18 **Abstract**

19 We investigated the resistance of individual constituent casein epitopes (α S₁-, α S₂-, β - and κ -CN)
20 in food-grade milk protein sodium caseinate (NaCN) to simulated human gastro-duodenal digestion.
21 The influence of NaCN adsorption to the surface of oil-in-water emulsion droplets and the effect of
22 crosslinking of the protein with enzyme transglutaminase (TG) on the proteolysis were studied by
23 indirect ELISA. TG crosslinking rendered fragments of casein molecules significantly resistant to
24 digestion. However, it depended on the type of casein and whether NaCN was presented in solution
25 or emulsion. The crosslinking was found to considerably hinder the digestion of several amino acid
26 regions in one of the major caseins of NaCN, β -CN. For α S₁- and α S₂-CN, only limited resistance to
27 digestive enzymes was observed after NaCN had been crosslinked in solution but not (or to a limited
28 extent) in emulsion. κ -CN proved to be the least resistant to the enzymatic hydrolysis regardless of
29 the TG treatment. Our work shows for the first time how the digestibility of individual components of
30 important food-grade protein ingredients can differ in a complex, colloidal food system. It also shows
31 an example of how the digestibility can be modulated by chemical and physical structuring.

34
35 **1. Introduction**

36 Micro- and macro-structural organisations of proteins in foods are often generated by various food
37 processing methods (e.g., emulsification, heating, gelation, enzymatic treatment, etc.). Although
38 required to create desirable, functional structures in food, the processing can render proteins either
39 significantly less or significantly more accessible for the digestive enzymes of the human

40 gastrointestinal tract and hence modify amino acid bioaccessibility during digestion (Singh & Ye,
41 2013; Gan, Bornhorst, Henrick, & German, 2018).

42 The digestion of a single protein leads to the release of hundreds of peptides in the gut lumen that
43 can be identified by mass spectrometry (Boutrou et al., 2013) but the information is only semi-
44 quantitative. It is therefore difficult to get a clear picture of the extent of hydrolysis of a specific
45 protein domain (Dupont, 2017). An alternative to the mass spectrometry has been proposed based
46 on the use of monoclonal antibodies with known specificity (Dupont, Rolet-Repecaud, & Senocq,
47 2003). The underlying idea is that when an antibody binds the epitope of a protein that contains a
48 protease cleavage site, it means that the epitope has not been cleaved by the enzyme. In contrast,
49 hydrolysis of the epitope causes a loss of interaction between the antibody and the target protein
50 that can be easily monitored by immunoassays such as ELISA. This strategy was successfully
51 applied to follow proteolysis events occurring during cheese ripening (Senocq, Dupont, Rolet-
52 Repecaud, & Levieux, 2002). As a result of their loose structure, caseins (CNs) are particularly
53 adapted to this approach as most of their epitopes are sequential, allowing the production of a wide
54 collection of monoclonal and polyclonal antibodies targeting several epitopes of αS_1 -, αS_2 -, β - and κ -
55 CN (Johansson et al., 2009).

56 Enzymatic crosslinking of proteins is an attractive and feasible food technology due to the
57 specificity of enzymes and the mild reaction conditions (Buchert et al., 2010). Modification with
58 crosslinking enzymes such as transglutaminase (TG) has been extensively used to change the
59 functionality of proteins and thereby to improve the textural quality, stability and function of protein-
60 based food products (Dickinson, 1997). The enzyme permanently crosslinks proteins through an acyl
61 transfer mechanism between glutamine and lysine residues (Griffin, Casadio, & Bergamini, 2002).
62 Monogioudi et al. (Monogioudi et al., 2011) showed that enzymatically crosslinked purified β -CN was
63 more resistant to pepsin than a non-crosslinked protein. The crosslinking was also shown to delay
64 the simulated human gastro-duodenal proteolysis of food-grade protein sodium caseinate (NaCN) in
65 emulsion, which prevented the emulsion from destabilising under the gastric conditions
66 (Macierzanka et al., 2012). Our recent *in vivo* human study (Juvonen et al., 2015) showed that even
67 subtle structural modification of NaCN interfacial layer in emulsion by TG was able to alter the early
68 postprandial profiles of glucose, insulin, CCK, appetite and satiety through a decreased protein
69 digestion, without significantly affecting the gastric emptying or an overall lipid digestion. Although we
70 showed significant differences in the extent of digestion between NaCN crosslinked in emulsion and
71 in solution (Macierzanka et al., 2012), the detailed roles of constituent casein epitopes of NaCN (i.e.,
72 αS_1 -, αS_2 -, β - and κ -CN) in exerting the resistance to digestion could not be evaluated. This
73 fundamental knowledge is required for developing novel foods as the nutritional interventions aiming
74 to modulate dietary protein bioaccessibility and amino acid bioavailability provides the best strategy
75 for preventing diet-related health problems such as food allergies or sarcopenia.

