Apollo: a flexible, powerful and customisable freeware package for choice model estimation and application

Stephane Hess^{*} David Palma[†]

May 24, 2019

Abstract

The community of choice modellers has expanded substantially over recent years, covering many disciplines and encompassing users with very different levels of econometric and computational skills. This paper presents an introduction to *Apollo*, a powerful new freeware package for **R** that aims to provide a comprehensive set of modelling tools for both new and experienced users. *Apollo* also incorporates numerous post-estimation tools, allows for both classical and Bayesian estimation, and permits advanced users to develop their own routines for new model structures.

Keywords: Apollo; choice modelling; estimation; discrete continuous; software

1 Introduction

A brief explanation is needed as to our choice of the name *Apollo*. After failing to come up with a clever acronym, we turned to Greek mythology. The obvious choice would have been Cassandra, with her gift of prophecy and the curse that nobody listened to her (a bit like choice modellers trying to sell their ideas to policy makers). Alas, the name is already used for a large database package, so we resorted to Apollo, the Greek god of prophecy who gave this gift to Cassandra in the first place. Choice modelling techniques have been used across different disciplines for over four decades (see McFadden 2000 for a retrospective and Hess and Daly 2014 for recent contributions and applications across fields). For the majority of that time, the number of users of especially the most advanced models was rather small, and similarly, a small number of software packages was used by this community. In the last two decades, the pool of users of choice models has expanded dramatically, in terms of their number as well as the breadth of disciplines covered. At the same time, we have seen the development of new modelling approaches, and gains in computer performance as well as

software availability have given an ever broader group of users access to ever more advanced models.

These developments have also seen a certain fragmentation of the community in terms of software, which in part runs along discipline lines. Notwithstanding the most advanced users who develop their own code for often their own models, there is first a split between the users of commercial software and those using freeware tools. Commercial packages have historically been computationally more powerful but may have more limitations in terms of available model structures or the possibility for customisation. On the other hand, freeware packages may have limitations in terms of performance and user friendliness but may benefit from more regular developments to accommodate new model structures.

[†]D.Palma@leeds.ac.uk; Institute for Transport Studies and Choice Modelling Centre, University of Leeds (UK)

A further key differentiation between packages is the link between user inputs and interface and the actual underlying methodology. Many existing packages, both freeware and commercial, are black box tools where the user has little or no knowledge of what goes on "under the hood". While this has made advanced models accessible to a broader group of users, a disconnect between theory and software not only increases the risk of misinterpretations and misspecifications, but can also hide relevant nuances of the modelling process and mistakenly give the impression that choice models are "easy tools" to use. On the other hand, software that relies on users to code all components from scratch arguably imposes too high a bar in terms of access.

Existing software also almost exclusively allows the use of only either classical estimation techniques or Bayesian techniques. This fragmentation again runs largely in parallel with discipline boundaries and has only served to further contribute to the lack of interaction/dialogue between the classical and Bayesian communities. A final difference arises in terms of software environment. While commercial software usually provides a custom user interface, freeware options in general (though not exclusively) rely on existing statistical or econometric software and are made available as packages within these. The latter at times means that *freeware* packages are not really free to use (if the host software is not), while there are also cases of software being accessible only in either Windows or Linux, not both.

The above points served in large part as the motivation for the development of *Apollo*. Our aims were:

Free access: Apollo is a completely free package¹ which does not rely on commercial statistical software as a host environment.

Big community: Apollo relies on R, a free software environment for statistical computing and graphics, which is very widely used across disciplines and works well across different operating systems (R Core Team, 2017)².

Transparent, yet accessible: *Apollo* is neither a blackbox nor does it require expert econometric skills. The user can see as much or as little detail of the underlying methodology as

 2 In the remainder of this paper, we do not provide details on common R functions and syntax used in the code, or how to run R code, and the reader is instead referred to R Core Team (2017). Most users will run R from a shell such as RStudio (RStudio Team, 2015). A full Apollo model file, or any other R script, can also be run from the command line, without accessing R directly. This can be useful when running many scripts unattended, or when submitting jobs to a computer cluster. The command to do this changes depending on the operation system and the local directory structure. In Linux, the command is as follows: R CMD BATCH model.R. In Windows, the command is for example as follows: "C:\Program Files\R\R-3.5.1\bin\R.exe" CMD BATCH model.R. Note that in both cases the working directory should be set within the model file using the setwd function. The output that would normally be printed to the R Terminal will instead be written in a file called model.Rout, which can be opened with any plain text editor. For the syntax shown in this paper, it is just worth noting that in R, a line starting with one or more # characters is a comment. We tend to use a single # for optional lines that a user can comment in and out, and ### for actual comments. In addition, two other points are worth raising. In complex models, the R syntax file for Apollo can become quite large, and a user may wish to split this into separate files, e.g. one for loading and processing the data, one for the actual model definition, etc, and then have a master file which calls the individual files (using source). Secondly, for the predefined functions, the order of arguments passed to the function should be kept in the order specified in this paper.

¹Apollo is licensed under GNU GENERAL PUBLIC LICENSE v2 (GPL-2) - https://cran.r-project.org/ web/licenses/GPL-2. It is provided free of charge and comes WITHOUT ANY WARRANTY of any kind. In no event will the authors or their employers be liable to any party for any damages resulting from any use of *Apollo*.

desired, but the link between inputs and outputs remains.

- **Ease of use:** Apollo combines easy to use R functions with new intuitive functions without unnecessary jargon or complexity.
- **Modular nature:** Apollo uses the same code structure independently of whether the simplest multinomial logit model is to be estimated, or a complex structure using random coefficients and combining multiple model components.
- **Fully customisable:** Apollo provides functions for many well known models but the user is able to add new structures and still make use of the overall code framework. This for example extends to coding expectation-maximisation routines.
- **Discrete and continuous:** *Apollo* incorporates functions not just for commonly used discrete choice models but also for a family of models that looks jointly at discrete and continuous choices.
- **Novel structures:** Apollo goes beyond standard choice models by incorporating the ability to estimate Decision Field Theory (DFT) models, a popular accumulator model from mathematical psychology.
- **Classical and Bayesian:** Apollo does not restrict the user to either classical or Bayesian estimation but easily allows changing from one to the other.
- **Easy multi-threading:** *Apollo* allows users to split the computational work across multiple processors without making changes to the model code.
- Not limited to estimation: *Apollo* provides a number of pre and post-estimation tools, including diagnostics as well as prediction/forecasting capabilities and posterior analysis of model estimates.

While *Apollo* is easy to use, we also remain of the opinion that users of choice modelling software should understand the actual process that happens during estimation. For this reason, the user needs to explicitly include or exclude calls to specific functions that are model and dataset specific. For example, in the case of repeated choice data, the user needs to include a call to a function that takes the product across choices for the same person (apollo_panelProd). Or in the case of a mixed logit model, the user needs to include a call to a function that averages across draws (apollo_avgInterDraws and/or apollo_avgIntraDraws). If calls to these functions are missing when needed, or if a user makes a call to a function that should not be used in the specific model, the code will fail, and provide the user with feedback about why this happened. This is in our view much better than the software permitting users to make mistakes and fixing them behind the scenes.

Apollo is the culmination of many years of development of individual choice modelling routines, starting with code developed by Hess while at Imperial College (cf. Hess, 2005) using Ox (Doornik, 2001). This code was gradually transitioned to R at the University of Leeds, with substantial further developments once Palma joined the team in Leeds, bringing with him ideas developed at Pontificia Universidad Católica de Chile (cf. Palma, 2016). No code is an island, and we have been inspired especially by ALogit (ALogit, 2016) and Biogeme (Bierlaire, 2003), and Apollo mirrors at least some of their features.

This paper presents a brief introduction to the capabilities of *Apollo*. We focus on the case of a hybrid choice model so as to give an illustration of the functionalities of the package. We

illustrate this using both classical and Bayesian estimation and also explain a number of preestimation and post-estimation functions. Of course, in the context of an academic paper, we can only scrape the surface of the full level of detail, and furthermore, software packages change over time. For this reason, a more detailed manual (which also shows full details on function inputs) along with numerous examples (with data) and a user forum is available on the *Apollo* website (www.ApolloChoiceModelling.com). The syntax in the present paper is for *Apollo* version 0.0.8, but should remain forward compatible where not otherwise noted in the online manual. We strongly recommend prospective users to study the actual manual in detail rather than just relying on the short overview in the present paper.

This paper does not include any comparisons with other packages in terms of capabilities or speed, so as not to risk misrepresentations but also given the growing number of freeware tools, some of which we might not be aware of. The code has been widely tested to ensure accuracy. In our view, any speed comparison offers little practical benefit. For simple models, there is a clear advantage for highly specialised code, while, for complex models, any benchmarking is impacted substantially by the specific implementation and degree of optimisation used.

The remainder of this paper is organised as follows. The following section briefly talks about installation. Section 3 discusses the econometric setup for our empirical example. Section 4 then presents the hybrid choice model application using classical estimation, with the Bayesian version covered in Section 5. A number of other functions are discussed in Section 6 before we present a summary in Section 7.

