Several studies suggest the potential for climate change to increase malaria incidence in cooler, marginal transmission environments. However, the effect of increasing temperature in warmer regions where conditions currently support endemic transmission has received less attention. We investigate how increases in temperature from optimal conditions (27 °C to 30 °C and 33 °C) interact with realistic diurnal temperature ranges (DTR: ± 0 °C, 3 °C, and 4.5 °C) to affect the ability of key vector species from Africa and Asia (*Anopheles gambiae* and *An. stephensi*) to transmit the human malaria parasite, *Plasmodium falciparum*. The effects of increasing temperature and DTR on parasite prevalence, parasite intensity, and mosquito mortality decreased overall vectorial capacity for both mosquito species. Increases of 3 °C from 27 °C reduced vectorial capacity by 51–89% depending on species and DTR, with increases in DTR alone potentially halving transmission. At 33 °C, transmission potential was further reduced for *An. stephensi* and blocked completely in *An. gambiae*. These results suggest that small shifts in temperature could play a substantial role in malaria transmission dynamics, yet few empirical or modeling studies consider such effects. They further suggest that rather than increase risk, current and future warming could reduce transmission potential in existing high transmission settings.

The dynamics and distribution of human malaria strongly depend on the interplay between the parasite, the mosquito vectors and the environment¹. The key parasite and mosquito life history traits that determine transmission intensity exhibit clear, non-linear relationships with temperature². This non-linearity means that small changes in environmental temperature can lead to large changes in transmission risk. Recent evidence suggests that malaria incidence is increasing in cooler regions of the world due to global warming^{3–8}. However, the effects of environmental change on malaria transmission are potentially complex^{5–7,9}, and the implications for malaria risk in optimum transmission settings remain poorly defined. Additionally, irrespective of climate change, mosquitoes are exposed to a range of microclimates due to variation in local habitat features, which affect mean ambient temperature and diurnal temperature range (DTR)^{10,11}. Here we investigate how shifts in temperature around optimum conditions representative of endemic transmission settings, affects the capacity of two key vector species - *Anopheles gambiae* from Africa and *An. stephensi* from Asia - to transmit the human malaria parasite *Plasmodium falciparum*.

To examine the effects of temperature on vectorial capacity, we provided female mosquitoes with either an uninfected or *P. falciparum*-infectious bloodmeal and then randomly placed them across three mean temperatures. These mean temperatures were 27 °C, representing conditions typically considered optimal for mosquito and parasite development, and 30 and 33 °C, representing warmer environments within the current transmission range and/or future environments after projected climate warming¹. We also included three diurnal temperature ranges (DTR of 0, 6 and 9 °C) for each mean temperature, because temperatures are not constant in nature and daily cycles in temperature can shape insect and parasite life history traits beyond the effect of mean temperature alone^{6,12}. We then quantified the effects of mean ambient temperature and DTR on measures of vector competence, such as parasite prevalence at different developmental stages (proportion of mosquitoes with oocysts or sporozoites) and parasite intensity (number of oocysts/midgut), as well as daily mosquito survival. To assess the effects of variation in mean temperature and DTR on overall transmission risk, we used these data to estimate changes in vectorial capacity, a standard metric used to define the transmission potential of a vector population.

Table 1. The results of generalized mixed effects models for investigating the effects of variation in mean ambient temperature and diurnal temperature fluctuation on measures of vector competence for both *Anopheles gambiae* and *An. stephensi*. Dashed lines indicate non-significant effects that were not included in the final model.

For both *An. gambiae* and *An. stephensi*, increases in mean ambient temperature resulted in significant decreases in oocyst prevalence, oocyst intensity, and sporozoite prevalence (Table 1; Fig. 1, SI Table S1). These results suggest that mean temperatures above 27 °C are less permissive for parasite establishment and development. The effects of warmer temperatures on vector competence were much more pronounced in *An. gambiae* than in *An. stephensi*. The effect of varying DTR was mixed and, again, dependent on vector species. For example, increasing DTR had a marginally significant effect on oocyst prevalence (Fig. 1A), and no effect on oocyst intensity (Fig. 1C) or sporozoite prevalence (Fig. 1E) in *An. gambiae* (Table 1). In *An. stephensi*, increasing diurnal temperature fluctuation also significantly reduced oocyst prevalence (Fig. 1B) and intensity (Fig. 1D, SI Table S2). However, the effect of DTR on oocyst intensity only occurred when *An. stephensi* were housed at a mean 27 °C (Fig. 1D, SI Table S2). Unexpectedly, the impact of DTR on sporozoite prevalence was marginally non-significant, despite effects of variation in DTR on oocyst establishment in *An. stephensi* (Table 1, Fig. 1F).

