3 ABSTRACT  
4  
5  
6

7 Many photonic and plasmonic structures have been proposed to achieve ultra-subwavelength  
8 light confinement across the electromagnetic spectrum. Notwithstanding this effort, however, the  
9 efficient funneling of external radiation into nano-scale volumes remains problematic. Here we  
10 demonstrate a photonic concept that fulfills the seemingly incompatible requirements for both  
11 strong electromagnetic confinement and impedance matching to free space. Our architecture  
12 consists of antenna-coupled meta-atom resonators that funnel up to 90% of the incident radiation  
13 into an ultra-subwavelength semiconductor quantum well absorber of volume  $V = \lambda^3 10^{-6}$ . A  
14 significant fraction of the coupled electromagnetic energy is used to excite the electronic  
15 transitions in the quantum well, with photon absorption efficiency 550 times larger than the  
16 intrinsic value of the electronic dipole. This system opens important perspectives for ultra-low  
17 dark current quantum detectors and for the study of light-matter interaction in the extreme  
18 regimes of electronic and photonic confinement.

Achieving strong light absorption is essential for the operation of many optoelectronic devices such as solar cells<sup>1</sup>, detectors<sup>2</sup>, and saturable absorbers<sup>3</sup>. The recent progress in nano-fabrication techniques has seen the emergence of experiments in which the absorption process is controlled at the single photon, single absorber level<sup>4,5,6</sup>. In bulk materials, light absorption can be simply optimized by increasing the interaction length between the light beam and the material. However, achieving strong absorption in a highly subwavelength structure is a far more difficult task, and is currently an active research topic in the field of nano-optics<sup>7</sup>. This endeavor is particularly pertinent for solid state systems such as quantum wells and dots, as well as for two-dimensional materials<sup>8,9,10</sup>. In all of these systems, the typical de Broglie carrier wavelength is orders of magnitude smaller than the photon wavelength corresponding to the quantum transition of interest. The problem can be illustrated by considering an isolated nanostructure illuminated with intensity  $I_{in}$  (Figure 1a), where the efficiency of the absorption process is quantified by the absorption cross section  $\sigma_{abs}=P_{abs}/I_{in}$ , with  $P_{abs}$  the absorbed power. Following Tretyakov,<sup>11</sup> the resonant absorption cross section can be expressed as:

$$(1) \quad \sigma_{abs} = \frac{3\lambda^2}{8\pi\epsilon} \frac{4\gamma_p\Gamma_{rad}}{(\gamma_p + \Gamma_{rad})^2}$$

Here  $\gamma_p$  is the non-radiative loss,  $\Gamma_{rad}$  is the radiation loss (emission rate) of the quantum system, and  $\epsilon$  the dielectric constant of the medium surrounding the absorber. The maximum value of  $\sigma_{abs}$  is achieved at the ‘‘critical coupling’’ condition  $\gamma_p = \Gamma_{rad}$ , but this condition is difficult to satisfy in solid-state systems where the linewidth is dominated by non-radiative decay channels  $\gamma_p \gg \Gamma_{rad}$ .<sup>4</sup> The situation is very severe in the mid-infrared and THz frequency ranges, where the spontaneous emission rate of a single electron is orders of magnitude slower than other

1  
2  
3 dissipation mechanisms. As illustrated in Figure 1a, in this work we consider a  $1 \times 1 \mu\text{m}^2$  absorber  
4  
5 that consists of a 32-nm-wide semiconductor quantum well (QW) containing  $\sim 10^3$  electrons. The  
6  
7 first electronic transition of the QW is at  $f_p = 3.3 \text{ THz}$ ,<sup>12</sup> corresponding to a wavelength  $\lambda = 90 \mu\text{m}$   
8  
9 that is much larger than the size of the absorber. Eq.1 provides an intrinsic absorption cross  
10  
11 section  $\sigma_{\text{abs}} = 0.047 \mu\text{m}^2$ , three orders of magnitude smaller than the theoretical maximum  $3\lambda^2/8$   
12  
13  $\varepsilon\pi = 77 \mu\text{m}^2$ , with  $\varepsilon = 12.4$ . Indeed, the non-radiative rate  $\gamma_p = 0.2 \text{ THz}$  of the QW is much larger  
14  
15 than the radiation loss,  $\Gamma_{\text{rad}} = 3.2 \times 10^{-5} \text{ THz}$  (see Supplementary Information for estimations of  $\gamma_p$   
16  
17 and  $\Gamma_{\text{rad}}$ ).  
18  
19  
20  
21  
22