2 Installing Apollo

Apollo runs in R, with a minimum R version of 3.1.0. The easiest way to install Apollo is directly from CRAN using

```
install.packages("apollo")
```

This requires a working internet connection, but it has the benefit of installing all dependencies, i.e. other packages used by *Apollo*, automatically. Users of macOS (i.e. Apple computers) are advised to select the binary version of the package when prompted during installation. Alternatively, the source code of *Apollo* can be downloaded from www.ApolloChoiceModelling.com or from CRAN and *Apollo* can then be compiled from source.

Users are encouraged to check for updated versions of the package every few months. Updates, when available, can be acquired by simply re-installing the package. Installation from CRAN will install the latest release. Previous releases will be available from the software website, where users also have access to versions with new features that are under development prior to a full release. These versions need to be compiled locally, and users require Rtools for this purpose.

3 Empirical example setup

In this section, we describe the setup of the empirical example used in the remainder of this paper. The data file (apollo_drugChoiceData.csv) and the source files for the model using

classical (hybrid_model_classical.r) or Bayesian (hybrid_model_bayesian.r) estimation are available from the software website (www.ApolloChoiceModelling.com).

3.1 Data

We use a synthetic stated preference (SP) dataset looking at drug choices for the treatment of headaches for 1,000 individuals. For each person, the data contains 10 SP tasks, each giving a choice between four alternatives, the first two being products by recognised drug companies while the final two are generic products. In each choice task, a full ranking of the four alternatives is given. The drugs are described in terms of brand (two recognised brands and three generic brands), country of origin (six countries), drug features (three types of features), risk of side effects and price. The possible levels for the attributes differ between the first two (branded) and last two (generic) alternatives. For each individual, the dataset additionally contains answers to four attitudinal questions as well as information on whether an individual is a regular user, their education and their age. A summary of the data is shown in Table 1.

3.2 Model specification

We next describe the structure of our hybrid choice model (see Abou-Zeid and Ben-Akiva, 2014, for a recent overview), where we look at the implementation of a model with a single latent variable but with additional random and deterministic heterogeneity in the utility functions³.

We use a dummy coded specification for the three categorical variables, along with a continuous specification for risk and cost. We specify a structural model for the latent variable that uses the three socio-demographic characteristics included in the data, and then use this latent variable in the utilities for the two branded alternatives as well as in the measurement models for the four attitudinal indicators. We additionally incorporate the same socio-demographic characteristics directly in the utility for the two branded alternatives, with brand-specific parameters, and also make the brand parameters for the Novum and Artemis brands random, in line with best practice for hybrid choice models (see theoretical discussions in Vij and Walker 2016 and an application in Kløjgaard and Hess 2014). We use an ordered logit model for the indicators, as discussed by Daly et al. (2012b).

Figure 1 presents the structure of the model. We use a subscript n to refer to individual decision makers $(n=1,\ldots,N)$; where N=1,000, t to refer to tasks $(t=1,\ldots,T)$; where T=10, and j to refer to alternatives $(j=1,\ldots,J)$; where J=4. We have individual specific responses to attitudinal questions (subscript n) and observation specific choice outcomes (subscript n). Similarly, the error terms in the latent variable and the first two brand parameters are individual-specific. In Figure 1, we do not show the additional observation-specific error terms in the choice model and measurement models.

 $^{^{3}}$ Different specifications of the model would of course be possible, but this example is only included for the sake of illustration of the code.

Individuals | 1,000 Observations | 10,000

Variable	Description	Values
ID	Unique respondent ID	1 to 1,000
task	Index for SP choice tasks	1 to 10
best	first ranked alternative	1 to 4
second pref	second ranked alternative	1 to 4
third pref	third ranked alternative	1 to 4
worst	worst ranked alternative	1 to 4
brand 1	brand for first alternative	Artemis; Novum
country 1	country for first alternative	Switzerland; Denmark; USA
char_1	characteristics for first alternative	standard; fast acting; double strength
side_effects_1	rate of side effects for first alternative (out of 100,000)	Min: 1, mean: 37, max: 100
price_1	price (\pounds) for first alternative	Min: 2.25, mean: 3.15, max: 4.5
brand 2	brand for second alternative	Artemis; Novum
country 2	country for second alternative	Switzerland; Denmark; USA
char 2	characteristics for second alternative	standard; fast acting; double strength
side effects 2	rate of side effects for second alterna-	Min: 1, mean: 37, max: 100
	tive (out of 100,000)	
$price_2$	price (\pounds) for second alternative	Min: 2.25, mean: 3.15, max: 4.5
brand_3	brand for third alternative	BestValue; Supermarket; PainAway
$country_3$	country for third alternative	USA; India; Russia; Brazil
char_3	characteristics for third alternative	standard; fast acting
$side_effects_3$	rate of side effects for third alternative	Min: 10, mean: 370, max: 1,000
	(out of 100,000)	
price_3	price (\pounds) for third alternative	Min: 0.75, mean: 1.75, max: 2.5
brand_4	brand for fourth alternative	BestValue; Supermarket; PainAway
country_4	country for fourth alternative	USA; India; Russia; Brazil
char_4	characteristics for fourth alternative	standard; fast acting
side_effects_4	rate of side effects for fourth alternative	Min: 10, mean: 370, max: 1,000
	(out of 100,000)	
$_{\rm price}_4$	price (\pounds) for fourth alternative	Min: 0.75, mean: 1.75, max: 2.5
regular_user	dummy variable for regular users	1 for regular users, 0 otherwise
university_educated	dummy variable for university edu- cated	1 for university educated, 0 otherwise
over_50	dummy variable for age over 50 years	1 for age over 50 years, 0 otherwise
$attitude_quality$	Answer to "I am concerned about the	Likert scale from 1 (strongly disagree)
	quality of drugs developed by unknown companies"	to 5 (strongly agree)
$attitude_ingredients$	Answer to "I believe that ingredients are	Likert scale from 1 (strongly disagree)
	the same no matter what the brand"	to 5 (strongly agree)
$attitude_patent$	Answer to "The original patent hold-	Likert scale from 1 (strongly disagree)
	ers have valuable experience with their medecines"	to 5 (strongly agree)

	helpful"	

Table 1: Data dictionary for apollo_drugChoiceData.csv

6

Figure 1: Structure of the hybrid choice model

Specifically, we have that the latent variable for individual n is given by:

$$\alpha_n = \gamma_{\text{LV,regular user}} \cdot z_{n,\text{regular user}} + \gamma_{\text{LV,univ. educ}} \cdot z_{n,\text{univ. educ}} + \gamma_{\text{LV,over 50}} \cdot z_{n,\text{over 50}} + \eta_n,$$
(1)

where $z_{n,k}$ is a dummy variable which is equal to 1 if characteristic k applies to individual n, γ_{LV} is a vector of estimated parameters capturing the impact of these variables on α_n and η_n is a random disturbance which follows a standard Normal distribution across individuals, i.e. $\eta_n \sim N(0, 1)$.

The utility specification differs between the first two (branded) and last two (unbranded) alternatives. In particular, for the branded alternatives, where j = 1, 2, we have that the utility

(net of the extreme value term) in choice situation t for individual n is given by:

$$\begin{split} V_{j,n,t} &= \beta_{n,\text{Artemis}} \cdot \left(x_{brand_{j,n,t}} == \text{Artemis} \right) \\ &+ \gamma_{\text{Artemis,regular user}} \cdot z_{n,\text{regular user}} \cdot \left(x_{brand_{j,n,t}} == \text{Artemis} \right) \\ &+ \gamma_{\text{Artemis,univ. educ}} \cdot z_{n,\text{univ. educ}} \cdot \left(x_{brand_{j,n,t}} == \text{Artemis} \right) \\ &+ \gamma_{\text{Artemis,over 50}} \cdot z_{n,\text{over 50}} \cdot \left(x_{brand_{j,n,t}} == \text{Artemis} \right) \\ &+ \beta_{n,\text{Novum}} \cdot \left(x_{brand_{j,n,t}} == \text{Novum} \right) \\ &+ \gamma_{\text{Novum,regular user}} \cdot z_{n,\text{regular user}} \cdot \left(x_{brand_{j,n,t}} == \text{Novum} \right) \\ &+ \gamma_{\text{Novum,univ. educ}} \cdot z_{n,\text{univ. educ}} \cdot \left(x_{brand_{j,n,t}} == \text{Novum} \right) \\ &+ \gamma_{\text{Novum,univ. educ}} \cdot z_{n,\text{univ. educ}} \cdot \left(x_{brand_{j,n,t}} == \text{Novum} \right) \\ &+ \gamma_{\text{Novum,over 50}} \cdot z_{n,\text{over 50}} \cdot \left(x_{brand_{j,n,t}} == \text{Novum} \right) \\ &+ \beta_{\text{Switzerland}} \cdot \left(x_{brand_{j,n,t}} == \text{Switzerland} \right) \\ &+ \beta_{\text{Denmark}} \cdot \left(x_{brand_{j,n,t}} == \text{Denmark} \right) \\ &+ \beta_{\text{standard}} \cdot \left(x_{characteristic_{j,n,t}} == \text{standard} \right) \\ &+ \beta_{\text{fast acting}} \cdot \left(x_{characteristic_{j,n,t}} == \text{double strength} \right) \\ &+ \beta_{side_effects} \cdot x_{side_effects_{j,n,t}} \\ &+ \beta_{price} \cdot x_{price_{j,n,t}} \\ &+ \lambda \cdot \alpha_n \end{split}$$

