avoid oxidation.³⁹ Thin flakes of few layer BP were identified using their optical contrast and then sandwiched
7 between two graphene (G) or hBN crystals. For STEM experiments, monolayer graphene or hBN sheets were
8 used to encapsulate thin (2-5 layer) BP flakes, which were then transferred to a TEM support film. The full
9 encapsulation and transfer procedure was performed immediately after the BP exfoliation in the same argon
10 chamber via the van der Waals pick-up technique⁴⁵⁻⁴⁶ using our specially developed motorized
11 micromanipulation stage.⁴⁷⁻⁴⁹

Figure 1: (a) Schematic of the graphene-encapsulated BP sample. (b) Optical micrograph of a 3-4 layer BP flake after exfoliation on an oxidized silicon substrate. (c) The same BP flake after top and bottom graphene encapsulation. The dashed lines highlight edges of mechanically exfoliated crystals. All exfoliation and transfer is performed in an argon environment glove box to prevent oxidation of BP during the sample fabrication. (d) The same sample after transfer to a silicon nitride TEM support film. Scale bars for (b)-(d) are 20 μm . (e) Atomic-resolution Wiener-filtered aberration-corrected TEM image of a 5-layer thick area of pristine BP flake. The insets show an image simulation and ball-and-stick model of the [001] orientation. Scale bar is 1 nm. (f) Diffraction pattern from the area imaged in (e), showing two sets of spots corresponding to the upper and lower graphene sheets (misoriented by $\sim 20^\circ$), and the expected BP diffraction spots. The inner BP spots are forbidden reflections which are only visible in few-layered BP flakes. (See supporting information Figure S3 for diffraction pattern without overlays). Scale bar is 2 nm^{-1} .

1
2
3 Figure 1b shows an optical micrograph of an exfoliated BP flake prior to encapsulation. Thin BP flakes
4 deposited on thin thermal silicon oxide layers exhibit an enhanced optical contrast with a constant contrast
5 difference as the layer number is increased, making it simple to identify layer numbers in exfoliated flakes⁵⁰, as
6 with other 2D materials⁵¹⁻⁵². Figures 1c and 1d show the same BP flake (from figure 1b) after encapsulation
7 within a G/BP/G stack on an oxidized silicon wafer and after transfer onto a silicon nitride support grid
8 respectively. Atomic-resolution TEM images obtained at many locations across such encapsulated crystals
9 show the long-range pristine atomic structure of BP with no visible lattice defects in few layer crystals after 5
10 months of storage in air. Low magnification high angle annular dark field (HAADF) STEM images of a
11 previously unimaged area after encapsulation for more than 6 months are included in Figure S6 in the
12 supporting material. Figure 1e shows a typical TEM image where the atomic lattice is clearly visible even
13 without filtering out the spatial frequencies of the encapsulating graphene layers. The high crystal quality of
14 our samples is further confirmed with electron diffraction, as shown in Figure 1f. The spots marked with blue
15 and green are the $\{10\bar{1}0\}$ and $\{11\bar{2}0\}$ reflections for two single layer graphene sheets with the upper and lower
16 graphene lattices twisted relative to each other by $\sim 20^\circ$. Figure 1e also contains the expected spot pattern for
17 BP viewed along $[001]$ where the lattice parameters are $a = 3.31 \text{ \AA}$, $b = 4.38 \text{ \AA}$ and $c = 10.5 \text{ \AA}$, as defined by
18 Hultgren.⁵³ We note that other works have defined the unit cell with the b-axis being longest.^{4, 22, 54-56} The
19 number of layers in our BP samples can be confirmed using the ratio of the $(110)/(200)$ spot intensities in the
20 diffraction pattern.⁴ For the sample presented in Figure 1 the ratio was found to be ~ 0.1 , confirming that this
21 area of BP crystal is 5 layers thick ($\sim 2.6 \text{ nm}$, see Figure S3 in supporting material).

