Abstract. The deposition of ozone to seawater is an important ozone sink. Despite constituting as much as a third of the total ozone deposition, it receives significantly less attention than the deposition to terrestrial ecosystems. Models have typically calculated the deposition rate based on a resistance-in-series model with a uniform waterside resistance. This leads to models having an essentially uniform deposition velocity of approximately 0.05 cm s^{-1} to seawater, which is significantly higher than the limited observational dataset. Following from Luhar et al. (2018) we include a representation of the oceanic deposition of ozone in the GEOS-Chem model of atmospheric chemistry and transport based on its reaction with sea-surface iodide. The updated scheme halves the calculated annual area-weighted mean deposition velocity to water from 0.0464 cm s^{-1} (25th and 75th percentiles of 0.0461 cm s^{-1} and 0.0471 cm s^{-1} respectively) to 0.0231 cm s^{-1} (25th and 75th percentiles of 0.0121 cm s^{-1} and 0.0303 cm s^{-1} respectively). The calculated ozone deposition velocity varies from 0.009 cm s^{-1} in polar waters to 0.040 cm s^{-1} at the tropics. This improves comparisons to observations. The variability is driven mainly by the temperature-dependent rate constant for the reaction between iodide and ozone, the temperature dependence of the solubility, and variations in the ocean iodide concentration. The calculated annual deposition flux of ozone to the ocean is reduced from 222 to 122 Tg yr^{-1} , and overall deposition of ozone to all surface types reduces from 862 to 758 Tg yr^{-1} . Tropospheric ozone burdens and global mean OH increase from 324 to 328 Tg , and from 1.17×10^6 to $1.18 \times 10^6 \text{ molec. cm}^{-3}$, respectively. A total of 34 % of surface grid boxes experience a 10 % or greater increase in

ozone concentration. Comparisons between observations of surface ozone and the model are improved with the new parameterization notably around the Southern Ocean. Process-level representation of oceanic deposition of ozone thus appears essential for representing the concentration of surface ozone over the planet.

1 Introduction

Tropospheric ozone is an important secondary pollutant. Globally it causes one million premature deaths a year (Malley et al., 2017), degrades ecosystems (Fowler et al., 2008) and is a greenhouse gas (IPCC, 2013). Transport from the stratosphere and in situ chemical production are balanced by chemical destruction and dry deposition to the surface. Total dry deposition of ozone is thought to amount to $\sim 978 \text{ Tg yr}^{-1}$ (Hardacre et al., 2015) compared to $\sim 500 \text{ Tg yr}^{-1}$ transported from the stratosphere, $\sim 5000 \text{ Tg yr}^{-1}$ for chemical production and $\sim 4500 \text{ Tg yr}^{-1}$ for chemical loss (Young et al., 2018). Whilst dry deposition velocity to the ocean is thought to be slow ($\sim 0.05 \text{ cm s}^{-1}$) compared to vegetation ($\sim 0.1 \text{ cm s}^{-1}$), the larger area of the ocean compared to the land results in ozone deposition to the ocean representing approximately one-third of the total deposition (Ganzeveld et al., 2009).

The ultimate sink of ozone to the ocean is due to chemical reactions. The reaction of ozone with iodide (I^-) in the surface layer of the ocean via the simplified Reaction (R1) (Garland and Curtis, 1981; Sakamoto et al., 2009; Hayase et al., 2010; Carpenter et al., 2013) is believed to be the

dominant mechanism (Garland et al., 1980). The transport of ozone within the ocean surface also plays an important role in this process; a simplified version of the relevant processes is shown in Fig. 1.

In addition, dissolved organic carbon (DOC) has been shown to react with dissolved ozone and have an enhancing effect on ozone deposition similar to that of iodide (Martino et al., 2012; Shaw and Carpenter, 2013), but it is less well understood. Dimethyl sulfide (DMS) and bromide have also been shown to enhance ozone deposition velocity but by small amounts (Sarwar et al., 2016).

The net flux of a gas to a surface F is calculated as the atmospheric concentration at the ocean surface C multiplied by the deposition velocity, v_d , shown in Eq. (1).

$$F = -v_d C \quad (1)$$

The deposition velocity (v_d) in many models is calculated using the resistance-in-series scheme (Wesely and Hicks, 1977) shown in Eq. (2). This describes the different limiting factors of the deposition: transport to the surface through turbulent transport (r_a); transport through the quasilaminar sub-layer, which is the air directly in contact with a surface (r_b); and the physical, chemical or biological loss of the molecule at the surface (the ocean in this case) (r_c).

$$v_d = \frac{1}{r_a + r_b + r_c} \quad (2)$$

The relative importance of the different resistances is dependent primarily on the gas being considered. Gases that are highly soluble (such as sulfur dioxide) will have a small r_c , so their limiting factors are the atmospheric resistances (r_a and r_b). Less soluble gases such as ozone are limited by the chemical loss at the surface (r_c). Wesely (1989) gives a value of $r_c = 2000 \text{ s m}^{-1}$ for ozone in all water types, and this is used in most atmospheric chemistry models (Hardacre et al., 2015; Luhar et al., 2017, 2018). This chemical loss of ozone is the limiting factor for ozone deposition (95 % of the sum of the resistances is the value of r_c ; Chang et al., 2004) and so yields an almost constant (0.05 cm s^{-1}) overall deposition velocity, with only small variation due to meteorological variation in r_a and r_b . However, observations of ozone deposition show significant variability. From the observations collated by Ganzeveld et al. (2009), fresh water deposition velocities range from 0.01 to 0.1 cm s^{-1} , with ocean observations ranging from 0.01 to 0.15 cm s^{-1} . The higher values of ocean observations are likely influenced by coastal effects such as those described by Bariteau et al. (2010), with the open-ocean observations being substantially lower (0.009 – 0.065 cm s^{-1}) (Helmig et al., 2012).

Given this observed variability, the fixed r_c approach appears overly simple. Based on Fairall et al. (2007) and Luhar

et al. (2017), Luhar et al. (2018) formulated a new scheme for calculating r_c which explicitly takes into account the simultaneous effects of chemical reactions in the ocean with iodide and the physical processes of molecular diffusion and turbulent transfer in the ocean surface. This considers three oceanic layers (Fig. 1): a very shallow “surface reaction–diffusion” layer that represents the region of the ocean through which the O_3 can diffuse from the ocean before it reacts in the ocean, which lies above a thicker turbulent layer which is mixed by wind-stress-driven turbulence, which in turn lies above the “bulk” ocean. The loss of O_3 is determined by the chemical reactivity within the reaction–diffusion layer, which is supplied by I^- from below. The resulting scheme, derived by Luhar et al. (2018), is based on solving the fundamental equation for the conservation of mass of a reacting and diffusing substance in water (Fairall et al., 2007) and yields Eq. (3).