Increasing mean ambient temperatures significantly reduced daily mosquito survival for both *An. gambiae* and *An. stephensi* (SI Table S3, Fig. 2), and these effects were again more marked in *An. gambiae*. *An. stephensi* experienced higher daily survival across all treatment groups throughout the course of each experiment relative to *An. gambiae* (Fig. 2). There were also significant main effects of variation in DTR on adult longevity (SI Table S3); however, the effect was dependent upon mean ambient temperature (SI Table S3) and was qualitatively different for each vector species (SI Table S4). For example, in *An. gambiae*, modest diurnal temperature fluctuation (DTR 6 °C) around the hottest mean temperature (33 °C) buffered mosquitoes from the effects of hot mean temperatures on daily mosquito survival, while more extreme temperature fluctuation (DTR 9 °C) exacerbates these effects relative to mosquitoes housed in a thermally constant, hot environment (Fig. 2A). In *An. stephensi*, diurnal temperature fluctuation in general decreased daily mosquito survival only in mosquitoes housed at a mean 27 °C (Fig. 2B).

Whether or not mosquitoes were infected with *P. falciparum* significantly affected the daily survival probability for both *An. gambiae* and *An. stephensi* (SI Table S3), although the effects again were qualitatively different for each mosquito species (SI Fig. S1, SI Table S5). *P. falciparum* infection in *An. gambiae* increased mosquito survival at extreme ambient temperatures relative to bloodfed controls. In contrast, *P. falciparum* infection significantly decreased *An. stephensi* survival in constant temperature treatments only (SI Fig. S1, Table S5). The species-specific effects of ambient temperature and DTR on mosquito survival illustrate complex ‘mosquito x environment’ interactions, which might partially explain the mixed evidence for fitness effects of malaria infection on mosquitoes, with the majority of studies reporting negative or no effects reviewed in¹³, and only one reporting positive effects of infection on mosquito survival¹⁴.

The effects of increasing mean ambient temperatures and DTR on individual vector-parasite traits translate into dramatic reductions in overall vectorial capacity for both *An. gambiae* and *An. stephensi*, with the impact most pronounced for *An. gambiae* (Fig. 3A). When rate summation was used to predict additional effects of DTR on the extrinsic incubation period of the parasite and daily mosquito biting rates, we see even further reductions in vectorial capacity in mosquitoes housed at all temperatures (Fig. 3B).

We demonstrate that relatively small increases in mean temperature and diurnal temperature range around the temperature optimum can both lead to marked reductions in vectorial capacity. For example, an increase of 3 °C from a highly permissive temperature of 27 °C reduced vectorial capacity of *An. stephensi* by 51–66%. For *An. gambiae* the effects were even greater, with vectorial capacity reduced by as much as 84–89%, depending on DTR. This also means that a decrease in temperature from 30 to 27 °C (as might occur seasonally) could increase transmission potential by 629–814%, depending on DTR. Furthermore, increases in DTR alone could halve vectorial capacity. The effects of DTR are highly relevant to ongoing changes in housing design that are taking place in many parts of Africa¹⁵. The transition from traditional materials such as mud and thatch to modern brick and metal alters indoor microclimate and can increase DTR by 2–5 °C (SI Fig. S2). Such changes to indoor climate could yield almost instantaneous reductions in vectorial capacity of highly endophilic vectors such as *An. gambiae*. Note that in the current study our estimates of vectorial capacity assume all blood meals are taken from human hosts. In reality, mosquitoes can exhibit different levels of anthropophagy depending on species and local host diversity. *Anopheles stephensi*, for example, is known to be strongly zoophilic¹⁶ and this is likely to reduce absolute values of vectorial capacity in nature. Nonetheless, the relative changes in vectorial capacity we observe should remain unchanged.