The encapsulated specimen area was found to be relatively robust during prolonged STEM or TEM imaging
at 80 kV, while unencapsulated areas were more beam sensitive. Enhanced resistance to beam-induced damage
has been previously reported in thin molybdenum disulphide (MoS_2) crystals when encapsulated by
graphene.⁵⁷⁻⁵⁸

TEM imaging with electron energies above 80 kV is known to produce defects and holes in graphene and
hBN, with both materials having similar electron beam damage thresholds.⁵⁹ Once a vacancy is formed, the
under coordinated atoms surrounding the vacancy have lowered sputtering energy barriers, and are
preferentially removed forming nanopores.⁶⁰ Although point defects and point defect clusters are impermeable

1
2
3 even to molecular He, theoretical calculations have found that water and oxygen can permeate graphene and
4 hBN when pore diameters exceed ~ 1 nm (as discussed in supplementary material section 4). We thus propose
5 a novel two-stage process for patterning encapsulated BP flakes using the encapsulating flake as a ‘resist’
6 layer. Firstly, a pattern is exposed using an electron beam, creating defects in the encapsulation layer.
7
8 Secondly, the sample is exposed to air, allowing oxidizing species to penetrate through the beam-induced holes
9 and damage the BP crystal underneath, etching it to produce the exposed pattern. In common with direct write
10 techniques⁴³, combining this approach with electron diffraction allows flake patterning to be performed along
11 specific crystallographic directions. Black phosphorus shows strong directional anisotropy in electronic¹⁴ and
12 thermal³ transport due to its ridged structure, and therefore prior knowledge of the crystal orientation is
13 invaluable when fabricating electronic devices to control transport behavior.

Figure 2: HAADF STEM images showing the controlled cutting of nm-resolution lines in an encapsulated (3 layer) BP flake. The width of the 100 nm long cuts is controlled by varying dwell time per pixel (i) 0.05, (ii) 0.1, (iii) 0.25, (iv) 0.5, (v) 1, and (vi) 2.5 seconds. Lines were drawn using a probe current of 1.3 nA, an accelerating voltage of 200 kV and 1 pixel/nm. (a) shows the area immediately prior to patterning. (b) shows the cuts immediately after patterning. (c) shows the same cuts after exposing sample to air at room temperature for 2 days. (d) The solid lines are a comparison of line widths on initial sculpting in the electron microscope (blue data) and after oxidation in air (red data) taken from the area shown in (a)-(c). The dashed lines show the change in line widths in a 2 layer sample as pictured in supporting material Figure S10. The inset in (a) is a demonstration of electron beam writing of “UOM” into a 10 nm thick BP crystal (scale bar: 20 nm).

To demonstrate local etching of BP we exposed a set of 100 nm long lines into a graphene encapsulated 3 layer BP crystal using a focused STEM probe, as shown in Figure 2. By progressively increasing the electron

1
2
3 dose used to make the cuts (pixel dwell-times varied between (i) 0.05 and (vi) 2.5 seconds with 100 pixels and
4
5 1.3nA beam current, 200 kV) we change the amount of damage induced which becomes clearly visible at the
6
7 dose of (iv) $\sim 3 \times 10^9 \text{ e.nm}^{-1}$ as a clear cut approximately 3 nm wide through the entire BP film thickness. Further
8
9 increase in dose leads to effective broadening of the cut up to 5 nm at $2 \times 10^{10} \text{ e.nm}^{-1}$. We then exposed the
10
11 sample to air and ambient light for two days and repeated the imaging to find that the cuts have expanded
12
13 laterally and had identical contrast for all exposure doses above 10^9 e.nm^{-1} . The resulting line width was found
14
15 to be 6 -10 nm wider than before air contact giving the smallest feature size of 9 nm (for the 0.25s dwell time).
16

17 We also patterned a series of 50 nm lines on a thinner encapsulated BP crystal (2 layers), with similar line
18
19 doses, as pictured in Supporting Material Figure S10, and achieved a smaller minimum feature size of 6 nm.
20
21 The line widths are plotted along with those from the 3 layer flake in Figure 2c. The difference in these two
22
23 measurements could be a result of the smaller flake thickness leading to a reduction in the electron beam
24
25 spreading and a resulting decrease in the damage region for the graphene, or to differences in the passivation
26
27 behavior for different BP layer thicknesses. However, we note that the difficulty of accurately focusing the
28
29 electron beam prior to etching, while simultaneously minimizing imaging of the sample to prevent unwanted
30
31 holes being created in the graphene sheet, could also affect the ultimate spatial resolution of the features we
32
33 observe.
34