76

77 **2. Materials and methods**

78 **2.1. Materials**

79 Food-grade sodium caseinate (NaCN; 90% protein) was obtained from DMV International (The
80 Netherlands). Microbial transglutaminase (TG) and triglyceride oil were treated as described before
81 (Macierzanka et al., 2012). Details have also been given in the Supplementary Material (SM; S1.1.).
82 Eighteen monoclonal antibodies and one polyclonal antibody (SM; Table S1, Fig. S1) were taken
83 from the INRA's collection in order to cover as much of the sequences of αS_{1-} , αS_{2-} , β - and κ -CN as
84 possible (Johansson et al., 2009; Fig. S1). More details have been given in the SM (S1.1.).

85 **2.2. NaCN in emulsion and solution; sample preparation and characterisation**

86 The preparation of NaCN-stabilised emulsions and NaCN solutions, TG crosslinking, *in vitro*
87 gastro-duodenal digestion experiments, and SDS-PAGE characterisation of the digestion samples
88 were done as described previously (Macierzanka et al., 2012). For convenience, detailed
89 experimental procedures have also been given in the SM.

90 **2.3. Indirect ELISA**

91 The indirect ELISA was performed for selected time-point samples from digestion of NaCN in
92 order to detect protein regions (in αS_{1-} , αS_{2-} , β - and κ -CN) resistant to digestion, using the
93 antibodies listed in Table S1. Detailed experimental procedure has been described in the SM (S1.7.)
94

95 **3. Results and discussion**

96 **3.1. SDS-PAGE characterisation**

97 We have investigated the impact of NaCN adsorption to the oil-water interface in an emulsion and
98 its subsequent crosslinking with TG on the susceptibility of constituent casein polypeptides to
99 simulated human gastro-duodenal proteolysis. SDS-PAGE was used initially to provide a rapid
100 screening of the overall behaviour of NaCN during the digestion experiments carried out for the
101 protein presented in different physical-chemical states (i.e., in solution vs. adsorbed, and non-
102 crosslinked vs. covalently crosslinked by TG) and under different conditions (i.e., +/- vesicular PC in
103 the gastric digestion compartment). This initial part of the study was carried out using a similar
104 approach to the work presented previously (Macierzanka et al., 2012). Therefore, it was important to
105 demonstrate that the SDS-PAGE characterisations of the digestion products in the present study
106 were consistent with the results shown in that report. This offers a coherent experimental
107 introduction to the original ELISA results reported in this paper. The SDS-PAGE results are shown in
108 the Supplementary Material (SM; Fig. S2). Because of their consistency with the previously
109 published work (Macierzanka et al., 2012), detailed description and discussion of the results have
110 only been given in the SM (S2.1.).
111

112 **3.2. ELISA study**

113 An important consideration before analysing ELISA results is an effect that crosslinking might
114 have on the binding properties of antibodies, i.e., whether the crosslinking could block antibodies
115 even though the peptides they are specific to remain intact during the digestion. Crosslinking could
116 theoretically affect antibody binding the target protein, causing a decrease in immunoreactivity due to
117 steric hindrance. Nevertheless, in the present study, ELISA results were expressed as residual

118 immunoreactivity (RI) normalised against the immunoreactivity detected for undigested protein
119 (native i.e. non-crosslinked, or crosslinked), thereby accounting for potential changes in antibody
120 binding efficiency resulting from crosslinking. A loss of signal, therefore, means a hydrolysis of the
121 epitope and not steric hindrance.