$$r_c = \frac{1}{\alpha \sqrt{aD}} \left[\frac{\Psi K_1(\xi_\delta) \sinh(\lambda) + K_0(\xi_\delta) \cosh(\lambda)}{\Psi K_1(\xi_\delta) \cosh(\lambda) + K_0(\xi_\delta) \sinh(\lambda)} \right] \quad (3)$$

Here α is the dimensionless solubility, a is the chemical reactivity of O_3 with sea-surface iodide (the product of $[\text{I}^-]$ and the second order rate-coefficient, k), D is the diffusivity of O_3 in water, Ψ is defined in Eq. (5) where u_w^* is the water-side friction velocity, δ_m is the thickness of the reaction–diffusion layer of the sea-surface microlayer, κ is the von Kármán constant (≈ 0.4), ξ_δ defined in Eq. (4), λ is defined in Eq. (6), and K_0 and K_1 are modified Bessel functions of the second kind with order zero and one respectively.

$$\xi_\delta = \left[\frac{4a}{\kappa u_w^*} \left(\delta_m + \frac{D}{\kappa u_w^*} \right) \right]^{\frac{1}{2}} \quad (4)$$

$$\Psi = \left[1 + \left(\frac{\kappa u_w^* \delta_m}{D} \right) \right]^{\frac{1}{2}} \quad (5)$$

$$\lambda = \delta_m \sqrt{\frac{a}{D}} \quad (6)$$

In this paper we include this description of ozone deposition to the ocean in the GEOS-Chem model and explore the impact on the composition of the troposphere. In Sect. 2 we describe the GEOS-Chem model and the implementation of the new scheme. In Sect. 3 we describe the impact of the new scheme on the deposition velocities of ozone to the ocean in the model and assess them against observations of deposition velocities. The impacts of the new deposition scheme on the composition of the troposphere are described in Sect. 4 together with comparison to observations of surface ozone. Finally we draw some conclusions in Sect. 5.

2 Modelling

We use here version 12.1.1 of the 3-D global chemical transport model GEOS-Chem “Classic” (Bey et al.,

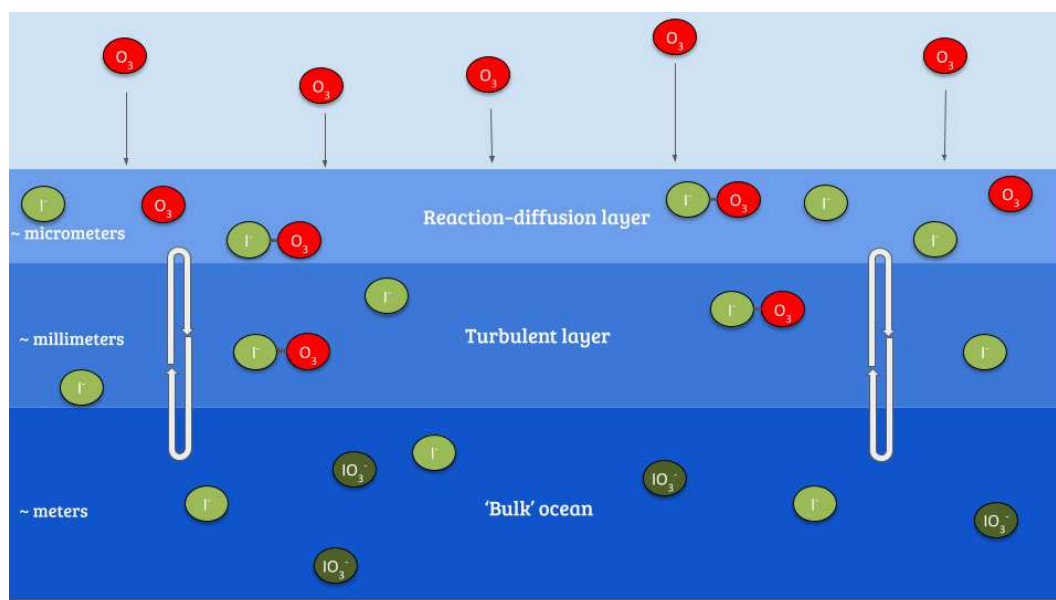

Figure 1. Illustration of the reaction of ozone with I^- in the sea surface, also demonstrating a simplified version of the surface structure where the reaction occurs.

2001) (<http://www.geos-chem.org>, last access: 20 February 2020) driven by assimilated meteorology from the NASA Global Modeling and Assimilation Office. GEOS-Chem includes HO_x – NO_x –VOC ozone–halogen–aerosol tropospheric chemistry with the halogen (chlorine, bromine and iodine) chemistry being the most recent addition, as described by Sherwen et al. (2016b). In this work we use global simulations run at a spatial resolution of $2^\circ \times 2.5^\circ$ with meteorological data from MERRA-2 (Gelaro et al., 2017). Whilst $2^\circ \times 2.5^\circ$ is a relatively coarse model resolution, we do not believe that there is any significant sub-grid-scale correlation between tropospheric ozone concentration and sea-surface I^- concentration; therefore this should not result in a resolution dependence. We run simulations for 2006–2008, 2013 and 2014 so that field observations are compared with the appropriate meteorology. Analysis of the sensitivity of the ozone deposition velocity to its controlling factors uses model runs for 2014. For the analysis of the impact on atmospheric composition, a 1-year “spin-up” was used to allow the tropospheric composition to reach equilibrium before the subsequent analysis year.

As with many other atmospheric chemistry and transport models, the dry deposition in GEOS-Chem uses a resistance-in-series scheme based on that of Wesely (1989). The details of this implementation are described by Wang et al. (1998). For terrestrial land types, the dry deposition in GEOS-Chem is generally consistent with observations (Silva and Heald, 2018).

We follow the Luhar et al. (2018) methodology, and as shown in Eq. (3), this requires the calculation of α , D , k , $[I^-]$ and δ_m . Where these require the sea surface

temperature (K), T , we use the skin temperature from the MERRA-2 meteorological fields.

We use the dimensionless solubility of ozone in water α from Morris (1988).

$$\alpha = 10^{-0.25-0.013(T-273.16)} \quad (7)$$

We use the diffusivity D ($m^2 s^{-1}$) from Johnson and Davis (1996).

$$D = 1.1 \times 10^{-6} \exp\left(\frac{-1896}{T}\right) \quad (8)$$

The temperature-dependent k ($M^{-1} s^{-1}$) for the aqueous phase reactions between ozone and iodide is from Magi et al. (1997).

$$k = \exp\left(\frac{-8772.2}{T} + 51.5\right) \quad (9)$$

The reaction–diffusion sub-layer thickness (m) is defined as

$$\delta_m = \sqrt{\frac{D}{a}} \quad (10)$$

and the global ocean iodide concentration distribution $[I^-]$ (M) is taken from the most recent global climatology (Sherwen et al., 2019).