while for j = 3, 4, we have:

$$V_{j,n,t} = \beta_{\text{BestValue}} \cdot (x_{brand_{j,n,t}} == \text{BestValue}) + \beta_{\text{Supermarket}} \cdot (x_{brand_{j,n,t}} == \text{Supermarket}) + \beta_{\text{PainAway}} \cdot (x_{brand_{j,n,t}} == \text{PainAway}) + \beta_{\text{USA}} \cdot (x_{brand_{j,n,t}} == \text{USA}) + \beta_{\text{India}} \cdot (x_{brand_{j,n,t}} == \text{India}) + \beta_{\text{Russia}} \cdot (x_{brand_{j,n,t}} == \text{Russia}) + \beta_{\text{standard}} \cdot (x_{characteristic_{j,n,t}} == \text{standard}) + \beta_{\text{fast acting}} \cdot (x_{characteristic_{j,n,t}} == \text{fast acting}) + \beta_{side_effects} \cdot x_{side_effects_{j,n,t}}$$
(3)

A number of differences arise between Equation 2 and 3. Some of these are a result of the data, namely in that the possible brands and countries differ between the first two and last two alternatives and the double strength characteristic is only possible for the first two brands.

In addition, we allow for socio-demographic shifts only in the sensitivities to the two branded products, and allow the utilities for Artemis and Novum to follow a Normal distribution across individuals, with $\beta_{n,\text{Artemis}} \sim N(\mu_{\text{Artemis}}, \sigma_{\text{Artemis}})$ and $\beta_{n,\text{Novum}} \sim N(\mu_{\text{Novum}}, \sigma_{\text{Novum}})$. This means that e.g. $\beta_{n,\text{Artemis}} = \mu_{\text{Artemis}} + \sigma_{\text{Artemis}} \cdot \xi_{n,\text{Artemis}}$, where $\xi_{n,\text{Artemis}}$ is a standard Normal error term, distributed across individuals. In terms of normalisation, we use dummy coding, setting β_{PainAway} , β_{USA} and β_{standard} to zero. Finally, the impact of the latent variable α_n is solely on the first two utilities, i.e. the branded products.

For ease of notation, we group together the parameters into vectors, such that β_n combines the various β terms from Equations 2 and 3, where this is person specific due to the random heterogeneity in $\beta_{n,\text{Artemis}}$ and $\beta_{n,\text{Novum}}$. We also define γ_V to group together the deterministic heterogeneity used in Equations 2 and 3. We thus get that the likelihood of the observed sequence of T_n choices for person n, is given by:

$$L_{C_n}(\beta_n, \gamma_V, \alpha_n) = \prod_{t=1}^{T_n} \frac{e^{V_{j_{n,t}^*}}}{\sum_{j=1}^4 e^{V_{j,n,t}}},$$
(4)

where $j_{n,t}^*$ is the alternative chosen as the best one by respondent n in task t, and where this probability is distributed across the random components in β_n and α_n .

The latent variable α_n is also used to explain the value of the four attitudinal questions, where, with the ordered logit model, we have that:

$$L_{I_n, ordered}(\tau, \zeta, \alpha_n) = \prod_{i=1}^{4} \left(\sum_{s=1}^{S} \delta_{(I_{n,i}=s)} \left[\frac{e^{\tau_{i,s} - \zeta_i \alpha_n}}{1 + e^{\tau_{i,s} - \zeta_i \alpha_n}} - \frac{e^{\tau_{i,s-1} - \zeta_i \alpha_n}}{1 + e^{\tau_{i,s-1} - \zeta_i \alpha_n}} \right] \right),$$
(5)

where ζ_i is an estimated parameter that measures the impact of α_n on the attitudinal indicator I_i , and τ_i , is a vector of threshold parameters for this indicator. Again, τ and ζ are defined to group together the various parameters used in the measurement model. Equation 5 is distributed across the random component in α_n .

The combined log-likelihood for the model is then given by:

$$LL(\Omega) = \sum_{n=1}^{N} \log \int_{\beta_n} \int_{\alpha_n} L_{C_n}(\beta_n, \gamma_V, \alpha_n) L_{I_n, ordered}(\tau, \zeta, \alpha_n) f(\alpha_n) g(\beta_n) d\alpha_n d\beta_n,$$
(6)

where Ω combines all model parameters. This log-likelihood function requires integration over the random component in the latent variable, and the random component in β_n . In classical estimation this integral is calculated using Monte Carlo methods, instead, when Bayesian methods are used, the Metropolis-Hasting algorithm is employed.

4 Hybrid choice model example: classical estimation

In this section, we look at classical estimation of the hybrid choice model defined in Section 3. The structure of an *Apollo* model file varies across specifications, but a general overview is shown in Figure 2.

Initialisation

- Clear memory (optional but recommended)
- Load Apollo library
- Set core controls

Data

- Load data into *database* object
- · Optionally add any additional variables or apply transformations as required
- Optionally run pre-estimation analysis of the data

Model parameters

- Define model parameters
- · Optionally indicate any parameters that are to be kept fixed
- For continuous mixture models, define a pollo_draws settings and create a pollo_randCoeff function
- For latent class models, define *apollo_lcPars* function

Run apollo_validateInputs function

Model definition

- Define apollo_probabilities function
 - Create likelihood functions for individual model components
 - Combine into overall model likelihood if multiple components exist
 - Depending on the model, average over draws, latent classes and take products across choices
 - Return output with one likelihood value per individual in estimation

Estimation and model output

- Run *apollo_estimate* function
- Run *apollo_modelOutput* for on screen output
- Run apollo_saveOutput for on output to file

Run optional post estimation procedures

Figure 2: General structure of an *Apollo* model file

4.1 Code initialisation

The first step in every use of Apollo is to initialise the code. These steps are illustrated in Figure 3. In an optional step, we clear the memory/workspace by using rm(list = ls()). Every time users want to estimate a model, they should load Apollo into memory. This can be achieved by simply running the following line of code in R, or by including it in the source file of each model, prior to running any Apollo functions.

```
library(apollo)
```

This is followed by calling the apollo_initialise function, which 'detaches' variables⁴ and makes sure that output is directed to the console rather than a file. This function is called without any arguments and does not return any output variables, i.e.:

```
apollo_initialise()
```

The user next sets a number of core controls inside a list called apollo_control. In our case, we set the name of the model in modelName (where any output files will use this name too), give a brief description of the model in modelDescr (for use in the output) and provide in indivID the name (in quotes) of the column in the data which contains the identifier variable for individual decision makers. We also indicate that our model uses continuous random distributions by setting mixing to TRUE, and enable multi-core estimation by setting the number of cores in nCores. Each time, the entry on the left is an *Apollo*-defined variable whose name is not to be changed, and the user provides the value on the right, followed by a comma, except for the last element.

```
rm(list = ls())
library(apollo)
apollo_initialise()
apollo_control = list(
    modelName = "hybrid_model_classical",
    modelDescr = "Hybrid_choice_model on drug_choice_data, classical_estimation",
    indivID = "ID",
    mixing = TRUE,
    nCores = 25
)
```

Figure 3: Code initialisation

Only setting the individual ID is a requirement without which the code will not run. For any other settings, the code will use default values when not provided by the user - details on these optional settings are given in the online manual.

4.2 Reading and processing the data

Apollo makes use of a format where all relevant information for a given observation is stored in the same row. Using a simple discrete choice context, this would imply that the data for all alternatives is included in the same row, rather than one row per alternative. Some choice

⁴In R, a user can 'attach' an object, which means that individual components in it can be called by name.

modellers refer to this as the *wide* format, as opposed to the *long* format, which would have one row per alternative.

The next step is to load the data into an object called database, in our case from a *csv* file, via the command:

database = read.csv("apollo_drugChoiceData.csv",header=TRUE)

Three additional points need to be mentioned here. Firstly, the code is not limited to using *csv* files, and R allows the user to read in tab separated files too, for example (see R Core Team 2017 for more details). Secondly, some applications may combine data from multiple files. The user can either combine the data outside of R or do so inside R using appropriate merging functions, but at the point of validating the user inputs (Section 4.5), all data needs to be combined in a single R data.frame called database. Thirdly, any new variables created by the user inside R need to be created in the database object rather than the global environment, and this needs to happen prior to validating the user inputs.

With labelled choice data (or even unlabelled data), it can be useful to analyse the choices before model estimation to determine whether the characteristics of individuals choosing specific alternatives differ across alternatives. This is made possible by apollo_choiceAnalysis, which is called as follows:

where choiceAnalysis_settings has the following contents:

- alternatives: A named vector containing the names of the alternatives and the corresponding value for the choice variable.
- avail: A list containing one element with availabilities per alternative.
- choiceVar: A vector of length equal to the number of observations, containing the chosen alternative for each observation.
- explanators: A dataframe containing a set of variables, one per column and one entry per choice observation, that are to be used to analyse the choices.