23 A solution inspired from microwave technology<sup>13</sup> is to couple the nano-absorber to an  
24  
25 antenna that increases the overall radiation loss of the system<sup>14,15</sup>. Such optical antennas can  
26  
27 be used to build ultra-fast thermal emitters<sup>16</sup>, novel non-linear devices<sup>17,18</sup>, and ultra-low  
28  
29 dark current infrared detectors<sup>19</sup>. In the optical domain, we can also draw inspiration from the  
30  
31 Purcell effect for the emission process<sup>20</sup>, which states that the spontaneous emission rate is  
32  
33 strongly dependent on the electromagnetic environment. Coupling an emitter to a resonant  
34  
35 microcavity can boost or inhibit the spontaneous emission rate<sup>21,22</sup>. In the case of the absorption  
36  
37 process, the benefit of microcavities and meta-atom resonators is that they enable electric field  
38  
39 confinement into highly subwavelength volumes  $V_{\text{eff}}$ , comparable with the nano-absorber  
40  
41 size<sup>23</sup>(Figure 1b). As the light-matter interaction strength scales as  $1/V_{\text{eff}}^{1/2}$ , the absorption  
42  
43 rate is increased, and eventually the regime of strong and ultra-strong light-matter coupling  
44  
45 can be achieved<sup>12,24,25</sup>. However, a strong electromagnetic confinement suppresses the cavity  
46  
47 radiation loss rate, which scales as  $V_{\text{eff}}^{26,27}$  and therefore the microcavity-coupled nano-  
48  
49 absorber becomes almost inaccessible to external electromagnetic radiation. In the visible  
50  
51 and the near infrared spectral region, several strategies have been proposed to achieve

4  
5

6  
7 In this work we demonstrate that is possible to reconcile the antenna concept with the  
8 microcavity effect, and to achieve very efficient funneling of incident radiation into a highly  
9 subwavelength quantum nano-structure. We introduce a THz photonic arrangement that  
10 combines antennas with metamaterial LC (inductor-capacitor)-resonators and concentrates the  
11 electric field into nano-volume capacitors filled with semiconductor quantum wells, as illustrated  
12 in Figure 1c. In this configuration, the mode of the resonator is matched to free space and (ultra-)  
13 strongly coupled with the QW electronic transition.

23  
24 These concepts, and the following experimental results, have been analyzed in the  
25 framework of the temporal coupled mode theory (CMT).<sup>31,32</sup> The CMT provides a set of linear  
26 differential equations that describe the temporal evolution of the amplitudes  $P$ ,  $a$ ,  $A$  of,  
27 respectively, the matter oscillator ( $P$ ), the electric field of the micro resonator ( $a$ ), and the  
28 antenna ( $A$ ), as a function of the incident wave amplitude ( $S_{in}$ ). We compare three different cases:  
29 matter oscillator  $P$  in free space (Figure 1a,d);  $P$  coupled with a meta-atom resonator  $a$ , which  
30 interacts with free space (Figure 1b,e); and,  $P$  interacts with an antenna ( $A$ )-coupled meta-atom  
31 ( $a$ ) (Figure 1c,f). Each oscillator has its own non-radiative loss rate ( $\gamma_P$ ,  $\gamma_a$ ,  $\gamma_A$ ). By design, the  
32 transmission port is absent in our devices, and we consider only the reflection port ( $S_{out}$ ). As  
33 shown in the Supplementary Information, our formalism leads to eq.1 for the case of a single  
34 absorber in free space (Figure 1a,d).