The waterside friction velocity u_w^* (ms^{-1}) can be calculated from the MERRA-2 atmospheric friction velocity u^* using Eq. (11), where ρ_a and ρ_w are the density of the atmosphere and seawater respectively. This assumes that drivers of atmospheric stress result in an equivalent oceanic stress

(Fairall et al., 2007).

$$u_w^* = \sqrt{\frac{\rho_a}{\rho_w}} u^* \approx 0.0345 u^* \quad (11)$$

Three significant differences exist in our choice of parameters compared to the work of Luhar et al. (2018). Firstly, we use the Sherwen et al. (2019) ocean iodide distributions, whereas they use MacDonald et al. (2014). Sherwen et al. (2019) is based on a recent collation of sea surface iodide observations (Chance et al., 2019) which are interpolated using a machine learning approach. MacDonald et al. (2014) is based on a more restrictive observational dataset and uses a simple temperature-based parameterization. Sherwen et al. (2019) calculate a global average sea-surface $[I^-]$ of 105.8 ± 45.6 nM, which is a significant increase from the global mean of 58.9 ± 34.9 nM found by MacDonald et al. (2014). Secondly, we include a variable thickness for the reaction–diffusion sub-layer (Eq. 10). Luhar et al. (2018) explored various options for this parameter and decided upon a fixed value of δ_m (3.0×10^{-6} m) as this gave the best fit of v_d to observations from Helmig et al. (2012). We decide to use the variable definition in our work as this is more physically based and produces comparable results in our simulations. However, it should be noted that using this definition of δ_m results in terms cancelling in Eq. (6) such that $\lambda = 1$. This thus simplifies Eq. (3) somewhat as $\sinh(1) \approx 1.175$ and $\cosh(1) \approx 1.543$. Some of the implications for different choices for δ_m are explored in Luhar et al. (2018). Finally, we differentiate between salt and fresh water, using a salinity map from the World Ocean Atlas 2013 (Zweng et al., 2013). The new ozone deposition scheme is only applied to ocean water. Anywhere with water and a salinity below 20 PSU or no salinity value (fresh water) is assigned a constant $r_c = 2000$ s m⁻¹. One further difference between this work and that of Luhar et al. (2018) is in the global chemistry transport model and its chemistry scheme, GEOS-Chem includes halogen chemistry which has a notable effect on tropospheric ozone (Sherwen et al., 2016b).

Any additional computational expense of implementing this improved r_c calculation will be small as the deposition velocity calculation remains a two-dimensional problem, unlike the chemistry or transport calculations which are three dimensional problems.

It would be possible to apply this method of calculating r_c to other chemical species, if the appropriate sink processes were understood, chemical kinetics available and concentrations of reactant species known. For this to be useful, the species would need to have a high dependence on r_c (rather than the physical resistances), but also for dry deposition to form a substantial part of the species budget. It is not clear whether any species, other than O₃, would meet these requirements.

3 Impact of new parameterization on deposition

3.1 Change in global distribution of deposition velocities

Figure 2 shows the annual average global distribution of oceanic ozone deposition velocity for both the standard model and the updated surface resistance scheme, along with the percentage difference between the two. Table 1 gives a statistical description of global ozone dry deposition in the model. The near-uniform value of v_d with the standard uniform surface resistance can be observed in Fig. 2a. The small variability in deposition velocity seen is driven by differences in the meteorology. This contrasts with the variability calculated with the new scheme (Fig. 2b). The two schemes also differ in the magnitude of the deposition velocities. The largest change occurs in the coolest waters towards the poles, with the Southern Ocean having a reduction of over 90 % compared to the standard scheme, whereas the tropics can have as little as a 10 % reduction. The distribution of v_d is similar to that shown in Luhar et al. (2018), despite our use of the variable thickness for the reaction–diffusion sub-layer and the use of the Sherwen et al. (2019) iodide. On an area-weighted basis, the deposition of ozone to the ocean surface is reduced from 0.0464 cm s⁻¹ (25th and 75th percentiles of 0.0461 and 0.0471 cm s⁻¹ respectively) to 0.0231 cm s⁻¹ (25th and 75th percentiles of 0.0121 and 0.0303 cm s⁻¹ respectively). This amounts to a halving of the mean ocean deposition velocity. The reduction of deposition velocity to the ocean results in a reduction of 17 % in the global average deposition velocity (Table 1). The total annual loss of tropospheric ozone to dry deposition decreases by 104 to 758 Tg yr⁻¹, substantially lower than the average of 978 ± 127 Tg yr⁻¹ from the multi-model comparison found by Hardacre et al. (2015) but comparable to the value obtained by Luhar et al. (2018) of 722 ± 87.3 Tg yr⁻¹. The seasonal changes in ozone oceanic deposition velocities from the new annual mean are shown in Fig. 3. This shows the response of the ozone deposition velocity to changes in sea-surface temperature, with the highest value in the summer for each hemisphere and the lowest values occurring in the winter. In the extra-tropical oceans, deposition velocities are predicted to vary by roughly 50 % between summer and winter. Deposition velocities in the tropics remain relatively constant over the year.

3.2 Comparison to observations

Here we evaluate the modelled deposition velocities against the open-ocean measurements from Helmig et al. (2012), who measured ozone fluxes to the ocean surface using eddy covariance. These measurements are from a series of five cruises between 2006 to 2008 that took place in the Gulf of Mexico, eastern Pacific Ocean, western Atlantic Ocean and Southern Ocean (Fig. 4). These cruises were made in waters

Table 1. Area-weighted annual average deposition velocity and deposition flux for 2014 by land type for ozone in GEOS-Chem using the default (constant) and new (variable) scheme for calculating r_c . The 25th and 75th percentiles are the subscripts and superscripts respectively for each land type's deposition velocity. The average deposition velocities and 25th and 75th percentiles were calculated from monthly average model values for grid boxes containing 100 % of the land type specified unless otherwise stated.

Land type	Constant r_c		Variable r_c	
	O_3 v_d (cm s ⁻¹)	O_3 deposition flux (Tg yr ⁻¹)	O_3 v_d (cm s ⁻¹)	O_3 deposition flux (Tg yr ⁻¹)
Land	0.2370 _{0.1486} ^{0.2612}	383	0.2370 _{0.1486} ^{0.2612}	386
Ocean	0.0464 _{0.0461} ^{0.0471}	222	0.0231 _{0.0121} ^{0.0303}	122
Mixed*	0.1501 _{0.0489} ^{0.1785}	255	0.1426 _{0.0332} ^{0.1755}	248
Ice	0.0098 _{0.0094} ^{0.0100}	2	0.0098 _{0.0094} ^{0.0100}	2
All	0.0937 _{0.0319} ^{0.0582}	862	0.0781 _{0.0124} ^{0.0460}	758

*Mixed is defined as any grid box containing less than 100 % water and less than 100 % land.