We illustrate this process for our example in Figure 4. In most cases, this function would be used for labelled data, where a given alternative refers to a specific product. In our dataset, we have five different brands which are associated with different alternatives in different choice tasks. Some transformations are needed before running our analysis. We first define these five brands as being the *pseudo-alternatives* for our analysis of choices. We then create availabilities for these alternatives, where the **Artemis** alternative is for example available if the brand in the first or second alternative corresponds to **Artemis** (remembering that this brand is only possible for the first two alternatives in the data). We then similarly create a *pseudo choice variable*, where e.g. the new alternative 11, which corresponds to **Artemis**, is chosen if either the first or second alternative in the data is given as the highest ranked (i.e. best) and if its brand is equal

```
choiceAnalysis_settings <- list (
    alternatives = c(Artemis=11, Novum=12, BestValue=21, Supermarket=22, PainAway=23),
    avail = with(database, list (
        Artemis=(brand_1=="Artemis") | (brand_2=="Novum"),
        BestValue=(brand_3=="BestValue") | (brand_4=="BestValue"),
        Supermarket=(brand_3=="Supermarket") | (brand_4=="BestValue"),
        Supermarket=(brand_3=="Supermarket") | (brand_4=="PainAway"))),
choiceVar = with(database,
        (11*((best==1)*(brand_1=="Artemis")+(best==2)*(brand_2=="Novum"))
        +12*((best==1)*(brand_1=="Novum")+(best==2)*(brand_2=="Novum"))
        +21*((best==3)*(brand_3=="BestValue")+(best==4)*(brand_4=="BestValue"))
        +23*((best==3)*(brand_3=="PainAway")+(best==4)*(brand_4=="BestValue"))
        +23*((best==3)*(brand_3=="PainAway")+(best==4)*(brand_4=="PainAway"))),
explanators = database[,c("regular_user","university_educated","over_50")]
apollo_choiceAnalysis(choiceAnalysis_settings, apollo_control, database)</pre>
```

	Mean for regular_user if chosen	Mean for regular_user if not chosen	t-test for difference
Artemis	0.315	0.3877	6.94
Novum	0.3199	0.368	4.48
BestValue	0.4329	0.3364	-5.8
Supermarket	0.4417	0.3345	-6.82
PainAway	0.4387	0.334	-5.43

Figure 4: Running apollo_choiceAnalysis (syntax and excerpt of output)

to Artemis. Finally, we define three explanatory variables for our analysis, which are the three socio-demographic characteristics⁵.

The function produces a *csv* file with one row per alternative, and three columns per variable included in **explanators**. In a given row, i.e. for a given alternative, these three columns contain the mean value for the given explanatory variable for those choices where the alternative is chosen, the mean value where it is not chosen (but available), and the test statistic for the two-sample t-test comparing the means in these two groups (where the null hypothesis states that the difference between the means is equal to 0, and the alternative hypothesis says that it is different from zero.). The results of this process are shown in the bottom part of Figure 4 (for the first explanator only), clearly highlighting differences across brands in terms of the share of choices made by regular users. These value are also returned silently by the function, so they can be stored in a variable, by using e.g. output=apollo_choiceAnalysis(choiceAnalysis_settings,apollo_control,database).

4.3 Model parameters

The user next needs to define the parameters and their starting values, and also indicate whether any of the parameters are to be kept fixed at their starting values. This process is illustrated in Figure 5. We first create an R object of the *named vector* type, called apollo_beta, with the name and starting value for each parameter, including any that are later on fixed to their starting

 $^{{}^{5}}$ The syntax used in this function is standard R syntax, where the use of with allows us to omit database\$ when referring to individual attributes.

values. Typically users will use one line per parameter, we have placed two on each line simply for formatting reasons. In our case, we then keep some of these parameters fixed to their starting values by including their names in the character vector $apollo_fixed$, where this vector is kept empty ($apollo_fixed = c()$) if all parameters are to be estimated.

apollo beta = c(mu brand Artemis	= 0, sig brand Artemis	= 0,
gamma Artemis reg user	= 0, gamma Artemis university	= 0,
gamma Artemis age 50	= 0, mu brand Novum	= 0,
sig brand Novum	= 0, gamma Novum reg user	= 0,
gamma Novum university	= 0, gamma Novum age 50	= 0,
b brand BestValue	= 0, b brand Supermarket	= 0,
b brand PainAway	= 0, b country CH	= 0,
b country DK	= 0, b country USA	= 0,
b country IND	= 0, b country RUS	= 0,
b country BRA	= 0, b char standard	= 0,
b char fast	= 0, b char double	= 0,
b_risk_	= 0, b price	= 0,
gamma LV reg user	= 0, gamma LV university	= 0,
gamma LV age 50	= 0, lambda	= 1,

tau dominance 3	= 1, tau dominance 4	= 2)
apollo_fixed = c("b_brand_PainAway", "b_o	country_USA", "b_char_standard")	

Figure 5: Setting names and starting values for model parameters, and fixing some parameters to their starting values

4.4 Draws and random parameters

The next step concerns the generation of draws for random distributions. In our case, we need to produce normally distributed inter-individual draws for $\beta_{n,\text{Artemis}}$, $\beta_{n,\text{Novum}}$ and the random component η_n in the latent variable α_n . Draws are generated by *Apollo* whenever mixing==TRUE in apollo_control, using the settings defined in a list called apollo_draws.

We first set the type of draws in interDrawsType, where different pre-defined types of draws are available in *Apollo*, including (but not limited to) pmc for pseudo-Monte Carlo draws, halton for Halton draws Halton (1960) and mlhs for MLHS draws (Hess et al., 2006). The number of draws per individual is set in interNDraws for inter-individual draws. Finally, the user needs to define the actual random disturbances or sets of draws, by giving each set of draws a name which can be used later in the model specification, and by determining whether the draws are Normally or Uniformly distributed, by including their names in interNormDraws or interUnifDraws, respectively. These two distributions (standard Normal and Uniform between 0 and 1) can later be transformed to any other distribution by the user inside apollo_randCoeff.

The process used for this is illustrated in the first part of Figure 6. In our example, we create three sets of draws, each time with 500 draws per individual, where these are transformed into standard Normal distributions. The settings that are not used in our example, namely any intra-individual draws (cf. Section 6.3.1) and uniformly distributed inter-individual draws, are omitted (or alternatively could be left empty, or set to zero).

Some users may want additional flexibility to combine different types of draws or to generate their own draws. This is possible in *Apollo* by giving the name of a user generated object with uniformly distributed draws in apollo_draws\$interDrawsType instead of providing one of the specific types of draws listed above. Using the example from Figure 6, the user would need to replace halton by for example ownInterDraws, where this is a list, with one element per random set of draws. Each entry in the list needs to have a name, where this same set of names is then used across interUnifDraws and interNormDraws to instruct the code to either leave the draws untransformed or apply an inverse Normal CDF. The user also still needs to specify interNDraws.

Figure 6: Defining draws and random parameters

After defining the draws, the next step concerns the actual definition of those coefficients in the model that follow a random distribution, in our case the latent variable and the two random brand coefficients. For this, the user creates an additional function, namely apollo_randCoeff. Just as with apollo_probabilities, which we will see below, this is a function that the user does not call but which the user defines. This function takes apollo_beta and apollo_inputs as inputs and generates a new list which contains the random coefficients, incorporating any deterministic effects too. This is illustrated in the second part of Figure 6, where the correspondence with e.g. Equation 1 for the LV component should be clear. The contents of apollo_randCoeff will vary across model specifications, only the first line (randCoeff = list()) and final line (return(randCoeff)) are to remain as in the example.

In the example used here, the three random coefficients all follow Normal distributions. If the user for example wants to use a negative Lognormal distribution for β_1 , a symmetrical Triangular distribution for β_2 and a Johnson S_B distribution for β_3 , then this could be specified as:

where draws1 and draws3 need to be defined in interNormDraws and draws2a and draws2b in interUnifDraws. The other terms are parameters to estimate, namely means (e.g. log_b1_mu), standard deviations means (log_b1_sig), bounds (b2_a) and ranges (b2_b).

4.5 Validation and preparing user inputs

The final step in preparing the code and data for model estimation or application is to call apollo_validateInputs. The function runs a number of checks and produces a consolidated list of model inputs. It is called as:

apollo_inputs=apollo_validateInputs()

This function takes no arguments but looks in the global environment for the various inputs required for a model. The function also looks for a number of optional objects and sets default values for any missing ones as illustrated in Figure 7.