50 As a first step we are interested in understanding how the absorption cross section (eq. 1)  
51 is modified in the presence of the resonator, Figure 1b,e and Figure 2. Our resonator is a THz LC

2  
3 circuit, as described in ref. **12**, where the electric field is compressed into ultra-subwavelength  
4 volume,  $V_{\text{eff}} \sim 10^{-6} \lambda^3$ , between the two double-metal capacitive parts of  $1 \mu\text{m}^2$  area and thickness  
5 300 nm (Figure 1a). The 300-nm-thin wires of length  $P_L$  connecting the capacitors act as  
6 inductors and allow the resonant frequency to be tuned in the THz range. The absorbing region,  
7 which contains five 32-nm-wide highly doped quantum wells, is placed only in the two  
8 capacitive parts (more information in the supplementary material), but owing to surface  
9 depletion effects, only the central well is effectively populated at  $1.4 \times 10^{11} \text{ cm}^{-2}$  electrons. The  
10 interaction between the QW and the LC resonator is quantified by the coupling strength  $\Omega_R$ , also  
11 known as vacuum Rabi frequency<sup>12</sup>:

$$(2) \quad \Omega_R = \frac{1}{2} \sqrt{\frac{f_{12} e^2 (N_1 - N_2)}{m^* \epsilon \epsilon_0 V_{\text{eff}}}}$$

12 where  $f_{12}$  is the oscillator strength of the transition,  $e$  is the electron charge,  $N_1$  and  $N_2$  are the  
13 total electron populations in the first and second subbands, respectively,  $\epsilon_0$  is the vacuum  
14 permittivity, and  $m^*$  is the electron effective mass.

15 As shown in Figure 2, in order to increase the interaction with the incident light, the  
16 antenna-coupled LCs are periodically repeated to form a metamaterial, made up of a unit cell of  
17 area  $\Sigma$  such that the beam spot size  $S$  of the incident wave covers many unit cells.<sup>11,23</sup> In the  
18 metamaterial configuration the ratio between the absorbed and incident power  $P_{\text{abs}}/P_{\text{in}}$  for each  
19 unit cell corresponds to  $\sigma_{\text{abs}}/\Sigma$ . In the framework of the CMT, a general expression for the  
20 absorption cross section as a function of the power dissipated by the quantum system is:

$$(3) \quad \frac{\sigma_{\text{abs}}}{\Sigma} = \frac{2\gamma_p |P|^2}{|S_{\text{in}}|^2} =_{\text{def}} \eta,$$

1  
2  
3 Here,  $|P|^2$  is proportional to the energy stored in the electronic polarization, and can be related to  
4 the density of microscopic dipoles excited by the electric field of the resonator, and  $|S_{in}|^2 = \Sigma P_{in}/S$   
5 is the power incident per array unit cell. Eq.3 is a direct consequence of energy conservation and  
6 the definition of the absorption cross section<sup>33</sup>. Note that the parameter  $\eta$  quantifies the fraction  
7 of photons absorbed by the QW only. The other loss channels, such as the metal losses in  
8 the electromagnetic resonators, can also be inferred from CMT, as shown in the  
9 Supplementary Information.

10  
11 The quantity  $\eta$  is not directly provided by experiments, where one instead probes the  
12 reflectivity of the system,  $R(\omega) = |S_{out}|^2/|S_{in}|^2$ . By fitting the experimental reflectivity  $R(\omega)$  we can  
13 infer the CMT parameters ( $\gamma_p, \Omega_a, \gamma_R, \Gamma_a$ ) and evaluate the absorption cross section from eq.3.  
14 The reflectivity spectra  $R(\omega)$  were recorded with a dry-air purged Fourier transform  
15 infrared spectrometer (FTIR) (Bruker Vertex 70v). We use a proprietary experimental  
16 arrangement where a pair of f/1 parabolic mirrors focus the radiation from a Global source  
17 onto the sample and collect the reflected light, which is detected using a He-cooled  
18 Ge bolometer (QMC instruments). Light is linearly polarized along the two capacitors  
19 of the meta-atoms, and impinges at  $45^\circ$  onto the sample in a transverse magnetic  
20 configuration. All spectra are normalized to the reflectivity of a flat Au surface. As a  
21 result of the fabrication process, the meta-atoms are placed on the top of  $3 \mu\text{m}$  thick  $\text{Si}_3\text{N}_4$   
22 layer, which has a flat Au mirror on the bottom that blocks the transmission port<sup>12</sup> (see  
23 Supplementary Information for full structure details). Typical reflectivity spectra for a meta-  
24 atom ( $P_L = 11 \mu\text{m}$ ,  $f_{LC} = 3.2 \text{ THz}$ ) resonant with the electronic transition are shown in Figure  
25 2b at both room temperature and 7 K. At room temperature, the effect of the electronic  
26 absorption is negligible<sup>12</sup>, and one observes only the response of the meta-atoms (blue solid  
27 line). At 7 K (red solid line), the QW absorption is activated, and the LC mode splits into  
28