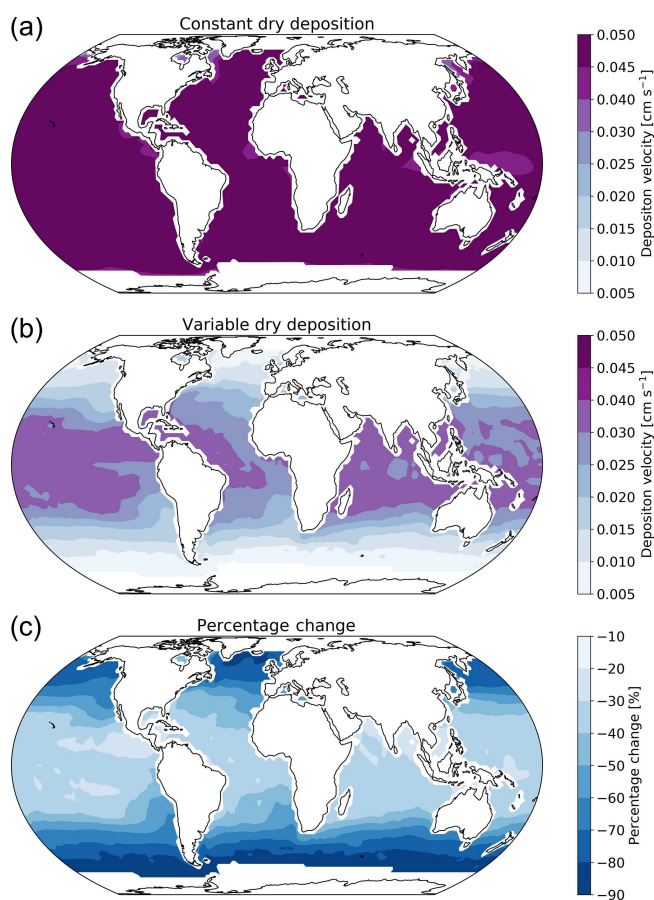

Figure 2. Annual average ozone deposition velocities for 2014 as calculated by GEOS-Chem using the default deposition scheme (a), the new parameterization (b) and the percentage change between the two schemes (c). A $2^\circ \times 2.5^\circ$ land mask has been applied to the deposition velocities to show only the deposition velocity to the ocean.

of significantly different sea surface temperature (SST) and show a trend between deposition velocity and the SST. The comparisons between observations and model were made using daily average values with model output selected from grid boxes that the ship track passed through in that 24 h period. The old scheme (grey line) overestimates the rate of dry deposition substantially and fails to capture any of the temperature dependencies seen in the observations. The new scheme (black line) is a significant improvement, agreeing more with the magnitude and the temperature dependence of the observations. It should be noted that there are significant uncertainties in the measured deposition velocities at low values (Helmig et al., 2012). Combining all the measurements made by Helmig et al. (2012) and comparing to the model predictions for deposition velocity, the root mean square error for the model agreement was reduced from 0.04 cm s^{-1} using the default scheme to 0.01 cm s^{-1} using the new scheme. Whilst the overall agreement of the model with the observations has been improved, the model still fails to capture all of the variability of the deposition velocity measurements. This may be an issue with the resolution of the model ($2^\circ \times 2.5^\circ$), which may fail to capture local conditions. Uncertainties in sea-surface iodide concentration or the lack of other sea-surface reactions (reaction between ozone and DOC) may also contribute.

3.3 Sensitivity of new scheme

We explore here the sensitivity of the new scheme to our choice of parameterization for u_w^* , Γ^- , k , D and α . Five model simulations were each run for a year, with only one of the parameters allowed to vary. When constrained, the value of each parameter was set to a representative value of the global average (α , D , k calculated with an SST of 289 K, sea-surface iodide concentration of 106 nM and u_w^* of 0.01 m s^{-1}). A sixth model simulation was run with all r_c

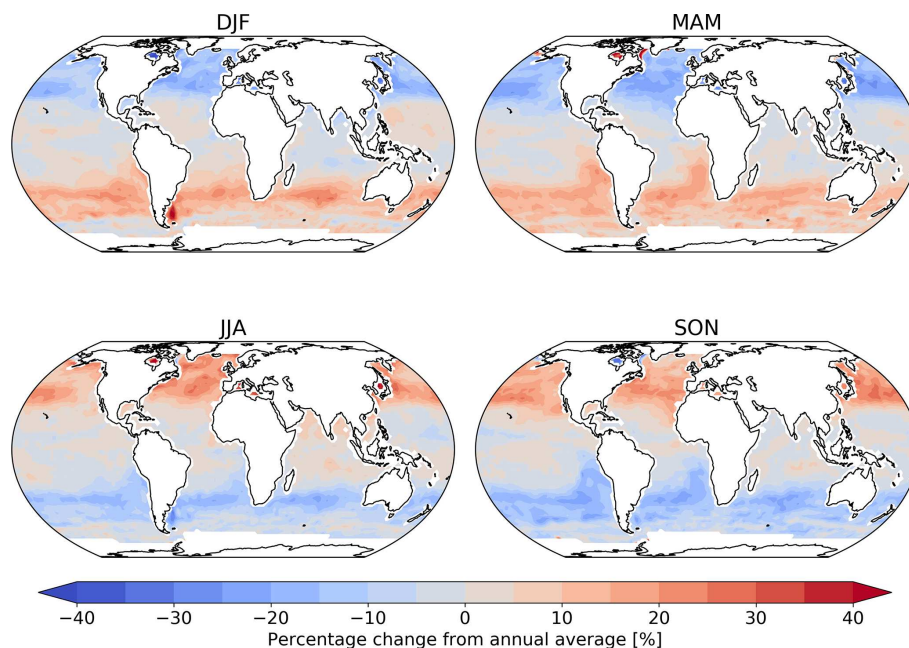

Figure 3. Percentage change from the annual mean deposition velocity for 2014 in December, January and February (DJF); March, April and May (MAM); June, July and August (JJA); and September, October and November (SON) for the new parameterization (shown in Fig. 2), demonstrating the deposition velocity responding to changes in sea-surface temperature and ocean I^- concentration, with the lowest values of deposition velocity seen in the winter of each hemisphere. Land and ice grid boxes have been masked out.