In our experiments, mosquito larvae were maintained under standard insectary conditions before being transferred to the different temperature treatments as adults. This approach reflects the fact that temperatures in

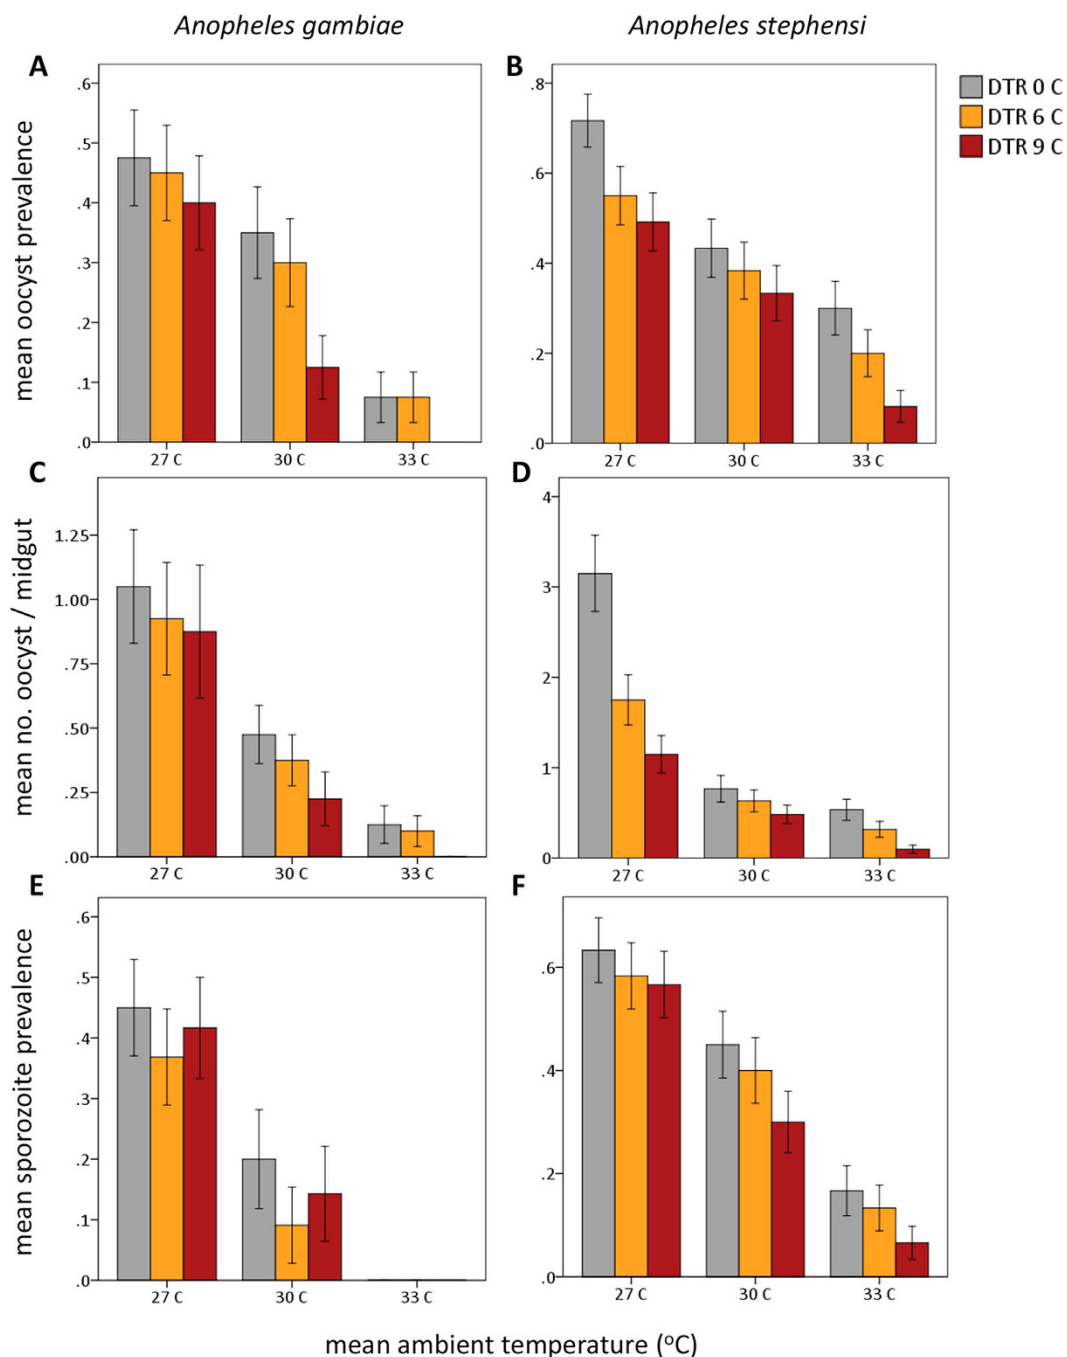

Figure 1. The effects of increasing mean ambient temperature and diurnal temperature range (DTR 0 C, grey bars; DTR 6 C, orange bars; and DTR 9 C, red bars) on measures of vector competence for *Anopheles gambiae* (left panel) and *An. stephensi* (right panel): mean oocyst prevalence (A,B), oocyst burdens (C,D), and sporozoite prevalence (E,F). Bars represent standard errors around the mean.