1  
2  
3 lower (LP) and upper (UP) polariton modes, separated by the vacuum Rabi splitting  $2\Omega_R$ . At low  
4  
5 temperature, CMT fits provide typical values  $\gamma_a = 0.15$  THz,  $\Gamma_a = 0.013$  THz and  $\Omega_R = 0.4$  THz.  
6  
7 These studies were complemented with data from four other LC structures with  $P_L = 9$   $\mu\text{m}$ , 10  
8  
9  $\mu\text{m}$ , 12  $\mu\text{m}$ , and 14  $\mu\text{m}$  (see Supplementary Information). As described in Ref.12, these  
10  
11 measurements allow the effective volume  $V_{\text{eff}} = \lambda^3 10^{-6}$  to be obtained from eq.2, which was  
12  
13 found to be very close to the geometrical volume of the capacitive parts  $V_0 = 0.6$   $\mu\text{m}^3$ ,  $V_{\text{eff}} = 1.2$   
14  
15  $V_0$ .  
16  
17  
18  
19

20  
21 The CMT analysis, detailed in the Supplementary Information, shows that the absorbing  
22  
23 cross-section  $\sigma_{\text{abs}}$  is maximized at the onset of the strong coupling and is expressed as:  
24  
25

$$(4) \quad \frac{\sigma_{\text{abs}}}{\Sigma} = \frac{4\gamma_p\Gamma_a}{(\gamma_p + \gamma_a + \Gamma_a)^2} \frac{\Omega_R^2}{\Omega_R^2 + \Omega_{R0}^2}$$

26  
27  
28  
29  
30  
31 This expression is valid for both the weak and strong coupling regime. Here  $\Omega_{R0} = \gamma_p/(1+$   
32  
33  $\gamma_p/(\gamma_a + \Gamma_a)) = 0.09$  THz. If the system is in the strong coupling regime, such that  $\Omega_R \gg \Omega_{R0}$ ,  
34  
35 then eq.4 shows that the peak absorption saturates at a fixed value  
36  
37  $\sigma_{\text{abs}}/\Sigma = 4\gamma_p\Gamma_a/(\gamma_p + \gamma_a + \Gamma_a)^2$ . This is similar to eq.1, except that now the intrinsic radiation  
38  
39 loss of the absorber is replaced with that of the meta-atom resonator,  $\Gamma_a$ .  
40  
41  
42  
43  
44  
45

46 The corresponding values of  $\omega(\eta)$  from eq.3 are plotted in Figure 2c, with peak values  $\eta \sim 0.08$  at  
47  
48 the two polariton states, in agreement with eq. 4. In this case,  $\Sigma = 40$   $\mu\text{m}^2$ , yielding an absorption  
49  
50 cross section  $\sigma_{\text{abs}} = 3.2$   $\mu\text{m}^2$ . This value is already a significant improvement with respect to the  
51  
52 single QW absorber. However, the value  $\eta \sim 0.08$  and the high reflectivity observed in  
53  
54 experiments (Figure 2b) indicate a strong photon rejection rate (85%–90%). Indeed, while the  
55  
56  
57  
58  
59  
60

1  
2  
3 strong coupling regime is favored because of the dependence  $\Omega_R \sim 1/V_{\text{eff}}^{1/2}$ , the radiative coupling  
4  
5 of the resonator vanishes in systems with strong electromagnetic confinement. For instance,  
6  
7 in double-metal resonators, the radiation loss is proportional to the thickness of the structure<sup>23</sup>.  
8  
9 This is the reason why the radiation loss of the  $LC$  is very low,  $\Gamma_a = 0.013$  THz.