Before returning the list of model inputs, apollo_validateInputs runs a number of validation tests on the apollo_control settings and the database. It also sorts the data by ID and adds an extra column called apollo_sequence which is a running index of observations for each individual in the data. The list that is returned, apollo_inputs, contains the validated versions of the various objects mentioned above, e.g. database.

```
> apollo_inputs = apollo_validateInputs()
Missing setting for workInLogs, set to default of FALSE
Missing setting for seed, set to default of 13
Missing setting for HB, set to default of FALSE
Several observations per individual detected based on the value of ID.
Setting panelData set to TRUE.
All checks on apollo_control completed.
All checks on data completed.
Generating inter draws ... Done
```

Figure 7: Running apollo_validateInputs

4.6 Likelihood component: the apollo probabilities function

The core part of the code is contained in the apollo_probabilities function, where we show this function for our hybrid choice model in Figure 8. As with apollo_randCoeff, this is a function defined by the user as it is specific to the model to be estimated. The function itself is never called by the user, but is used for example by the function for model estimation apollo_estimate discussed below. No limits on flexibility are imposed on the user with the *Apollo* package. A number of prewritten functions for common models are made available in the package, going beyond MNL, as discussed in Section 6.2. Additionally, the user can define his/her own models. Finally, this part of the code can contain either a single model or multiple individual model components, as shown in our example.

This function takes three inputs, namely the vector of parameters apollo_beta, the list of combined model inputs apollo_inputs, and the argument functionality, which takes a default value for model estimation, but other values apply for example in prediction, as discussed in Section 4.9.2. The value used depends on which function makes the call to apollo_probabilities and is controlled internally. The function returns probabilities, where the specific format depends on functionality.

In the following three subsections, we look at the individual components of the code shown in Figure 8.

```
apollo_probabilities=function(apollo_beta, apollo_inputs, functionality="estimate"){
  apollo_attach(apollo_beta, apollo_inputs)
on.exit(apollo_detach(apollo_beta, apollo_inputs))
  ### Create list of probabilities P
  P = list()
  #### Likelihood of choices
 V[['alt4']] = ( b_brand_BestValue*(brand_4=="BestValue") + b_brand_Supermarket*(brand_4=="Supermarket

→ ") + b_brand_PainAway*(brand_4=="PainAway")

+ b_country_USA*(country_4=="USA") + b_country_IND*(country_4=="India") + b_country_RUS

→ *(country_4=="Russia") + b_country_BRA*(country_4=="Brazil")

+ b_cchar_standard*(char_4=="standard") + b_cchar_fast*(char_4=="fast_acting")

+ b_risk*side_effects_4

+ b_price*price_4 )
  mnl settings = list (
     alternatives = c(alt1=1, alt2=2, alt3=3, alt4=4),
avail = list (alt1=1, alt2=1, alt3=1, alt4=1),
choiceVar = best,
     V
                       = V
  )
  P[["choice"]] = apollo_mnl(mnl_settings, functionality)
  #### Likelihood of indicators
  ol\_settings1 = list(outcomeOrdered=attitude_quality,
                              \begin{array}{l} V=zeta\_quality*LV, \\ tau=c\,(tau\_quality\_1\,,\ tau\_quality\_2\,,\ tau\_quality\_3\,,\ tau\_quality\_4\,)\,, \\ rows=(task==1)) \end{array} 
  ol_settings4 = list(outcomeOrdered=attitude_dominance, V=zeta_dominance*LV,
                             tau=c(tau_dominance_1, tau_dominance_2, tau_dominance_3, tau_dominance_4),
rows=(task==1))
 ### Likelihood of the whole model P = apollo_combineModels(P, apollo_inputs, functionality)
  return (P)
```

Figure 8: The apollo_probabilities function for a hybrid choice model using classical estimation (excerpt)

4.6.1 Initialisation

Any use of the apollo_probabilities function begins with a call to apollo_attach which enables the user to then call individual elements within for example the database by name, e.g. using brand_1 instead of database\$brand_1. This function is called as:

apollo_attach(apollo_beta, apollo inputs)

The function does not return an object as output and the user does not need to change the arguments for this function. The call to this function is immediately followed by a command instructing R to run the function apollo_detach once the code exits apollo_probabilities. This ensures that this call is made even if there is an error that leads to a failure (and hence hard exit) from apollo_probabilities. This call is made as:

We next initialise a list (a flexible R object) called P which will contain the probabilities for the model, where this is a requirement for any type of model used with the code.

4.6.2 Model definition

We create a list P which will in the end have five components, namely the probabilities from the choice model and the probabilities of the four measurement models. Conditional on the random parameters, the choice model component of the hybrid model is of the MNL type.

For a model with just a single component, the apollo_mnl function is called via:

The function returns probabilities for the model, where depending on functionality, this is for the chosen alternative only or for all alternatives. In our case, our model contains several individual model components, and we thus use P[["choice"]] for this component instead of P[["model"]]. The function takes as its core input a list called mnl_settings which has four compulsory inputs and one optional input. We will now look at these in turn.

- alternatives: A vector containing for each alternative its name and the value associated with it in the dependent variable in the data.
- avail: A list containing one element per alternative, using the same names as in alternatives, with each entry being a vector of values of the same length as the number of observations (i.e. a column from the data) or a scalar of 1 if an alternative is always available. A user can also set avail=1 which implies full availability for all alternatives.
- choiceVar: A vector of length equal to the number of observations, containing the chosen alternative for each observation.
- V: A list containing one utility for each alternative, using the same names as in alternatives, where any linear or non-linear specification is possible. The contents of V are complicated and are thus generally defined prior to calling the function.

rows: An optional vector of the same length as the number of rows in the data. This vector needs to use logical statements to identify which rows in the data are to be used for this model. For any observations in the data where the entry in rows is set to FALSE, the probability for the model will be set to 1, i.e. they will not contribute to model estimation.

As seen in Figure 8, each alternative is given a name, and in the setting alternatives inside mnl_settings, we associate each name with the corresponding value for the choice variable in the data (going from 1 to 4). Our four alternatives always have full availability, and we use the variable best for choiceVar. In the code example, we actually create the utilities V outside mnl_settings first just for ease of coding, but they can similarly be created directly inside the list. What matters is that they are then copied into a component called V inside mnl_settings. We define the utilities in line with Equations 2 and 3, where we can directly incorporate the random components LV, b_brand_Artemis and b_brand_Novum defined in apollo_randCoeff. After creating the settings for the MNL component, we make the call to apollo_mnl to compute the choice probabilities.

In the example shown here (and the rest of this manual), the user codes the utilities of all alternatives one by one. With very large choice sets, this may not be practical, and a user may create the utilities recursively, for example. We illustrate this in Figure 9 for a simple example, where we have 100 alternatives, and where the utility includes two attributes (x1 and x2). Values for these exist in the data for each alternative, with for example $x1_1$ being the value for the first attribute for the first alternative, and there is also a vector of availabilities for each alternative, e.g. av1 for the first alternative.

```
J = 100
V = list()
for(j in 1:J) V[[paste0("alt",j)]] = bl*database[,paste0("x1_",j)] + b2*database[,paste0("x2_",j)]
mnl_settings = list(
    alternatives = setNames(1:J, names(V)),
    avail = setNames(database[,paste0("av",1:J)], names(V)),
    choiceVar = choice,
    V = V
```

Figure 9: Defining utilities for large choicesets

We next turn to the measurement model component of our hybrid model. We have four indicators in our model, and use an ordered logit model for each. In *Apollo*, the apollo_ol function for a model with just one component is called as follows:

In our case, we have four indicators, so use for example P[["indic_quality"]]. The contents of ol_settings are a little different from MNL. In particular, we have:

outcomeOrdered: A vector indicating the level selected for the ordinal variable in each observation. This will usually be a column (variable) inside database.

V: A numeric vector containing the explanatory variable used in the ordered logit model, i.e. the utility.

tau: A vector containing the names of the threshold parameters that are used in the model. These should have one fewer element than the number of possible values for the dependent variable, as extreme thresholds are assumed to be $-\infty$ and $+\infty$.

coding: An optional argument of numeric or character vector type which is only required as an input if the dependent variable is in string format or does not use an incremental coding from 1 to a value equal to the number of possible values for the dependent variable outcomeOrdered. rows: The optional rows argument already described for MNL.

In Figure 8, we first create the four lists of settings for each individual ordered logit model, before making the four calls to apollo_ol. The utility is given by $\zeta \alpha_n$, and we estimate four thresholds for each indicator. As the answers to each attitudinal question are given once per respondent but are repeated in each line in the data for that respondent, we include rows=(task==1) which ensures that the measurement model is only used once for each attitudinal statement and for each individual, rather than contributing to the overall model likelihood in each row for that person.

The list P now contains five individual components, and the call to apollo_combineModels combines these into a joint model. This is called as follows:

```
P = apollo \_combineModels(P,
```

apollo_inputs,
functionality)

This function takes the list P which contains several individual model components and produces a combined model, where, with $L_{n,m}$ giving the likelihood of model component m for person n, the overall likelihood for person n is given by $L_n = \prod_{m=1}^M L_{n,m}$ (not showing here the presence of any integration over random terms, which would be carried out outside the product). The function apollo_combineModels creates the model object inside P as the product across individual components - when working with multiple model components, the individual components should thus not be called model themselves.