122 After crosslinking NaCN with TG, significant RIs of several β -CN fragments were observed in
123 digestion samples (Fig. 1). This suggests that the crosslinking restricted hydrolysis by digestive
124 enzymes. The RI was significantly lower for the non-crosslinked protein. The fragment f4-28 was the
125 only one, for which the RI of over 80% persisted until the end of the gastric phase and was still up to
126 ca. 60% during the first 5 min of the duodenal proteolysis (Fig. 1B,D). In emulsion, approximately
127 70% of the adsorbed β -CN is closely associated with the oil-water interface (Mackie, Mingins, &
128 North, 1991), with one exception being the sequence of 40–50 residues at the N-terminus. The
129 sequence is predominantly hydrophilic and thus oriented into the aqueous phase (Dickinson, 2006).
130 It contains four phosphoserine residues (Table S1). The electrostatic repulsion produced by this part
131 of the protein is crucial for preventing coalescence of emulsion droplets (Caessens, Gruppen,
132 Slangen, Visser, & Voragen, 1999). All the above suggests that the fragment f4-28 might remain
133 exposed to the TG, not only in solution but also after the protein had been adsorbed to oil droplets in
134 emulsion. This fragment contains one lysine (Table S1) that is the likely residue crosslinked and
135 responsible for the high RI observed during the gastric phase of digestion (Fig. 1B,D). In the
136 absence of crosslinking, the fragment was much more susceptible to pepsinolysis, and the RI fell to
137 ca. 10% after 60 min of gastric digestion (Fig. 1A,C).

138 Another segment of β -CN, which expressed increased resistance to pepsin after crosslinking was
139 the fragment f94-113 (Fig. 1F,H). At the end of the gastric digestion, its RI was up to ca. 40%
140 depending on the crosslinking and digestion conditions (i.e., solution vs. emulsion, +/- PC). This
141 short region of β -CN contains five lysine residues (Table S1) that could be crosslinked, and hence
142 restrict access of pepsin during the digestion. However, in the absence of PC, relatively high RI (up
143 to ca. 30% under the gastric conditions) of this fragment was also seen for the non-crosslinked
144 protein digested in emulsion (Fig. 1G). This suggests that adsorption to the interface alone might
145 have contributed to restricting access of pepsin. Much higher resistance to pepsinolysis (RI of ca.
146 95% in the absence of PC) was recorded for the adjacent fragment f133-150, regardless of the TG
147 pre-treatment in emulsion (Fig. 1K,L), but not in solution (Fig. 1 I,J), indicating protection must have
148 been limited to the protein segment adsorbed at the oil–water interface. Both, f133-150 and f94-113
149 are parts of the M_r 6 kDa peptide, which can persist during the pepsinolysis of purified β -CN in
150 emulsion (Macierzanka et al., 2009). The f133-150 contains several aliphatic residues and a
151 tryptophan (Table S1), which may be closely associated with the oil phase (Dickinson, Horne,
152 Pinfield, & Leermakers, 1997). Such a close interaction of the M_r 6 kDa peptide with the oil phase
153 was suggested to be the reason for its protection from pepsinolysis (Macierzanka et al., 2009). Here,
154 such behaviour has been confirmed by ELISA for β -CN adsorbed to the interface in the presence of
155 several other constituent caseins of a food-grade NaCN. In the presence of PC, the protective effect

156 of the interface was completely abolished for the f133-150 (Fig. 1K,L) and significantly reduced for
157 the f94-114 (Fig. 1G), so their resistance to digestion was similar to that observed in solution (Fig.
158 1I,J and 1 E, respectively). Vesicular PC introduced to the gastric digestion mix is very efficient in
159 displacing protein (including NaCN) from the oil–water interface into the surrounding aqueous phase
160 of emulsion as the lipid is more surface active (Macierzanka et al., 2009; Macierzanka et al., 2012)
161 After rapid desorption, the protein is then digested with the kinetics similar to those observed in
162 solution. Here, it has been clearly seen for both f133-150 and f94-113.