10  
11  
12  
13 We now demonstrate that this limitation can be lifted in a photonic arrangement based on  
14  
15 the strong coupling between antennas with a high radiation loss and the ultra-subwavelength  
16  
17 resonators (Figure 3 and Figure 1c,f). As shown in Figure 3a, the antenna element is a large  
18  
19 double-metal patch antenna of a total length  $L_A = \lambda_A/2n_{\text{eff}}$ , where  $\lambda_A$  is the resonant wavelength of  
20  
21 the antenna and  $n_{\text{eff}}$  is an effective index. The bulk of the patch antenna is filled with a  $3 \mu\text{m}$   
22  
23  $\text{Si}_3\text{N}_4$  layer, which is therefore much thicker than the capacitors of the  $LC$  structures. The electric  
24  
25 field of the fundamental antenna resonances is maximum at the edges, and changes sign in the  
26  
27 middle of the antennas<sup>27</sup> (Figure 3a). The symmetry of the antenna resonance thus matches that  
28  
29 of the  $LC$  mode. Therefore optimal coupling is achieved in the configuration described in Figure  
30  
31 1c and Figure 3a, where each antenna connects the capacitors of two neighboring meta-atoms.  
32  
33 Nevertheless, as this system allows a large number of degrees of freedom, many other  
34  
35 configurations can be considered, even ones with topologically distinct unit cells. Furthermore,  
36  
37 the antennas can be fabricated directly on the bare  $LC$  resonator arrays, thus allowing a  
38  
39 straightforward comparison between uncoupled and antenna-coupled meta-atoms. In Figure 3b,  
40  
41 we show reflectivity data for the same  $LC$  resonator as discussed above ( $P_L = 11 \mu\text{m}$ ) both before  
42  
43 (blue solid line), and after (dark green solid line), antenna fabrication. The length of the antenna  
44  
45 is  $L_A = 5 \mu\text{m}$  and it resonates at  $f_A = 4.65$  THz; this provides an effective index  $n_{\text{eff}} \sim 6$ . We see  
46  
47 that the  $LC$  resonance is split into two resonances,  $A_1$  (at 2.67 THz) and  $A_2$  (at 4.8 THz),  
48  
49 indicating strong non-perturbative coupling between the antenna and the  $LC$ . The reflectivity  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 contrast is strongly improved: 50% as compared to 15% without the antenna. In Figure 3b  
4  
5 we also provide electric energy maps obtained by numerical simulations, showing that  $A_1$  is LC-  
6  
7 like and  $A_2$  is antenna-like, with  $A_1$  having the same effective volume  $V_{\text{eff}}$  as the LC alone. CMT  
8  
9 fits provide a coupling constant  $G = -0.6$  THz as well as the antenna radiation and non-  
10  
11 radiation losses,  $\Gamma_A = 0.2$  THz and  $\gamma_A = 0.85$  THz, respectively. We also find that the radiation  
12  
13 loss of the antenna-coupled LC is strongly suppressed,  $\Gamma' = 0.0012$  THz, so that the  
14  
15 interaction with the free-space is essentially mediated by the antenna. The  $\text{Si}_3\text{N}_4$  layer also  
16  
17 introduces a  $-0.3$  THz shift of the LC frequency (Supplementary Information).  
18  
19  
20  
21  
22