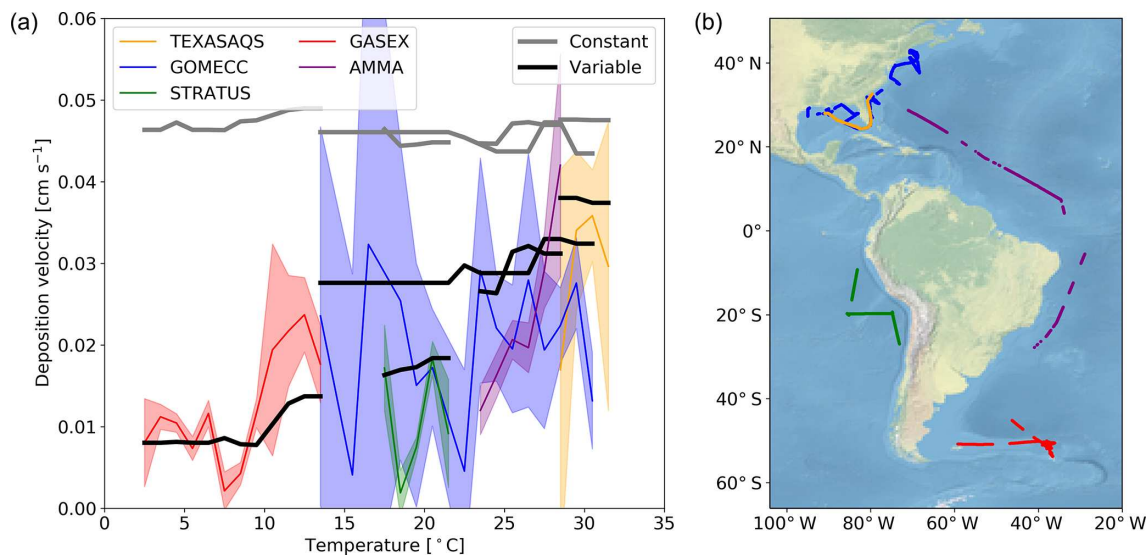

Figure 4. (a) The deposition velocities predicted by the model using the default (constant) value for r_c and the new (variable) parameterization of r_c compared against the five open-ocean cruise datasets of ozone deposition by Helmig et al. (2012). The solid lines represent the median of the deposition velocity for a 1° temperature window, with the shaded region representing the 25th to 75th percentiles. (b) The locations along the cruise tracks where the ozone deposition has been compared.

parameters kept constant at these representative values. The resulting dependence of deposition velocity for each simulation is shown in Fig. 5 as a function of sea surface temperature. If all of the terms needed to calculate r_c are kept constant (top left) the oceanic deposition velocity does not

vary with temperature. Similarly, if only the water side friction velocity is allowed to vary, no dependence on temperature is seen. Surprisingly the temperature dependence of the iodide concentration is not large, reflecting its square root dependence in the calculation of r_c . The two most important

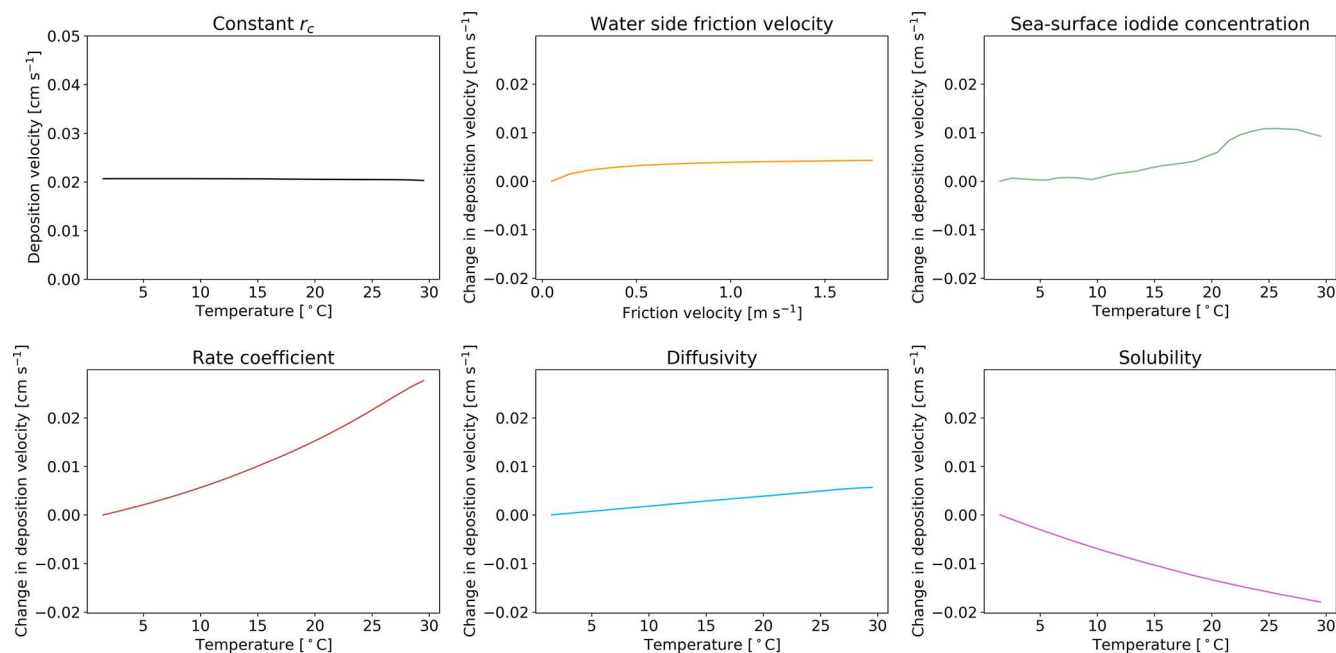

Figure 5. The response of deposition velocity to the variation of only a single parameter, with other parameters set to global average values. Sea-surface iodide concentration $[I^-]$, rate coefficient k , diffusivity D and solubility α are produced from global values averaged into 1 K temperature bins. Water side friction velocity u_w^* is averaged into 0.1 m s^{-1} friction velocity bins.

Figure 6. The response of deposition velocity to different laboratory measurements of k . Three are constant with respect to temperature (Garland et al., 1980; Liu et al., 2001; Hu et al., 1995) and the temperature-dependent parameterization of Magi et al. (1997), with two additional cases of k based on the error range of the Magi et al. (1997) measurements (shown in Eqs. 13 and 12). Each function is produced from global values averaged into 1 K temperature bins, with the shaded region representing the 25th to 75th percentiles.

factors for giving the observed temperature dependence are k and α . Of these two terms, the dependence on rate coefficient carries the most uncertainty.

Magi et al. (1997) is the only temperature-dependent rate constant in the literature. Other studies are at single temperatures and show differences (Luhar et al., 2018). We explore the impact of these differences by running a number of simulations with different values of the rate constants (Fig. 6). We use the single temperature rate constants given by Garland et al. (1980) ($2.0 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ at 298 K), Liu et al. (2001) ($1.2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ at 298 K) and Hu et al. (1995) ($4.0 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ at 277 K). We also use the upper (Eq. 12) and lower (Eq. 13) estimates of Magi et al. (1997) (based on the reported error of the series of measurements).

$$k = \exp\left(\frac{-9261.6}{T} + 53.6\right) \quad (12)$$

$$k = \exp\left(\frac{-8796.2}{T} + 50.8\right) \quad (13)$$

Figure 6 shows that the uncertainties in k can substantially impact the modelled deposition velocity, with the difference between a temperature-invariant and temperature-dependent k most notable. The temperature-independent rate constants do not correctly simulate the observed temperature variability in deposition velocity. The higher estimate from Magi et al. (1997) overestimates the deposition velocity in warm waters, with the lower estimate underestimating in cold waters. As discussed in Sect. 1 iodide is the dominant but not the only removal mechanism for ozone at the ocean surface. Given the upper and mid value of the Magi et al. (1997) rate constants there does not appear to be much potential for other oceanic components to play an important role. On the other

hand, if the lower values of the Magi et al. (1997) rate constant were correct, this would allow for the inclusion of additional reactions (such as that of ozone with dissolved organic carbon) in the model parameterization without overestimating deposition velocities.