35 Importantly the dimensions of the damaged regions were found to be stable after initial air exposure and not
36
37 degrade further after several weeks' exposure to ambient conditions. This self-limiting etching behavior is
38
39 likely caused by a self-passivation process and we performed chemical mapping using EEL spectroscopy to
40
41 investigate this phenomena. By studying the total core-loss peak intensities, we estimate that in the center of
42
43 the cut feature the carbon and phosphorus intensities are reduced to around 50% and 35% of the surrounding
44
45 values respectively, indicating that most of the reaction products escape through the holes in the encapsulation
46
47 layer and a relatively small amount of material is left inside of the etched volume often collecting into pockets
48
49 (visible by increased contrast on Fig 2c). High resolution TEM and STEM revealed that the remaining material
50
51 is amorphous and volatile on exposure to the electron beam. A similar etching methodology was applied to
52
53 thicker samples and it was found to be possible to employ high beam currents to etch through the entire BP
54
55 thickness even for a ~ 10 nm thick specimen (the 'UoM' inset from Figure 2).
56
57
58
59
60

1
2
3 One of the key advantages of this patterning technique is that above a critical threshold, the shape of
4 the patterned BP features is mostly invariant with the line dose used to pattern the encapsulating material.
5 Whether we have created isolated defects with a pore size $>\sim 5\text{\AA}$ (cut (ii) in Figure 2) separated by less than a
6 few nm, or continuously penetrated both the BP flake and encapsulating layer (eg. cut (vi) in Figure 2), the
7 self-passivating etching process means that resultant patterned BP area is remarkably similar. This means that,
8 in contrast to conventional STEM sculpting of 2D materials⁶¹⁻⁶³, the 2-step technique can be used to
9 consistently pattern a large area, as the patterning behavior/resultant line width (in BP) is less dependent on the
10 local level of surface contamination or the vacuum level. This effect also helps alleviate any difference in the
11 TEM focus across a sample; the need to prevent the ‘unexposed’ areas from damage due to electron exposure
12 means it is challenging to correctly focus the beam at the writing location, and minor focal differences can
13 otherwise lead to significantly different patterning behavior. The fact that we completely penetrate through BP
14 flakes up to 10nm thick and their encapsulating layers (inset, Fig 1), with similar spatial resolution as for the
15 thin flakes, implies the 2-step technique is likely to be suitable for patterning even thicker flakes.

Figure 3: EEL spectrum imaging of the cut feature labelled (iv) in Figure 2c after oxidation. (a) Shows maps of the absolute intensity of the carbon K edge and the phosphorus L edges obtained by model based least squares fitting of the spectra at every pixel, along with maps of the components of the phosphorus L edges extracted using NMF algorithm corresponding to BP and oxidized phosphorus (P_xO_y) (details of NMF decomposition in Supporting Material). Scale bars are 20 nm. (b) Shows the NMF factors corresponding to the BP and PO signals around the phosphorus L edges, as well as extracted carbon and oxygen K edges. The inset on the O K-edge plot is a map of the absolute intensity of the oxygen edge. (c) Shows the relative elemental intensities (shown by solid lines) along the profile indicated by the dotted line in (a). The dotted lines representing the separated BP and PO components are scaled by fitting their combined intensities to the elemental P intensity.

By performing non-negative matrix factorization⁶⁴ (NMF), the EEL spectra in the region of the phosphorus L edge was blindly separated into components corresponding to BP signals ($L_{2,3}$ onset around 132 eV, L_1 peak