23 Next, we examine the performance of such antenna-coupled LC structures for enhancing  
24  
25 the quantum well absorption. Two types of structures have been studied. The first are the LC  
26  
27 structures with variable  $P_L$  (9  $\mu\text{m}$ , 10  $\mu\text{m}$ , 11  $\mu\text{m}$ , 14  $\mu\text{m}$ ), which have been reprocessed with  
28  
29 antennas. In this case the antenna resonance is fixed ( $f_A = 4.65$  THz) and the LC resonance is  
30  
31 varied, Figure 4a. In the second type of structure, the antenna-coupled LC resonance is designed  
32  
33 with a fixed frequency,  $f_{LC} = 3.35$  THz, nearly resonant with the QW absorption ( $f_p = 3.3$  THz).  
34  
35 The antenna resonance  $f_A$  is then varied by changing the length  $L_A$  (5  $\mu\text{m}$ –14  $\mu\text{m}$ ), Figure 4b. In  
36  
37 Figures 4a,b we show only the low temperature reflectivity spectra (solid lines) where the QW is  
38  
39 active; more data is provided in the Supplementary Information. The full system consists of three  
40  
41 coupled oscillators, as described in Figure 1c,e, and therefore the reflectivity spectra display  
42  
43 three reflectivity minima. All spectra are fitted with the CMT model (dotted lines), which  
44  
45 provides almost constant values for  $G \sim -0.7$  THz, resonator loss  $\gamma_a = 0.15$  THz,  $\Gamma_a \sim 10^{-3}$  THz,  
46  
47 as well as the Rabi frequency  $\Omega_R = 0.4$  THz. In Figure 4b the loss rates of the antennas evolve  
48  
49 monotonically in the range  $\Gamma_A = 0.4$ – $0.2$  THz and  $\gamma_A = 0.75$ – $0.45$  THz owing to the frequency-  
50  
51 dependent loss of the  $\text{Si}_3\text{N}_4$  layer. All fitting parameters are provided in the Supplementary  
52  
53 Information. In Figure 4 the estimations of the photon collection efficiency are provided next to  
54  
55  
56  
57  
58  
59  
60

each experimental spectrum. The peak values have now increased to  $\eta \sim 0.2$  (Figure 4a) and  $\eta \sim 0.35$  (Figure 4b). In Figure 4b it is important to note that as the antenna length  $L_A$  increases, the antenna becomes resonant with both the LC and the QW systems, and the area  $\Sigma$  of the array unit cell is increased. As a result, the antenna array with  $L_A = 12 \mu\text{m}$  ( $f_A = 3.3 \text{ THz}$ ) and  $\Sigma = 69 \mu\text{m}^2$  has a maximum absorption cross-section  $\sigma_{\text{abs}} = 20 \mu\text{m}^2$ , which is on the same order of magnitude as the theoretical limit of a single absorber ( $77 \mu\text{m}^2$ ). However, maximum efficiency  $\eta \sim 0.35$  is obtained for an antenna with  $L_A = 9 \mu\text{m}$  ( $f_A = 3.9 \text{ THz}$ ), which displayed high radiation loss,  $\Gamma_A = 0.3 \text{ THz}$ , and a strong reflectivity contrast of 90%.

The analysis based on CMT further uncovers a benefit of the strongly antenna-coupled meta-atoms (Supplementary Information). It shows that the maximum absorption appears at the energy of the electronic transition, and for the case where all three resonators have the same frequency, in accordance with the data from Figure 4. Neglecting the radiation loss from the quantum wells and the meta-atom, the following expression is obtained:

$$(5) \quad \frac{\sigma_{\text{abs}}}{\Sigma} = \frac{\Gamma_A}{\Gamma_A + \gamma_A} \frac{g}{g + \gamma_a} \frac{4(\Omega_R / \Omega_{R1})^2}{[1 + (\Omega_R / \Omega_{R1})^2]^2}$$

In this formula we have defined  $g = G^2 / (\Gamma_A + \gamma_A)$  and  $\Omega_{R1}^2 = \gamma_P (\gamma^+ + g)$ . The absorption cross section is thus a bell-like function of the Rabi frequency squared  $\Omega_R^2$ , and optimal for  $\Omega_R \Omega_{R1} = \Omega_{R1}$ . Using the parameters of our structures, we have  $g = 0.74 \text{ THz}$  and  $\Omega_{R1} = 0.42 \text{ THz}$ . Our system with  $\Omega_R = 0.4 \text{ THz}$  thus operates very close to the optimal point with maximum possible absorption,  $\sigma = \eta_{\text{abs}} / \Sigma = 0.3$ . It is interesting to note that in the case where the antenna non-radiative loss  $\gamma_A$  can be neglected, and a high coupling constant  $G$  is achieved, eq.5 predicts

1  
2  
3 almost unity maximum absorption, regardless of the intrinsic loss  $\gamma_p$  of the absorber. This means  
4  
5 that such configuration always allows impedance matching to free space, independent of  
6  
7 the physical phenomena that govern  $\gamma_p$ .  
8  
9