4 Atmospheric impact

4.1 Global impacts

The net decrease in deposition of ozone to the surface results in an increase in both surface and column ozone mixing ratios (Fig. 7). The greatest increase in ozone concentration occurs in the boundary layer, with the magnitude of the change decreasing with altitude through the troposphere. The largest increases in the ozone mixing ratio is above the oceans, most notably the extra-tropics, with the Southern Hemisphere extra-tropics being the area of greatest increase. The increase in surface ozone concentration becomes small over land. Surface grid boxes that experience a 10 % increase or greater in ozone mixing ratio represent 34 % of the total surface grid box count. Table 2 gives diagnostics on the oxidative capacity of the troposphere for both the old and new schemes. The increase in ozone mixing ratio shown in Fig. 7 equates to an increase in the tropospheric ozone burden of 4 Tg yr^{-1} (1.2 %). This affects the global chemical production and loss of O_3 ; however, these changes are globally minimal, at -0.6% and 1.2% , respectively.

Another consequence of the increased ozone mixing ratio is a small increase in global mean OH concentration of 0.9 % (Table 2), resulting in a decrease in the tropospheric methane lifetime from 8.3 to 8.2 years.

Seasonal variations are also observed in the changes in surface ozone mixing ratio due to the new scheme (Fig. 8). The largest increase is observed over the oceans during the winter of each hemisphere due to both the lower deposition velocity that occurs in colder waters and due to the dry deposition playing a larger role in the ozone budget when photolysis is at a seasonal low.

4.2 Regional impacts

To assess the predictions of surface ozone mixing ratios in the model, comparisons were made with surface ozone measurements from a number of World Meteorological Organization (WMO) Global Atmosphere Watch (GAW; http://www.wmo.int/pages/prog/arep/gaw/gaw_home_en.html, accessed through EBAS: <http://ebas.nilu.no/>, last access: 20 February 2020; the database infrastructure is operated by NILU – Norwegian Institute for Air Research) sites around the world (Fig. 9, shown south to north).

The largest area of change in surface ozone in the model is in the Southern Ocean. GAW sites in this region (Cape Grim, Ushuaia and Neumayer) show increases in ozone prediction during their winter–spring, with the increase most notable in

Table 2. Summary of change to atmospheric oxidative capacity for GEOS-Chem using the default (constant) scheme for calculating r_c and the new scheme (variable) for 2014.

	Constant	Variable
Troposphere O_3 burden (Tg)	324	328
Net chemical O_3 rate (Tg yr^{-1})*	450	363
O_X production rate (Tg yr^{-1})*	5048	5017
O_X loss rate (Tg yr^{-1})*	4598	4654
O_3 loss to deposition (Tg yr^{-1})	862	758
Stratospheric O_3 flux (Tg yr^{-1})	412	395
Global annual mean OH ($10^6 \text{ molec. cm}^{-3}$)	1.17	1.18
Global CH_4 lifetime (years)	8.3	8.2

* Here, O_X is defined as $\text{O}_3 + \text{NO}_2 + \text{NO}_3 + \text{HNO}_4 + \text{HNO}_3 + \text{N}_2\text{O}_5 + \text{BrO} + \text{HOBr} + \text{BrNO}_2 + \text{BrNO}_3 + \text{IO} + \text{HOI} + \text{IONO} + \text{IONO}_2 + \text{OIO} + \text{I}_2\text{O}_2 + \text{I}_2\text{O}_3 + \text{I}_2\text{O}_4\text{ClO} + \text{HOCl} + \text{ClNO}_2 + \text{ClNO}_3 + \text{Cl}_2\text{O}_2 + \text{OCIO} + \text{PAN}$ (peroxyacetylnitrate) + PMN (peroxymethacryloylnitrate) + PPN (peroxypropionynitrate) + MPN (methyl peroxy nitrate) + ETHLN (ethanal nitrate) + R_4N_2 ($\geq \text{C}_4$ alkylnitrates) + R_4N_1 (RO_2 from R_4N_2) + isoprene nitrate (ISN1, ISOPNB, ISOPND, ISNP) + peroxy radical from isoprene (ISNOOA, ISNOOB, ISNOHOO) + MACRN (methacrolein nitrate) + MVKN (nitrate from methyl vinyl ketone) + PROPNN (propanone nitrate) + $\text{O}_2\text{NOCH}_2\text{C}(\text{OO})(\text{CH}_3)\text{CH}=\text{CH}_2$ (INO2) + $\text{O}_2\text{NOCH}_2\text{C}(\text{OOH})(\text{CH}_3)\text{CH}=\text{CH}_2$ (INPN) + $\text{HOCH}_2\text{C}(\text{ONO}_2)(\text{CH}_3)\text{CHO}$ (MAN2) + PRN1 (RO_2 from propene + NO_3) + PRPN (peroxide from PRN1) + MACRNO2 (result of $\text{HOCH}_2\text{C}(\text{ONO}_2)(\text{CH}_3)\text{CHO} + \text{OH}$). For further details on this tagging see the GEOS-Chem wiki <http://wiki.seas.harvard.edu/geos-chem/index.php/FlexChem> (last access: 20 February 2020).

Table 3. Root mean square error (RMSE) of the model with the default (constant) scheme for r_c and the new scheme (variable) when compared to the observations at GAW sites calculated from monthly mean values of observations and model predictions.

GAW site	Constant RMSE (ppbv)	Variable RMSE (ppbv)
Villum	4.2	4.5
Mace Head	5.0	3.4
Cape Verde	2.6	2.0
Cape Grim	3.5	1.5
Ushuaia	2.7	2.0
Neumayer	5.6	2.8

the Antarctic site of Neumayer. Previous works in GEOS-Chem by Schmidt et al. (2016) and Sherwen et al. (2016a) as well as inter-model comparison with ozonesonde observations by Young et al. (2013) show a low bias of GEOS-Chem and other models in the Southern Ocean and Antarctic region. The increased surface ozone mixing ratio brings the model predictions closer to the observations in the Southern Ocean region (Fig. 9), as well as the reductions in root mean square error (RMSE), a measure of disagreement between the model and observations, (Table 3) which is reduced by an average of 44 % across these three locations. Whilst there are considerable improvements in the Antarctic location of Neumayer, surface ozone demonstrate a “lag” in responding to Antarctic spring–summer. The model also fails to capture the springtime halogen-induced ozone depletion events that are observed at Neumayer.