4.6.3 Function output

Three further final steps are required. We first call apollo_panelProd which multiplies the probabilities across individual choice observations for the same individual, thus recognising the repeated choice nature of our data, in our case the product across choice tasks in Equation 4 (noting that for the indicators, only the first row is used for each person). This function is only to be used in the presence of multiple observations per individual, and is called as:

We next need to average across the inter-individual draws. The function apollo_avgInterDraws is called as:

```
P = apollo avgInterDraws(P,
```

apollo_inputs,
functionality)

Independent of the model specification, the function apollo_probabilities always ends with the same two commands. First is apollo_prepareProb which prepares the output of the function depending on functionality, e.g. with different output for estimation and prediction⁶. This is called as:

```
P = apollo prepareProb(P,
```

apollo_inputs,
functionality)

This is followed by

return(P)

which ensures that P is returned as the output of apollo_probabilities.

4.7 Model estimation

4.7.1 Deciding on number of cores and draws

Apollo allows for multi-threaded estimation for classical estimation⁷, leading to significant estimation speed improvements for some models (especially those using few iterations that each take a long time). To help decide how many cores to use, we provide the function apollo_speedTest, which calculates the loglikelihood function several times using different number of threads and draws, and reports both the calculation time and the memory usage. This function is called as:

The final argument, speedTest_settings, is optional and allows the user to change the number of draws and cores to try, as well as the number of times apollo_probabilities is calculated

⁶The user has the possibility of using weights by including the setting weights in apollo_control. Weights are only used in estimation, and if the user wants to use weights, then in addition to including the setting in apollo_control, the function apollo_weighting needs to be called prior to apollo_prepareProb. This is called as P = apollo weighting(P, apollo inputs, functionality).

⁷When using Bayesian estimation, the reliance on RSGHB means only single core processing is possible.

to ensure stable results. We illustrate the use of this function in Figure 10, which shows major benefits by moving away from using a single core. We again create the list of settings prior to the call to apollo_speedTest just for ease of coding. When running apollo_speedTest, progress and results of the test are printed to the console. Each row displays the set-up, progress, and results of a given configuration. The first column (*nCores*) indicates the number of computational threads in use, i.e. how many processor cores are being used simultaneously by R. The second (*inter*) and third (*intra*) columns indicate the number of inter-individual and intra-individual draws used. The third column (*progress*) indicates the progress of the test for each set-up, each dot representing 10% of the repetitions requested. The fifth column (*sec/LLCal*) indicates the average time in seconds required to complete one evaluation of the apollo_probabilities function. The sixth and last column (*RAM(MB)*) presents a lower bound of the memory required to evaluate the apollo_probabilities function. After completing the test, results are summarised in a table indicating the time required to evaluate apollo_probabilities under each configuration, as well as in a plot.

4.7.2 Actual model estimation

Now that we have defined our model, we can perform model estimation by calling the function apollo_estimate and saving the output from it in an object called model. This function uses the maxLik package (Henningsen and Toomet, 2011) for classical estimation, where Bayesian estimation is discussed in Section 5. The function is called via:

where we have already covered the first four arguments. The final argument, estimate_settings, is optional and default values will be used when it is not provided. As discussed in the online manual, this allows the user to change the optimisation and Hessian routines, set the maximum number of iterations, disable writing of intermediate results to file and control the level of detail for on screen printing. The writing of iteration-level estimates into a file in the working directory happens by default when using BFGS for estimation, and allows the user to monitor progress during estimation, which is useful especially for complex models.

Users can also impose constraints in estimation and apply scaling to individual model parameters. This can help estimation if the scale of individual parameters at convergence is very different. In classical estimation, the user can specify scales for individual model parameters - they are scaled by *Apollo* prior to estimation and then returned to their original scale after convergence. For Bayesian estimation, the scales are applied to the posterior parameter chains. Figure 11 illustrates what happens when running apollo_estimate on our model, where only part of the output is shown. After some initial checks (not shown here), *Apollo* splits the data across the cores. This is followed by the main estimation process and finally the calculation of the

Figure 10: Running apollo_speedTest

Hessian. Prior to that step, which can take a long time in complex models, the code also prints out the final estimates⁸. We can see from Figure 11 that the estimation uses minimisation of the negative of the log-likelihood, which is of course equivalent to maximisation of the log-likelihood itself.

⁸At the time of writing, *Apollo* relies on numerical gradients and Hessians only.

The outcomes of model estimation are saved in a list called model, which contains amongst other things the estimates (model\$estimates) and the classical and robust covariance matrices (model\$varcov and model\$robvarcov).

```
model = apollo_estimate(apollo_beta, apollo_fixed, apollo_probabilities, apollo_inputs)
Attempting to split data into 25 pieces.

Figure 11: Running apollo_estimate on hybrid choice model

4.8 Model outputs

Two separate functions are used for outputting results, namely apollo_modelOutput for output to the screen, and apollo_saveOutput for output to files. These two commands do not return an object as output, i.e. are called without an object to assign the output to. The functions are called via:

and

apollo_saveOutput(model,

saveOutput_settings)

The two lists modelOutput_settings and saveOutput_settings are optional and give the user the ability to control the level of detail produced in the output, for example enabling or disabling the reporting of classical standard errors (in addition to robust ones), p-values, t-ratios against 1 (in addition to against 0) and covariance and correlation matrices. The user also has control over what output files are produced when using apollo_saveOutput. An example of the on screen output is shown in Figure 12. For apollo_saveOutput, a text file containing output using the above settings will be produced, using a filename corresponding to apollo_control\$modelName. This is in addition to files contains estimates, covariance and correlation matrices, unless instructed not to do so. The default settings imply a more verbose output for the log file as opposed to the on screen output.

4.9 Processing of results

We now look at some of the additional functions that are provided in *Apollo* to allow the user to analyse model results after estimation.

4.9.1 Delta method

A key use of estimates from choice models is the calculation of functions of these estimates, for example in the form of ratios of coefficients, leading to marginal rates of substitution, and in the case of a cost coefficient being used as the denominator, willingness-to-pay (WTP) measures. It is then important to be able to calculate standard errors for these derived measures, where this can be done sraightforwardly and accurately with the Delta method, as discussed by Daly et al. (2012a). The function apollo_deltaMethod is implemented for this purpose for a limited number of operations, and is called as follows:

 $apollo_deltaMethod(model,$

deltaMethod_settings)

The list deltaMethod_settings has the following components:

operation: A character object operation, which determines which function is to be applied to the parameters. Possible values are sum, diff and ratio for the sum, difference and ratio of two parameters; exp for the exponential of a single parameter; logistic for a logistic transform with either one or two parameters, and lognormal for the mean and standard deviation for a Lognormal distribution on the basis of the mean and standard deviation for the logarithm of the coefficient.

parName1: A character object giving the name of the first parameter.

parName2: Like parName1, but for the second parameter.

                                                                                        0.1143
                                                                                                                18.59
```

multPar1: An optional numerical value used to multiply the first parameter, set to 1 if omitted. multPar2: Like multPar1, but for the second parameter.

An example application of this function is illustrated in Figure 13, where we calculate the WTP for a reduction in the risk of side effects, and also look at the significance of the difference between the means for the two branded products. For the first calculation (i.e. the WTP), we also apply a multiplication by 1,000 to the numerator, thus looking at the WTP for a change by one percentage point.

Figure 13: Running apollo_deltaMethod

Only a limited number of functions of parameters are covered by apollo_deltaMethod. Rather than relying on sampling based approaches such as the Krinsky & Robb method (Krinsky and Robb, 1986) for calculating the standard errors for more complex functions, users who wish to compute standard errors of other functions can for example use the R function deltamethod from the alr3 package (Weisberg, 2005). This uses symbolic differentiation of the user provided function.

4.9.2 Model predictions

A core capability of *Apollo* is that it covers model application (i.e. prediction) in addition to estimation. This is implemented in the function apollo_prediction. The function is called as follows:

The majority of these arguments have been discussed already. The only additional new argument is modelComponent, where this is the name of the model component for which predictions are requested. This argument is required for models with multiple components, and needs to be the name (string) of one of the elements in the list P used inside apollo_probabilities.

The application of this function is illustrated in Figure 14, where we look at what happens to the mean market share for the two branded products after a 50% increase in their cost. Of course, it is overly simplistic to make predictions on SC data alone, and the manual discusses in

detail the steps for rescaling to RP elasticities. Model predictions in *Apollo* always use database as an input, whether applying the model to the base data or a forecast scenario. This means that for looking at the impact of changes to explanatory variables, these changes need to be made in database, and can then of course be reversed after applying apollo_prediction.

```
> base_forecast <- apollo_prediction(model, apollo_probabilities, apollo_inputs, modelComponent="choice")
Updating inputs...Done.
Running predictions from model... Done.
> mean(base_forecast[,1]+base_forecast[,2])
(1 | 0.694406
> database&price_1=1.5*database&price_1
> database&price_2=1.5*database&price_2
> change_forecast <- apollo_prediction(model, apollo_probabilities, apollo_inputs, modelComponent="choice")
Updating inputs...Done.
Running predictions from model... Done.
> mean(change_forecast[,1]+change_forecast[,2])
(1 | 0.4959083
> database&price_1=1/1.5*database&price_1
> database&price_2=1/1.5*database&price_2
```

Figure 14: Running apollo_prediction

Model predictions are also implemented for MDCEV and MDCNEV, where instead of probabilities, the predictions will instead return expected values of consumption for each alternative at the observation level. Predictions are not implemented for exploded logit and Normal density models.