10  
11 In Figure 5, we compare the best results obtained for the photon absorption rate  $\eta$  in our  
12 structures with respect to the QW absorber where  $\sigma = \eta_{\text{abs}} / (3\lambda^2 / 8\epsilon\pi) = 6 \times 10^{-4}$ . The peak value  
13  
14  
15  
16  $\eta_{\text{abs}} = 3.3 \times 10^{-4}$  for the antenna-coupled LC is 550 times larger than  $\eta$ . Furthermore all CMT fits use the

17  
18  
19  
20  
21 same value of the light-matter coupling constant,  $\Omega_R = 0.4$  THz, meaning that the addition of the  
22  
23 antenna layer does not result in a delocalization of the electromagnetic energy and the effective  
24  
25 resonator volume remains the same,  $V_{\text{eff}} = \lambda^3 10^{-6}$ . This is confirmed by finite element  
26  
27 simulations, which show only a 5% reduction of the LC effective volume in the antenna-coupled  
28  
29 LC structures. Our system thus reconciles the seemingly incompatible requirements for both  
30  
31 strong electromagnetic confinement and impedance matching to free space. Such a photonic  
32  
33 architecture can be very beneficial for ultra-low dark current THz quantum detectors, where the  
34  
35 electrical area is strongly reduced with respect to the effective absorption cross section of the  
36  
37 device.<sup>19,23</sup> In that case, the detector responsivity is proportional to the  $\eta$  coefficient defined in  
38  
39 eq. 3, and the ratio between the photocurrent and dark current is provided by the quantity  $\sigma_{\text{abs}}/s$ ,  
40  
41 where  $s$  the surface of the absorbing region.<sup>19,23</sup> Such devices, which can also operate in the ultra-  
42  
43 strong light-matter coupling regime, can also be used to study the effect of the polariton states on  
44  
45 the electronic transport.<sup>34, 35</sup> The process that was developed for this demonstration can also be  
46  
47 exploited for a large variety of planar antennas coupled with double-metal meta-atoms, and  
48  
49 opens many possibilities for the design of perfectly absorbing infrared metamaterials.<sup>36</sup>