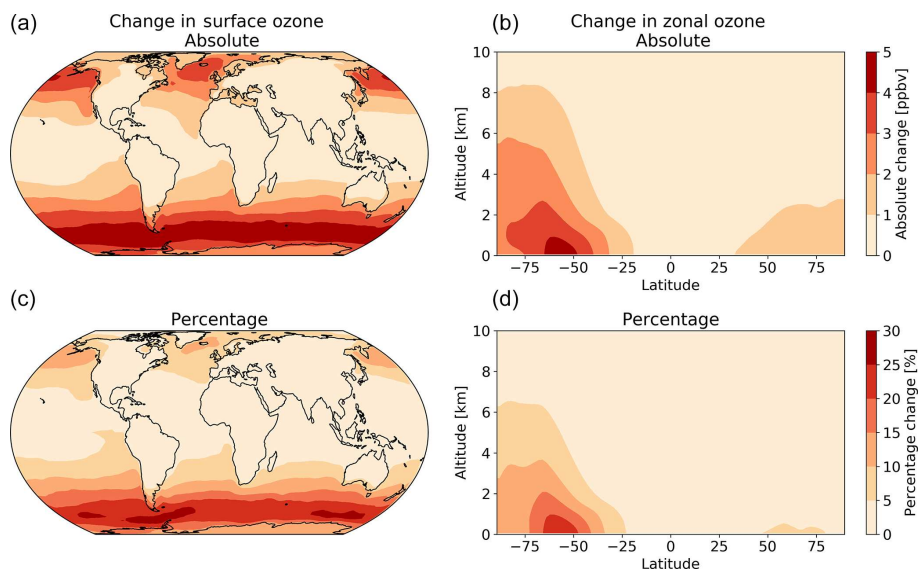

Figure 7. The annual absolute (a, b) and percentage (c, d) change in surface and column ozone mixing ratios for 2014 between the model using the default (constant) and new (variable) parameterization for r_c . The largest changes occur in the surface levels of the model, especially in higher latitudes, with the Southern Ocean boundary layer representing the area experiencing the most annual average change between the two model runs.

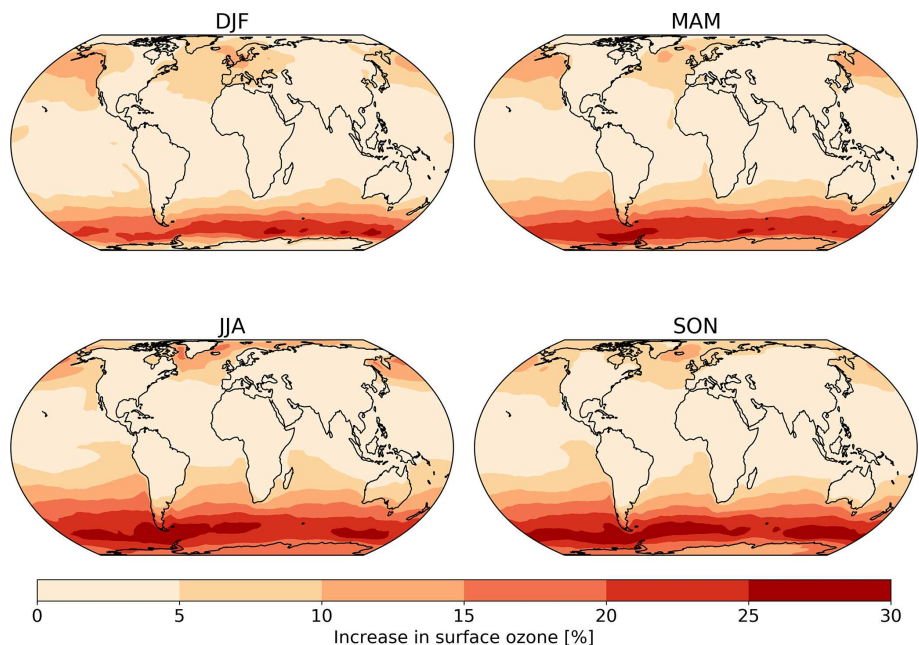

Figure 8. The absolute seasonal surface ozone mixing ratio change for 2014 between the model runs using the default (constant) and new (variable) parameterization for r_c .

A comparison to a clean tropical location is made using the GAW site in Cabo Verde. Tropical waters are where there has been the least change in ozone deposition velocity, as well as the least increase in ozone mixing ratio both annually and seasonally. Whilst there is a slight increase in predicted ozone compared to the observations at Cape Verde, both the model using the old and the model using new schemes for

ozone deposition are within the error of the observations, and there is a small reduction in RMSE.

Mace Head, Ireland, offers an evaluation of model performance in a mid-latitude inflow region, and the inflow of air from the North Atlantic at this site is the dominant component into Europe. Comparing the increase to the observations