1
2
3 around 188 eV)⁶⁵⁻⁶⁶ and oxidized phosphorus, or P_xO_y (L_{2,3} onset around 137 eV, L₁ peak around 193 eV).⁶⁷
4
5 Details of the decomposition are presented in the supporting information, along with the individual NMF
6
7 components (in Figure S12). The BP and P_xO_y characteristic spectra, and the maps of their strength, are shown
8
9 in Figure 3. The P_xO_y signal is clearly maximized around the edges of the cut region, suggesting that a
10
11 passivating barrier has indeed been formed. Mapping of the carbon K edge indicates that the graphene sheets
12
13 have not been affected by the oxidation process, whilst oxygen K-edge mapping suggests an increased level of
14
15 elemental oxygen in the etched region, although the signal to noise ratio is too low to observe increased levels
16
17 around the edge, as suggested by the P_xO_y map.
18

19 The ability of the BP to form a passivating oxide barrier along the edges of the cuts has important
20
21 implications. If the pattern is stable over time, we can employ the technique to define various electronic
22
23 structures (e.g. transistors, quantum dots, nanoribbons etc.) at an impressive resolution only limited by a
24
25 combination of the electron probe diameter and the thickness of the passivation layer. In order for this
26
27 approach to work the cuts must be electrically insulating.
28

29 To test the electrical transport properties of our patterned structures, we have produced and selectively
30
31 oxidized two hBN encapsulated BP devices, with BP thicknesses of 2 and 4 layers respectively as measured
32
33 using the atomic force microscope (AFM). The lower encapsulating hBN layer had a thickness of ~20 nm, and
34
35 the upper hBN layer was a monolayer. After encapsulation the sample was transferred to a silicon wafer coated
36
37 with a 300 nm thick thermal oxide layer, to enable electrical gating of the BP. Gold was then deposited to
38
39 create high quality electrical contacts as described in our previous glovebox work.⁴⁸
40

41 Prior to the selective oxidation process, both devices demonstrated classical field effect behavior with hole
42
43 mobilities of 2000 cm²/Vs and 200 cm²/Vs for 4L and 2L respectively, similar to earlier reports^{48, 68} on
44
45 encapsulated BP devices. We then used a 100 kV electron beam lithography instrument (Raith EBPG 5200) to
46
47 expose narrow lines across the conductive channel as indicated by the red lines in Figure 4 (a, b). After the
48
49 sample was exposed to ambient conditions, this exposure effectively separated contacts 2 and 3 from the rest
50
51 of the device with a low bias resistivity higher than 10⁸ Ω, well above the 10³ Ω value measured before the
52
53 etching procedure (Figure 4c). The realistic etched line width is estimated to be 12 nm taking into account the
54
55 4 nm pattern size exposed with a 2-3 nm beam diameter and including the 6 nm oxidation broadening. It is
56
57
58
59
60

1
2
3 surprising that a gap only 12 nm wide spanning across 1 μm sample size shows such a high resistivity at room
4
5 temperature (reproducible in both 2L and 4L devices). Furthermore, no leakage current was observed while
6
7 increasing the bias voltage up to 100 mV giving breakdown field of at least 10^7 V/m, better than that of
8
9 vacuum. While the etched regions of the sample changed their conductivity dramatically, other unexposed
10
11 areas (all other contacts) showed very little change, ruling out the possibility of accidental device degradation
12
13 between the measurements.

Figure 4: Electrical characterization of patterned few layer BP. (a) Optical micrograph of the device with multiple metallic contacts highlighted by black dashed line. Blue line shows edges of 4 layer BP flake (4L) and green line 2 layer BP flake (2L). Red lines indicate etched lines (b) AFM topography of the 2L device with crystal edges highlighted with green. (c) Electrical current measured in a two terminal configuration (between contacts 1-2 for the 4L flake and 2-3 for the 2L flake) before and after the etching procedure. The inset shows the dotted traces (voltages after patterning) with a reduced vertical scale to enhance visibility. (d) Current voltage characteristics measured across the 2L and 4L devices compared to unetched 4L sample (contacts 1-4). Scalebars (a) $2\ \mu\text{m}$, (b) $500\ \text{nm}$.