4.9.3 Summary of random heterogeneity

After model estimation, it may be useful to an analyst to have at their disposal the actual values used for random coefficients, especially if these included interactions with socio-demographics or (non-linear) transforms that may lead to a requirement for simulation to calculate moments (as in the semi-non-parametric approach of Fosgerau and Mabit 2013).

For continuous random coefficients, the function apollo_unconditionals is called as follows:

The function produces a list as output, with one element per random coefficient, where this is a matrix for coefficients using inter-individual draws (one row per individual, one column per draw), and a 3-dimensional array (i.e. a cube) for coefficients using inter and intra-individual draws (with one row per observation, and draws in the second and third dimensions). The outputs from this function can then readily be used for summary statistics or to produce plots.

4.9.4 Posterior distributions

There is also extensive interest by choice modellers in posterior model parameter distributions, as discussed in Train (2009, chapter 11) for continuous mixture models and Hess (2014) for latent class. We implement functions for this for both continuous mixed logit and latent class models.

The calculation of posteriors for models with continuous random heterogeneity is implemented in the function apollo_conditionals, which is called as follows:

The function produces a list object with one component per continuous random coefficient (element defined in apollo_randCoeff). Each of these components is a matrix with one row per individual, containing the ID for that individual, the mean of the posterior distribution for that individual for the coefficient in question, and the standard deviation. As apollo_conditionals uses the contents of apollo_randCoeff, any socio-demographic interactions included there will also be included in the calculation for the conditionals.

Figure 15 illustrates the calculation of unconditionals and conditionals for the latent variable in our example. We also show how the results can be contrasted for different subgroups of the data. To do this, we make use of the function apollo_firstRow, which produces a subset of the input data it receives, only retaining the first row for each individual⁹. This is required here as the data has one row per observation, but the conditionals and unconditionals only have one row per person. It is then also possible to use the conditional means for example in regression analysis against characteristics of the individual, as discussed by Train (2009, chapter 11), and as illustrated in the online manual.

5 Extension to Bayesian estimation

Apollo allows the user to replace classical estimation by Bayesian estimation, for all models. We do not provide details here on Bayesian theory but instead refer the reader to Lenk (2014) and the references therein. Bayesian estimation in Apollo makes use of the RSGHB package, and the user is referred to the documentation in Dumont and Keller (2019) for RSGHB-specific settings.

The key advantage for the user is that *Apollo* provides a wrapper around RSGHB so that the syntax in apollo_probabilities does not change when a user moves from classical to Bayesian estimation. To explain the process, we now look at Bayesian estimation of the same model implemented in Section 4. We only discuss those steps where the code differs from the classical estimation case.

The first steps in the model definition are shown in Figure 16. We first set apollo_control\$HB = TRUE and we now also omit the setting apollo_control\$mixing = TRUE as this relates to classical estimation. We then define the individual coefficients and their starting values in apollo_beta as before, with the key difference that for any random coefficients, we now define a single parameter, not a mean and a standard deviation. The definition of apollo_fixed is the same as before.

We next create a list called apollo_HB which can contain any of the settings used in RSGHB (Dumont and Keller, 2019), where we only use a small subset here. One further difference arises.