163 The crosslinking also improved the RI of f167-178 (Fig. 1N), although to a lesser extent in
164 emulsion (Fig. 1P). This short protein fragment contains two lysine and two glutamine residues
165 (Table S1), which could have been crosslinked and therefore contributed to restricting the hydrolysis.
166 Other fragments of β -CN (i.e., f33-49 and f184-202) showed very little RI (SM; Fig. S3).

167 We have observed a rapid degradation of α S₁-CN in non-crosslinked NaCN (Figs. 2, S4). The TG
168 crosslinking improved resistance of two protein fragments (i.e., f56-74 and f75-92) to hydrolysis by
169 pepsin, however the protection was predominantly observed for the protein crosslinked in solution
170 (Fig. 2B,F) than in emulsion (Fig. 2D,H). The adsorbed α S₁-CN molecule is depicted as a tri-block
171 polymer, with a hydrophobic region at each end and a hydrophilic central loop containing several
172 phosphoserines (Dickinson, 2006). Thus, one can expect that in both emulsion and solution the TG
173 should have accessed and crosslinked the central region of the protein more easily than the terminal
174 regions. Interfacial rheology studies (Faergemand, Murray, Dickinson, & Qvist, 1999) demonstrated
175 that the structural build-up for adsorbed α S₁-CN was slower than for either β -CN or NaCN. This was
176 assumed to be caused by slower adsorption of α S₁-CN and/or possibly faster crosslinking of the
177 other proteins. A significant decrease in crosslinking kinetics (calculated from the loss of monomeric
178 caseins during the incubation with TG) upon protein adsorption to lipid droplet was found to be a
179 general phenomenon for all constituent caseins of NaCN (Macierzanka et al., 2011). However,
180 crosslinking of α S₁-CN was reduced much more significantly than other caseins. Hence, the limited
181 crosslinking of adsorbed α S₁-CN might have accounted for the low RI of f56-74 and f75-92 observed
182 here (Fig. 2D,H).

183 Increased RI has been recorded for another fragment of α S₁-CN, f133-151, although similar
184 results were observed for both non-crosslinked and crosslinked samples, and only after the protein
185 had been adsorbed at the oil–water interface (Fig. 2K,L). This segment of α S₁-CN contains 7
186 hydrophobic residues (i.e., Val, Ile, Met, 2x Phe, 2x Met), and was previously shown to reside very
187 close to the interface after protein adsorption (Dickinson et al., 1997). This close interaction with the
188 oil might have offered protection from proteolysis in a similar way as for fragments f133-150 and f94-
189 113 of β -CN (Fig. 1G,H,K,L), although, to a more limited extent. As with the β -CN fragments, the
190 protection was reduced when the digestion was carried out in the presence of PC (Fig. 2K,L),
191 suggesting that also in this case PC might have displaced the protein from the oil-water interface, so
192 the protein was digested mainly in the aqueous phase of emulsion. Other fragments of α S₁-CN (i.e.,
193 f1-19, f19-37, Nat f125-132 and f149-166) showed very little RI (SM; Fig. S4).

194 We have also investigated the digestibility of the two minor constituents of NaCN: α S₂-CN and κ -
195 CN. For the digested emulsion samples, all of the α S₂-CN-specific antibodies returned very low RI,
196 regardless of the pre-treatment with TG (data not shown). α S₂-CN is the most hydrophilic of all
197 caseins, which is the result of three clusters of anionic groups in the amino acid sequence,
198 composed of phosphoserine and glutamyl residues (Farrell et al., 2004). The overall hydrophilic
199 nature of α S₂-CN could make it more exposed to the aqueous phase of emulsion than β -CN and
200 α S₁-CN after NaCN had been adsorbed to the oil droplets, therefore making α S₂-CN more
201 vulnerable to the digestive enzymes. This, coupled with its lower crosslinking rate in emulsion than in
202 solution (Macierzanka et al., 2011), would possibly explain that the limited resistance of the protein
203 to digestion was only seen after the crosslinking in solution (Fig. S5). The most pronounced effect
204 was observed for f96-114 (Fig. S5 F). This region of α S₂-CN contains one lysine and three glutamine
205 residues (Table S1) that offer potential sites for TG. However, it remains unclear why the other two
206 epitopes (f16-35 and f76-95) showed more modest resistance to digestion after the incubation with
207 TG (Fig. S5 B,D) despite the fact that they contain 5-6 TG amino acid substrates each (Table S1).