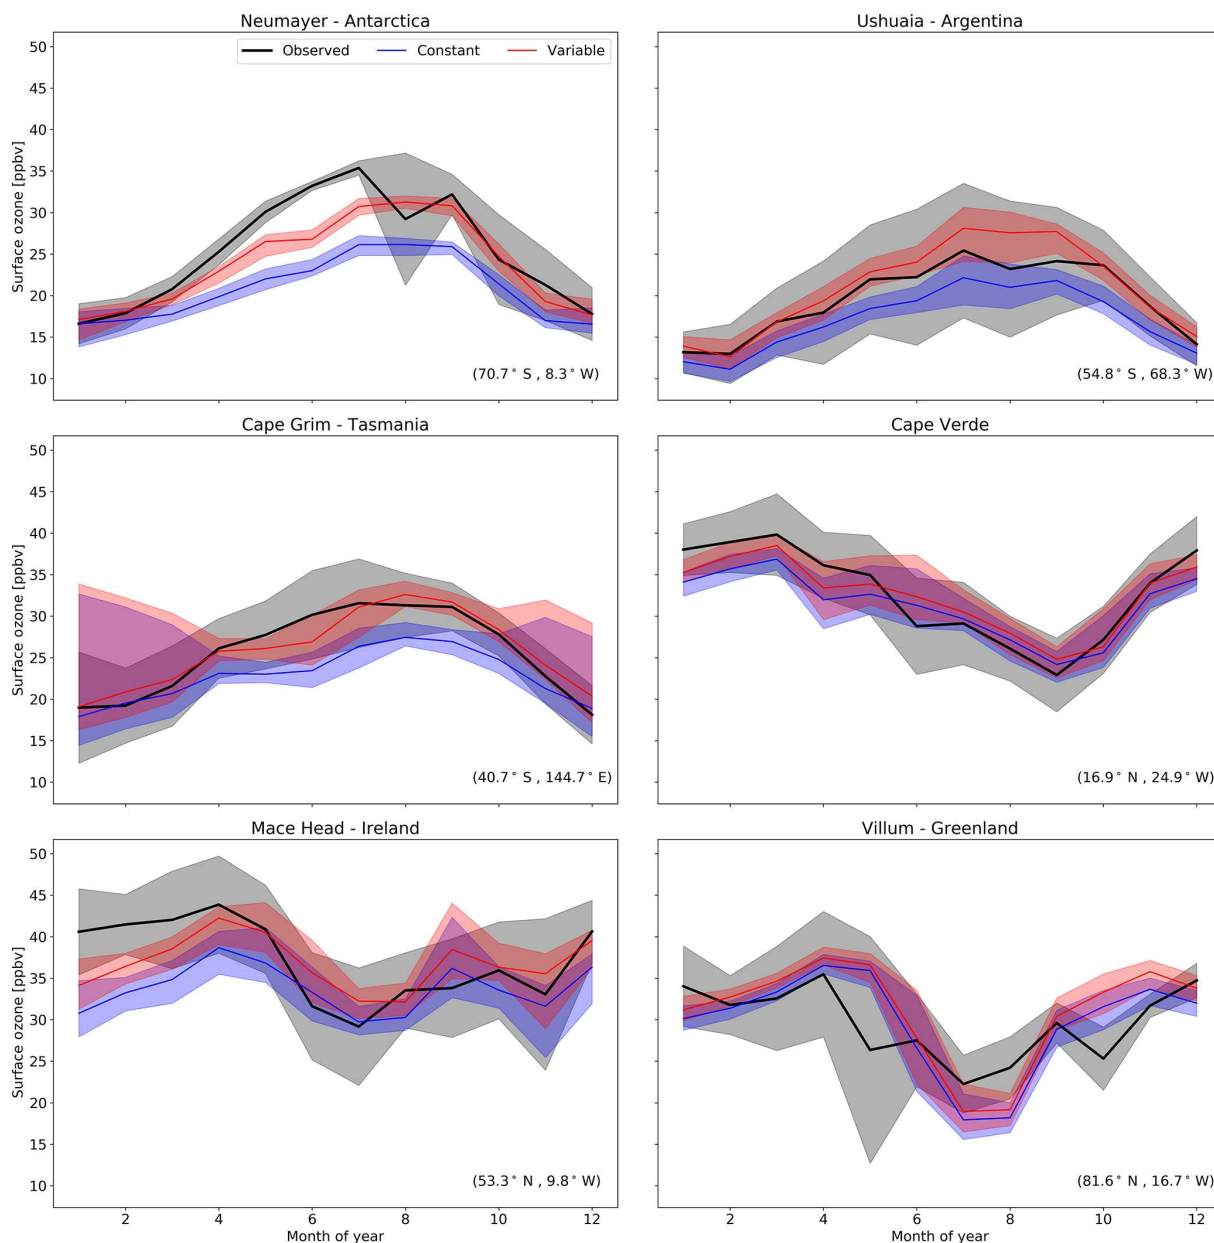

Figure 9. Predictions and observations of monthly average surface ozone mixing ratio for 2014 from the model using the default (constant) and new (variable) parameterization for r_c for six GAW stations (with the latitude and longitude for each station at the bottom right), with the shaded region representing the 25th to 75th percentiles.

at Mace Head the improvement is notable, with the model error reduced by approximately 30%.

The most northerly of the GAW sites in this comparison is the Villum research station in Greenland. There is a minimal increase in predicted surface ozone (~ 1 ppbv) at this site and the resulting RMSE (Table 3) shows for Villum an increase of 0.3 ppbv with the new parameterization. The observations at Villum also show springtime ozone depletion events and, as with Neumayer, the model fails to capture this.

Overall, the majority of GAW sites show improved comparisons with observations due to the implementation of the new r_c scheme and, supporting that, this change is an improvement to the model.

5 Conclusions

We have implemented a new scheme for the deposition of ozone to the ocean into the GEOS-Chem chemistry transport model based on the work of Luhar et al. (2018). This con-

siders the physical and chemical controls of ozone loss in the sea surface. In contrast to Luhar et al. (2018), our work has used a variable surface micro-layer depth and the higher ocean iodide concentrations from Sherwen et al. (2019). The new scheme results in a halving of the global mean ozone deposition velocity to the ocean, leading to a small increase in the global tropospheric ozone burden and some regional increases in ozone mixing ratios of up to 30% in the high latitude boundary layer, notably around the Southern Ocean. The new scheme improves comparisons between the model and observations in oceanic regions. The increase in tropospheric ozone concentration also has a minor effect on the global mean OH and CH₄ lifetimes.

The new parameterization improves comparisons between the model and observed oceanic dry deposition velocities. However, no account has been made of potential additional processes such as the reaction of O₃ with DOC, DMS and bromide at the ocean surface. Uncertainties in the rate constant for the reaction between I⁻ and O₃ could allow room for such additional reactions to play a role. Reduced uncertainty in the temperature-dependent rate constant for this reaction would be useful. In addition it seems likely that the interaction between DOC and ozone would be complex. It seems likely that some compounds will act as deposition enhancers, whilst others may act as inhibitors (Martino et al., 2012; Shaw and Carpenter, 2013). Further lab, field and modelling studies will be required to better constrain this.

Code availability. GEOS-Chem version 12.1.1 was used in this project: <https://doi.org/10.5281/zenodo.2249246> (The International GEOS-Chem User Community, 2018). This code will be available from version 12.8 of GEOS-Chem onwards and can be found at <https://github.com/geoschem/geos-chem/tree/master>. Code is also available on request.

Author contributions. RJP performed the model development, ran the simulations and analysed the output. MJE, LJC and RJP developed the project. TS assisted in model development. DH provided ozone deposition data. The paper was written by RJP with contributions from all co-authors.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We thank WMO GAW and the individual sites that make up this network, for the availability of the surface ozone data.

This project was undertaken on the Viking Cluster, which is a high-performance computing facility provided by the University of York. We are grateful for computational support from the University of York High Performance Computing service, Viking and the Research Computing team.

Ryan J. Pound thanks NERC SPHERES DTP (NE/L002574/1) for funding his PhD studies.

Lucy J. Carpenter, Mat J. Evans and Tomás Sherwen are thankful for funding from Natural Environment Research Council (NERC) through the grant “Iodide in the ocean: distribution and impact on iodine flux and ozone loss” (NE/N009983/1)

Lucy J. Carpenter acknowledges funding from the European Research Council (ERC) under the European Union’s horizon 2020 programme (grant agreement no. 833290)

Financial support. This research has been supported by the Natural Environment Research Council (grant no. NE/L002574/1).

Review statement. This paper was edited by Frank Dentener and reviewed by two anonymous referees.