While fabricating such devices it was found to be especially important to avoid any areas which had pockets of trapped contamination - a common feature seen in heterostructures fabricated by the crystal stacking technique.^{47, 69} In the STEM we observed that the action of the electron beam caused such contamination bubbles to etch down through the BP crystal (Figure S3 shows growth of such a hole at a dose rate of $2500\ \text{e}\ \text{nm}^{-2}\ \text{s}^{-1}$). While the exact chemical composition of the trapped material inside the bubbles can vary depending on the techniques and conditions employed during the stacking procedure, we have previously shown that they contain hydrocarbon and oxygen species.⁶⁹ We hypothesize that these hydrocarbons are reduced to more chemically reactive species by the electron beam, which subsequently chemically etch the BP. After an

1
2
3 extended period of time the etching process appears to cease, after which the holes are stable for extended
4 periods (as shown in Figures S4 and S5 in the supporting material). Electron diffraction and EEL spectrum
5 imaging of this region indicate that crystalline phosphorus is entirely absent from the center of the hole
6 although a small amount of oxidized phosphorus remains. The encapsulating graphene layers remain intact
7 although we cannot rule out the presence of small holes. A ring of oxidized phosphorus (P_xO_y) is seen around
8 the edge of the hole, and outside this ring, no loss of crystallinity of the BP is observed. This suggests a similar
9 self-passivation process to that which we observe for the etched lines, where the stable, P_xO_y , reaction product
10 accumulates around the edge of the hole and prevents any further etching and which has been found to provide
11 a passivation barrier for thicker BP flakes (>50 nm)²⁸. Similar behavior was observed in regions that had
12 undergone high resolution TEM or STEM imaging, were then exposed to ambient conditions for up to 2.5
13 months and then returned to the microscope (Figure S9 in the supporting information). Low dose and low
14 accelerating voltage imaging conditions should therefore be employed to prevent the introduction of unwanted
15 point defects while identifying the region of interest for pattern etching.

30 31 CONCLUSION

32
33 In conclusion, we have developed a new method for nanometer scale patterning of few-layered BP.
34 Encapsulation with graphene or hBN is found to provide an impermeable barrier which extends the long-term
35 stability of few-layer BP crystals from a few minutes to at least several months, protecting it from
36 environmental oxidation caused by the presence of light, air and moisture. By selectively damaging the
37 encapsulating layer with an electron probe the protection is locally removed and subsequent exposure to
38 ambient conditions causes etching of the BP crystal that extends 2-3 nm from the damaged region.
39 Importantly, the patterned features are stable and do not expand during subsequent air contact due to
40 passivation by oxygen-containing groups. With spatial resolutions of 6 nm readily achievable in few layer BP
41 crystals, we demonstrate that features as narrow as 10 nm are already electrically insulating. This result
42 highlights a potential route to harnessing the exciting properties of air-sensitive crystals in real applications.
43 Minimizing levels of trapped contamination, and encapsulation with defect free graphene are likely to be

7

8 9 EXPERIMENTAL METHODS

10 11 **Device Fabrication**

12
13 BP samples were mechanically exfoliated from bulk crystals (supplied by HQ Graphene) in an argon filled
14 glovebox (oxygen and water levels below 0.1 ppm) onto a thin film of polypropylene carbonate (PPC). They
15 were then immediately encapsulated using the van der Waals pickup technique, where the top encapsulating
16 flake (supported by a PMMA membrane) is lowered onto the chosen BP flake, and used to slowly lift it away
17 from the PPC substrate. The stack is then lowered onto the lower encapsulating flake. For the TEM/STEM
18 samples, monolayer graphene was used as the encapsulation material, and the stack was transferred onto a
19 Quantifoil or silicon nitride TEM support film, before the PMMA was removed by immersion in Acetone. The
20 TEM support was then dried supercritically in a CO₂ atmosphere to prevent membrane damage due to the
21 liquids surface tension. For the transport samples, hBN was used as the encapsulation material, with a
22 monolayer piece on top, and a ~20 nm thick piece below. The stack was then transferred to a 290 nm thick
23 oxidized silicon film supported by a silicon wafer, which acted as the back gate during transport
24 measurements. Gold contacts were then fabricated using a lift off process after mask definition using EBL.
25 Care was taken to avoid areas where trapped contamination bubbles were observed as these features caused
26 unwanted local BP etching.