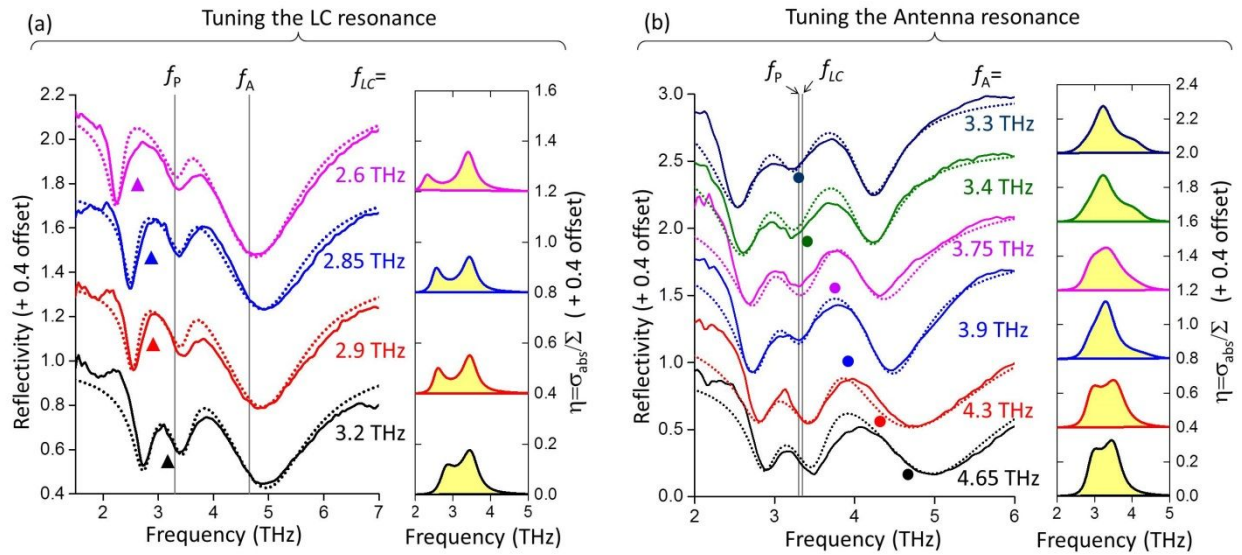

**Figure 1. Absorption engineering in a quantum well particle** (a) Single nano-absorber (two-level quantum well) interacting with incident infrared radiation. (b) The QW no longer interacts with free space directly, but is coupled to a resonant meta-atom with a coupling rate  $\Omega_R$ . (c) The coupling to free space is mediated by an additional antenna element interacting with the meta-atom with a coupling rate  $G$ . In all cases  $\sigma_{abs}$  denotes the absorption cross-section of the electronic transition only. (d,e,f) Coupled-mode diagrams for the aforementioned cases  $P$ : electronic polarization strength,  $a$ : electric field amplitude of the LC resonator,  $A$ : electric field amplitude of the antenna.  $S_{in}$  and  $S_{out}$  are the incoming and reflected wave, respectively. The relevant coupling and loss rates are indicated.

**Figure 2. Quantum well coupled to meta-atom resonator** (a) Electron microscope image of an array of inductor-capacitor (LC) meta-atoms with unit cell  $\Sigma$  where the active region is embedded inside the capacitive elements of the meta-atoms (red squares).  $P_L$  denotes the internal perimeter of the inductive loop. (b) Room temperature (blue) and 7 K (red) reflectivity spectra of a structure with  $P_L = 11 \mu\text{m}$  and  $f_{LC} = 3.2 \text{ THz}$ . Solid lines are experimental data, and dashed lines are obtained using CMT fits. The dotted line shows the electronic transition frequency  $f_p$ . LP: lower polariton, UP: upper polariton. The Rabi-splitting extracted from this data is  $2\Omega_R = 0.8 \text{ THz}$ . (c) Fraction of photons absorbed  $\eta$  from the CMT fit of panel (b).

**Figure 3. Antenna-coupled meta-atom** (a) Electron microscope image of the coupled *LC* resonator – antenna array, with unit cell  $\Sigma$ . The antenna resonator is formed between a top metal strip and a bottom metallic plane, that also illustrates the fundamental half wavelength mode. The spacing between two *LC* meta-atoms is given by the antenna length  $L_A$ . (b) Room temperature reflectivity spectra of an array of *LC* meta-atoms (blue solid line) and of the same array coupled with antennas with  $L_A = 5 \mu\text{m}$  (dark green solid lines). The dotted curves are CMT fits.  $A_1$  and  $A_2$  denote the two coupled modes, for which we also provide the electric energy density obtained from finite element method simulations.

**Figure 4. Fully coupled system** (a) Low temperature (7 K) reflectivity spectra for antenna-coupled LC, for a fixed antenna resonance ( $f_A = 4.65$  THz) and variable LC resonant frequencies. The latter are indicated by numerical values and triangles with respect to the frequency axis. Experimental data is shown in solid lines and CMT fits in dotted lines. Right panel: photon absorption efficiency  $\sigma = \eta_{\text{abs}} / \Sigma$  from eq.3 for each spectrum. (b) Low temperature (7 K) reflectivity spectra in the case where LC and QW are nearly resonant at  $f_{LC} \sim f_P = 3.3$  THz, and the antenna frequency  $f_A$  varied. The latter is indicated by numerical values and dots with respect to the frequency axis. Experimental data is shown in solid lines and CMT fits in dotted lines; the corresponding spectra of  $\sigma = \eta_{\text{abs}} / \Sigma$  are indicated in the right panel.

**Figure 5. Absorption engineering from experiments.** Fraction of absorbed photons for the three systems considered in Figure 1. The “QW alone” is modelled as a Lorentzian shape with full width at half maximum  $2\gamma_p=0.4$  THz and peak value  $\eta_0 = \sigma_{\text{abs}}/(3\lambda^2/8\pi\epsilon) = 6 \times 10^{-4}$ . The “QW+LC” curve corresponds to Figure 2c, and the “QW+LC+Antenna” curve corresponds to the highest values derived from the measurements in Figure 4b ( $f_A = 3.9$  THz).