208 The antibodies specific to κ -CN only showed insignificant RI of this protein in NaCN samples
209 digested in solution or in emulsion (data not shown). The κ -CN contains lowest proportion of lysine
210 and glutamine residues, and less phosphoserine than other caseins (Farrell et al., 2004). It also
211 comprises a considerable amount of β -structure (Huppertz, Fox, & Kelly, 2018). Both of these factors
212 have been used to explain much poorer crosslinking of κ -CN compared to the other caseins in NaCN
213 (Macierzanka et al., 2011). In general, caseins in NaCN solutions exist as a dynamic system of
214 casein monomers, complexes, and aggregates (Lucey, Srinivasan, Singh, & Munro, 2000),
215 depending on conditions such as protein concentration, pH, ionic strength, temperature, etc. For
216 example, at low ionic strength (3 mM) NaCN was found to be present as individual molecules
217 (HadjSadok, Pitkowski, Nicolai, Benyahia, & Moulai-Mostefa, 2008) but formed small aggregates
218 (hydrodynamic radius = 11 nm) at high ionic strength (>100 mM). In dilute aqueous solutions at
219 neutral pH, NaCN consists predominantly of protein nanoparticles (up to 20 nm) in equilibrium with
220 free casein molecules, and some supramolecular species composed largely of κ -CN (Dickinson,
221 2010). Recent discussion on NaCN suspensions and casein micelles (Huppertz et al., 2017)
222 proposed a model where NaCN particle suspension consist of assembled non-spherical primary
223 casein particles (PCPs, which are naturally present in casein micelles). The κ -CN rich domains are
224 likely to be located on the surface of the assembled structures. The above characteristics may reflect
225 conditions of the NaCN solutions used in our present study. The possible easy access of digestive
226 enzymes to κ -CN together with its poor ability to crosslinking may therefore account for the rapid
227 hydrolysis of the protein under the *in vitro* digestion conditions.

228 For the α S₁-CN and the α S₂-CN, the crosslinking seemed to offer more protection to digestion
229 after the incubation of NaCN with TG in solution than in emulsion (Figs 2 and S5). Apart from the
230 aforementioned higher rate/degree of crosslinking of the caseins in solution (Macierzanka et al.,
231 2011), the reason might also lie in the type of the crosslinking observed in the two systems. In the
232 same studies, it was shown that incubation of NaCN with TG in solution might have led to some

233 intramolecular crosslinking as the oligomers formed were found to be more mobile on SDS-PAGE
234 than their counterparts formed from NaCN crosslinked at the oil-water interface, indicating that
235 intermolecular crosslinking might have prevailed at the interface. Therefore, the higher extent of
236 crosslinking and more compact structuring of the proteins offered by the intramolecular crosslinks
237 might account for some fragments of αS_1 -CN and αS_2 -CN incubated with TG in solution being more
238 resistant to digestion than those crosslinked in emulsion. This leads to the conclusion that the group
239 of oligomers of M_r ca. 50-100 kDa formed during the gastric digestion of crosslinked NaCN in
240 emulsion (Fig. S2 F), might have been mainly composed of the β -CN fragments that showed
241 significant resistance to pepsinolysis (Fig. 1).

242 Our results suggest that the TG crosslinking can improve resistance of casein molecules to
243 gastrointestinal digestion, if, for example, this is required for modulating phase behaviour of protein-
244 stabilised emulsions in the stomach and the rate of nutrients release (van Aken et al., 2011). The
245 findings might then be useful for optimising protein structuring in personalised nutrition in order to
246 modulate specific physiological responses to food, such as the ileal brake, which could in turn
247 determine satiety and calorie intake.