41 **TEM/STEM imaging**

42
43 TEM and STEM analysis of the encapsulated BP was performed with a FEI Titan 80-200 ChemiSTEM with
44 probe-side aberration correction at 200 kV and X-FEG electron source (Fig 2, Fig 3. Fig. S1-S3, S5 and S7-9).
45 STEM experiments were performed with a 21 mrad convergence angle probe and probe current between 75 pA
46 and 1.5nA. Whilst navigating to the region of interest for etching, low probe currents, low dwell times (1us)
47 and low magnification were employed to minimize unwanted irradiation damage. The HAADF detector
48 collected electrons scattered between 48 mrad and 191 mrad. EDX spectrum imaging was performed with a
49 Super-X detector with a solid angle of ~0.7 sr. EEL spectra were acquired using a GIF Quantum with an
50

55
56
57
58
59
60

1
2
3 energy dispersion of 0.25 eV and a collection angle of 38 mrad, providing an effective energy resolution of
4
5 1.75 eV. Complementary EELS data was also obtained from a Nion UltraSTEM100 aberration corrected
6
7 STEM operated at 60 kV with a beam current of 100 pA and showed similar features to that presented in Fig.
8
9 3. The cold field emission gun had an energy spread of 0.35 eV and core loss spectrum images were acquired
10
11 with a collection angle of 30 mrad. Aberration corrected TEM results were acquired on a JEOL ARM 200F at
12
13 an operating voltage of 80 kV (Fig 1). The BP flakes were found to be robust to prolonged STEM imaging at
14
15 200 kV over the acquisition time of 19 s, (total dose of $\sim 47 \text{ e.nm}^{-2}$ with a low dose rate of $2.5 \text{ e.nm}^{-2}\text{s}^{-1}$). The
16
17 encapsulated BP crystal structure also appears stable when imaged in TEM, showing little changes even after
18
19 extended atomic resolution imaging at 80 kV up to doses of $2.6 \times 10^7 \text{ e.nm}^{-2}$ and 200 kV up to doses of 4.8×10^6
20
21 e.nm^{-2} . However, imaged regions subsequently degraded when removed from the microscope vacuum,
22
23 demonstrating that the graphene encapsulation had been damaged.

24 25 **TEM/STEM Analysis and Simulation**

26
27 Principal Component Analysis (PCA) was performed on EELS spectrum imaging data using the Hyperspy
28
29 package to improve the signal to noise ratio.⁷⁰⁻⁷² For the EELS spectrum images shown in Figure 3, the non-
30
31 negative matrix factorization (NMF) algorithm packaged in Hyperspy was run on a section of the spectrum
32
33 image around the energy range of the phosphorus peak, after background removal and energy alignment using
34
35 the zero loss peak. The components were then visually divided into BP and PO components (components
36
37 pictured in Figure S12 in the supporting information), and summed to give reconstructed BP and P_xO_y spectra.
38
39 For Figure S8 in the supporting material, multiple linear least-squares regression (MLLS) was used to separate
40
41 P_xO_y and BP peaks. Both analysis approaches showed the same qualitative results. Further in depth
42
43 consideration of the EELS analysis is provided in supplementary material section 5.

44
45 TEM image simulation was performed using the JEMS software.⁷³ The settings for this simulation were
46
47 performed for a JEOL ARM200F: with accelerating voltage 80 kV; C_C 1.2 mm; C_S -0.01 mm; C_5 : 10 mm;
48
49 defocus: -8 nm and energy spread: 0.8 eV. The defocus spread was: 3 nm.

50 51 **Patterning Parameters**

52
53 Lines were exposed in suspended graphene encapsulated hBN flakes using a FEI Titan 80-200 ChemiSTEM
54
55 with a 200 kV accelerating voltage. Beam currents up to 1.3 nA were used, with a step size of 1 nm per pixel
56
57
58
59
60

1
2
3 and the pixel dwell time was varied, giving total line doses between 0.2-2 nC/nm. For EBL thin BP areas were
4 exposed in hBN encapsulated flakes using a 100 keV Raith EBPG 5200. A beam current of 200 pA was used,
5 with a step size of 0.85 nm per pixel and a pattern width of 4.25 nm. The dwell time was chosen to give a total
6 area dose of 1 C/cm².