⁹In particular, by calling $x = apollo_firstrow(x, apollo_inputs)$, we replace x by a version where only the first entry for each individual is retained. The object x can be a vector, matrix or 3-dimensional array.

```

Figure 15: Running apollo_unconditionals and apollo_conditionals

RSGHB requires the user to create an element called gdist with a numeric coding for distributions. *Apollo* instead requires the user to create a named character vector inside apollo_HB that is called hbDist and which contains one entry for each of the parameters in apollo_beta, setting the distribution to use, with the following definitions:

"F": non-random (fixed) parameters¹⁰;
"N": normally distributed random parameters;
"LN-": negative lognormally distributed random parameters;
"LN+": positive lognormally distributed random parameters;
"CN-": normally distributed random parameters, bounded above at 0;
"CN+": normally distributed random parameters, bounded below at 0; and
"JSB": Johnson SB distributed random parameters.

¹⁰This is also the obvious choice for parameters that are to be kept fixed at their starting values.

$\begin{array}{ll} \text{fixedD} &= \text{c(NA,NA,1)},\\ \text{gFULLCV} &= \text{FALSE} \end{array}$		

Figure 16: Bayesian estimation in Apollo: model settings

The entry hbDist is the only compulsory setting when using Bayesian estimation in *Apollo*. In our example, we also define six additional settings, namely:

gNCREP: number of burn-in iterations to use prior to convergence (default=100000); gNEREP: number of iterations to keep for averaging after convergence (default=100000); gINFOSKIP: number of iterations between printing/plotting information (default=250);

- fixedA: a vector of the same length as the number of random parameters, containing the value that the mean of each parameter should be kept fixed to, with NA for freely estimated random parameters (all NA by default);
- fixedD: a vector of the same length as the number of random parameters, containing the value that the variance of each parameter should be kept fixed to, with NA for freely estimated random parameters (all NA by default); and
- gFULLCV: a boolean variable indicating whether the full covariance matrix should be estimated between all random terms (default=TRUE).

In our example, we use these final three settings to constrain the mean and standard deviation of η , the random component in the latent variable, to be 0 and 1, respectively.

In Bayesian estimation, we no longer use *Apollo* to generate draws, and apollo_draws and apollo_randCoeff are thus not used. The apollo_probabilities function for a model estimated using Bayesian techniques uses the same approach as for a model without random heterogeneity, where RSGHB produces individual-specific values to be used for each parameter at each iteration.

Figure 17 shows the apollo_probabilities function for our example, where we only show those parts that have changes. As we no longer create random coefficients using apollo_randCoeff, we now compute the values for the two first brand parameters and the latent variable inside apollo_probabilities, where the random variation in these is introduced by RSGHB. The calculation of probabilities remains exactly the same as before. When using Bayesian estimation, the use of apollo_avgInterDraws and apollo_avgIntraDraws does not apply even in the presence of random coefficients. In addition, the call to apollo_panelProd is ignored as RSGHB automatically groups together observations for the same individual. The inclusion of any of these three commands however does no harm.

The call to apollo_estimate is made in exactly the same way as with classical estimation. In our example, we use scaling for those parameters that we saw obtain very small values in classical estimation. The estimation process is illustrated in Figure 18 for the text output and Figure 19 for a graphical output of the chains. In the text output, we show the first and final iteration, where this also highlights the way in which RSGHB confirms the distributions used at the outset.

The post-estimation output from a model using Bayesian estimation is substantially different from that with classical estimation, and is summarised in Figure 20. The early information on model name, description, and so forth is the same as with classical estimation. This is followed by average model fit statistics across the post burn-in iterations. Next, we have convergence reports for the parameter chains, where these use the Geweke test (Geweke, 1992). The next four parts of the output look at summaries of the parameter chains, each time giving the mean and standard deviation across the post burn-in iterations for each parameter, where these results are divided into the non-random coefficients, the means for the underlying Normals, and the covariance matrix (split across two tables, with the mean and standard deviations of each entry in the covariance matrix). Finally, the output reports the means and standard deviations for the posteriors, where these are for the actual coefficients, i.e. taking into account the distributions used, rather than looking at the underlying Normals. All the values used for these components are also available in the model object after estimation and can be used for plotting. The use of apollo_saveOutput

Figure 17: The apollo_probabilities function for a hybrid choice model using bayesian estimation

operates as before, but if saveEst==TRUE, the code additionally saves the output files produced by RSGHB, which can be very large in size (cf. Dumont and Keller, 2019). As highlighted in Figure 20, when using scaling in Bayesian estimation in *Apollo*, not all estimates are returned to their original scale after estimation. Indeed, the scaling is applied to the parameter chains directly, and producing scaled values for the underlying Normals is thus not convenient. We thus report the scaled outputs only for the fixed parameters, the random parameters after transformation to the actual distributions used, and the posterior means.

In classical estimation, *Apollo* creates an object estimates in the model list created after estimation, containing the final parameter values. When using Bayesian estimation, model\$estimates is also produced, combining non-random parameters with individual specific posteriors for random parameters. This allows the user to use apollo_prediction and apollo_llCalc on such outputs, where care is of course required in interpretation of outputs based on posterior means. As shown in Figure 21, the outcomes in prediction are in line with what we saw in classical estimation in Figure 14.

6 Additional functionalities

Apollo provides many additional functionalities beyond those covered in this paper. A full overview is provided in the online manual and only some brief highlights are presented here.

Figure 18: Bayesian estimation in Apollo: estimation process

6.1 Additional pre-estimation tools

Three additional functions provide some flexibility to a user before starting model estimation.

Markov Chains

Figure 19: Bayesian estimation in Apollo: estimation process (parameter chains)

- apollo_readBeta allows a user to read in estimates from a previous model to use as starting values.
- apollo_searchStart implements a simplified version of the algorithm proposed by Bierlaire et al. (2010) to find better starting values for a model with the hope of reducing the risk of convergence to a poor local optimum.
- apollo_llCalc allows the user to calculate the log-likelihood of the model (and subcomponents) for given parameter values, before or after estimation.

6.2 Additional model structures

Apollo provides ready made functions for many other model components beyond the MNL and ordered logit models discussed in this paper. While additional models will be added over time, at the time of writing this paper, Apollo version 0.0.8 included functions for seven additional model structures, as follows:

apollo_cnl provides an implementation of the cross-nested logit (CNL) model (Vovsha, 1997), where we follow the "Generalised Nested Logit" (GNL) model of Wen and Koppelman (2001), with all nesting parameters freely estimated, and the constraint on the allocation parameters

(showing the membership of alternative j in nest m) that $0 \le \alpha_{j,m} \le 1$, $\forall j, m$ and $\sum_j \alpha_{j,m} = 1$, $\forall m$. Only two-level versions of CNL are available through the apollo_cnl function.

- apollo_dft allows the user to estimate decision field theory (DFT) models, a popular dynamic preference accumulation structure in mathematical psychology (Busemeyer and Townsend, 1992, 1993) which has recently made the transition into mainstream choice modelling (Hancock et al., 2019).
- apollo_el provides an implementation of an exploded logit model for ranking data (or bestworst data, see Lancsar et al. 2013) where the user can allow for scale differences across stages. apollo_mdcev allows the user to estimate the Multiple Discrete Continuous Extreme Value (MDCEV) model (Bhat, 2008), where no restriction are imposed on the profile to be used and where the model can be used with or without an outside good.
- apollo_mdcnev provides an implementation of the Multiple Discrete Continuous Nested Extreme Value (MDCNEV) model of Pinjari and Bhat (2010). The implementation of MDCNEV in *Apollo* allows for only a single level of nesting and is also only valid for models with an outside good, i.e. a product that is consumed in every observation.
- apollo_nl allows the estimation of nested logit (NL) models (Daly and Zachary, 1978; Mc-Fadden, 1978; Williams, 1977) without any constraints on the number of layers in the nesting structure. We adopt the efficient implementation of Daly (1987) but adapt it to the more commonly used version which divides the utilities by the nesting parameter in the within nest probabilities (see the discussions in Train 2009, chapter 4, and Koppelman and Wen 1998).
- apollo_normalDensity is an implementation of the Normal probability density function for continuous dependent variables (or ordinal dependent variables that are treated as continuous).

In general, all models implemented in *Apollo* allow for prediction as well as estimation (except for apollo_normalDensity and apollo_el) and also allow for the inclusion of random heterogeneity in model parameters, with very few restrictions. In particular, only the α parameters in CNL, the σ parameters in MDCEV and the θ parameters in MDCNEV need to be kept non-random.

As already mentioned, users of *Apollo* are not restricted to those models for which functions are available in the code. Any model that yields a probability for an outcome can be used in the code and parameters for the model can be estimated using either classical or Bayesian estima-

tion. Users can either create new functions in R that are defined outside apollo_probabilities much in the same way as for example apollo_mml or simply code the probabilities for a model inside apollo_probabilities. An illustration of the latter approach is shown in the expectation-maximisation example in the online manual, which also discusses the requirements for user provided functions.

6.3 Other heterogeneity

6.3.1 Intra-individual heterogeneity

We have discussed in detail the implementation of continuous random heterogeneity at the level of individual decision makers. *Apollo* allows for a very general use of continuous random coefficients and works for models allowing for intra-individual mixing (i.e. heterogeneity at the level of individual choices), inter-individual mixing (i.e. heterogeneity at the level of individual people), as well as a mixture of the two.

A very flexible implementation is used that minimises the changes in the code that are required to introduce random coefficients or to change between the different layers of integration, with the code largely remaining the same. In terms of internal implementation, the package works with arrays in three dimensions. For a model without continuous random coefficients, the likelihood for a model (prior to multiplying across observations for the same individual) is contained in a column vector of length O, where O is the number of observations in the data. If we introduce continuous random heterogeneity at the level of individual people, with multiple choices per person, the likelihood is given by a OxR_1 matrix, with one row per observation, and one column per draw from the random coefficients, where we use R_1 draws per random coefficient and per individual. Here, the same draws would be reused across the T_n rows for a given individual n, meaning that we would have N sets of draws, where N is the number of individuals. In the presence of additional heterogeneity at the level of individual observations, the likelihood becomes a 3dimensional array (i.e. a cube) of dimensions OxR_1xR_2 , where in this third dimension, different draws are used across different choices for the same individual. As described by Hess and Train (2011), a given inter-individual draw is then associated with multiple intra-individual draws. If only intra-individual heterogeneity is used, the cube collapses to an array of dimensions $Ox_{1x}R_{2}$, i.e. a matrix but with columns going into the third dimension rather than second dimension.

The inclusion of intra-individual heterogeneity in *Apollo* simply requires the definition of a different type of draws, which are distributed across and within individuals (using intraDrawsType, intraNDraws, intraUnifDraws and intraNormDraws in apollo_draws) and the averaging across intra-individual draws (using apollo_avgIntraDraws) prior to taking the product across choices for the same individual (apollo_panelProd).

6.3.2 Discrete mixtures and latent class

Apollo offers the same degree of flexibility with latent class and discrete mixture models as with continuous mixture models. Full details of the implementation of latent class models are given in the online manual. The implementation follows an approach very similar to that for continuous random heterogeneity. The user implements a function called apollo_lcPars, which performs

a role analagous to apollo_randCoeff for continuous mixtures. Like apollo_randCoeff, this function takes apollo_beta and apollo_inputs as inputs and generates a new list which contains the parameters that vary across classes as well as the class allocation probabilities. The outputs from this function can then be used inside apollo_probabilities, typically with a loop over classes. Functions are also available to compute conditional and unconditional heterogeneity from latent class models, using apollo_lcConditionals and apollo_lcUnconditionals, respectively. *Apollo* also allows users to combine continuous random heterogeneity with latent classes (cf. Greene and Hensher, 2013). Continuous heterogeneity can be allowed for both in the within-class probabilities and in the class membership probabilities.

6.4 Additional post-estimation tools

A number of additional post-estimation tools are included in *Apollo*, namely:

- apollo_bootstrap allows estimation of the variance of parameters through a simple block bootstrap. Given a number of repetitions, this function generates as many new samples as requested, by sampling individuals (i.e. blocks of observations) with replacement from the original dataset. Then parameters are estimated for each of these new samples. Finally, the covariance matrix of the sequence of estimated parameters is calculated. This matrix is in itself an estimator of the covariance matrix of the parameter estimates.
- apollo_combineResults to produce an output file combining the estimates from multiple models run on the same data.
- apollo_fitsTest compares the performance of the estimated model to predict the chosen alternative for different subsets of the data
- apollo_loadModel allows the user to load into memory a model object previously saved using apollo_saveOutput, thus permitting the use of all post-estimation functions.
- apollo_lrTest provides an implementation of the likelihood ratio test.
- apollo_outOfSample estimates models on multiple subsets of the data and then compares the per observation log-likelihood to that in the remaining (hold-out) sample.
- apollo_sharesTest provides an implementation of a routine like *apply* tables in ALogit (ALogit, 2016), looking at the recovery of market shares in given subset of the data.

7 Summary

In this paper, we have given a brief overview of the capabilities of Apollo. We have illustrated how a popular class of models, namely hybrid choice structures, can be easily implemented in Apollo and estimated using either classical or Bayesian estimation. Numerous functions are then available for processing of the results. Of course, a user can also make use of the many tabulation and plotting functions available in **R** for further analysis and formatting of model results.

Throughout the paper, we made reference to the online manual which contains more extensive details on the available functions, as well as numerous examples showing the implementation of different models in *Apollo*. We again strongly recommend that any prospective user of *Apollo* studies the online manual in depth after the general introduction provided in this paper.

In the years to come, it is our hope to add many exciting new capabilities to *Apollo*. This includes functions for new model structures, further computational improvements by coding more of the underlying calculations in C++ (Eddelbuettel and François, 2011), and making further refinements to the implementation of expectation-maximisation (EM) routines (cf. Train, 2009, ch. 14).

8 Acknowledgments

While the *Apollo* package is the results of many years of development, the core of this work was carried out under the umbrella of the European Research Council (ERC) funded consolidator grant 615596-DECISIONS. We are grateful to the many colleagues who provided suggestions and/or tested the code extensively, including Chiara Calastri, Romain Crasted dit Sourd, Andrew Daly, Jeff Dumont, Joe Molloy and Basil Schmid. We would like to especially thank Thijs Dekker for his contributions to precursors of Apollo and his guidance on the EM algorithm, Thomas Hancock for his implementation of Decision Field Theory and Annesha Enam for her contributions on MDCEV without an outside good. We are also grateful to Kay Axhausen for making the Swiss public transport route choice dataset available. Finally, we would like to thank Michiel Bliemer and an anonymous referee for substantial comments on an earlier draft of this paper.