331 Figure captions

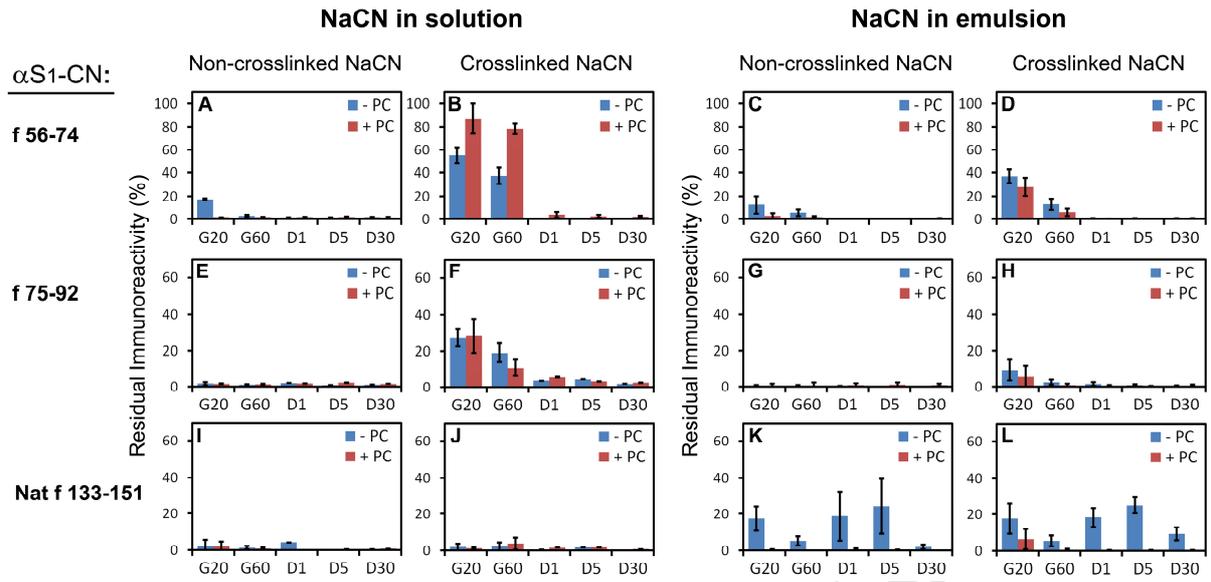

332
 333 **Fig. 1.** Residual immunoreactivity (RI) of β -CN fragments (f) determined in time-point samples
 334 collected during the *in vitro* digestion of NaCN (results were normalised against the immunoreactivity
 335 detected for undigested protein sample; native i.e. non-crosslinked, or crosslinked). Effect of (i)
 336 presenting NaCN in aqueous solution (1 mg/mL) or emulsion (1 mg/mL), (ii) crosslinking of the
 337 protein with TG before digestion, and (iii) carrying out the digestion experiments in the presence or
 338 absence of vesicular phosphatidylcholine (PC) in the gastric phase of digestion. Gastric samples
 339 have been marked with G and duodenal with D, followed by a number corresponding to the digestion

340 time (min) after which the samples were taken. Extended version of Fig. 1 has been shown in the
341 Supplementary Material (Fig. S3).

342 **Fig. 2.** Residual immunoreactivity (RI) of α S₁-CN fragments (f) determined in time-point samples
343 collected during the *in vitro* digestion of NaCN. For more details see caption of Fig. 1. Extended
344 version of Fig. 2 has been shown in the Supplementary Material (Fig. S4).

ACCEPTED MANUSCRIPT

Highlights:

- Transglutaminase crosslinking can impact on gastrointestinal proteolysis
- The crosslinking improves resistance to digestion of caseins in sodium caseinate
- The resistance strongly depends on the type of constituent casein (αS_1 , αS_2 , β , κ)
- The resistance depends on presenting protein in either solution or emulsion