natural larval habitats can differ substantially from ambient air temperatures experienced by adult mosquitoes¹⁷, and that adults emerging from a common larval habitat can potentially distribute across diverse local microclimates¹⁰. Nonetheless, we acknowledge that temperature variation can also impact larval life history traits¹⁸, and that temperature effects can integrate across life stages, potentially exacerbating the impact of climate warming¹⁹. How such effects play out in the field could be further shaped by variations in biotic factors²⁰, genotypic differences between local mosquito and parasite populations²¹ and mosquito behavior¹⁴ (although there is limited evidence to support precise behavioral thermoregulation in malaria mosquitoes^{22,23}). Transmission intensity and ultimately disease burden are also strongly determined by rainfall, control measures and socio-economic factors¹. Even so, direct effects of temperature on mosquito life history and malaria parasites remain important determinants of disease risk^{24–27}.

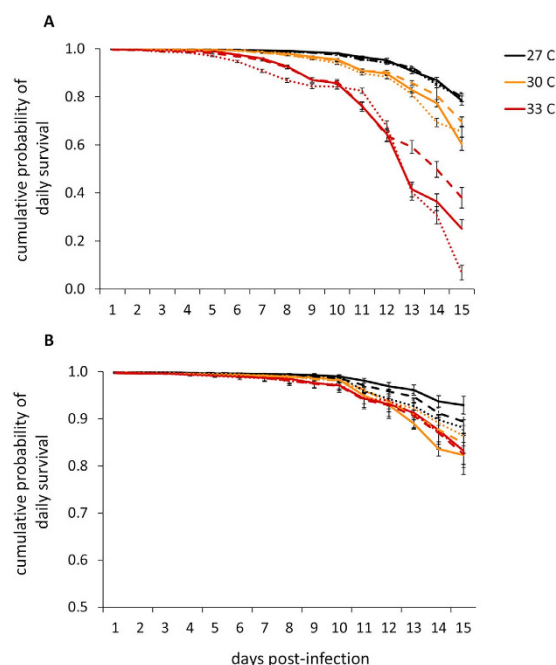

Figure 2. Increasing mean ambient temperature (27°C, black lines; 30°C, orange lines; 33°C, red lines) decreases the cumulative probability of daily survival for both *Anopheles gambiae* (A) and *An. stephensi* (B). Variation in diurnal temperature range (DTR 0°C, solid lines; DTR 6°C, hashed lines; DTR 9°C, dotted lines) differentially affects the cumulative probability of daily mosquito survival for each vector species.

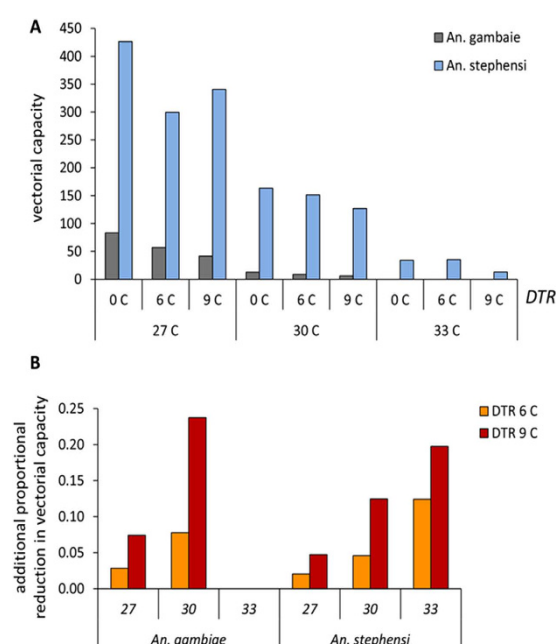

Figure 3. The effects of temperature and diurnal temperature range (DTR) on vectorial capacity. (A) Increasing mean ambient temperature (27, 30 and 33°C) and DTR of (0, 6, 9°C) decreases the vectorial capacity of both *Anopheles gambiae* (grey bars) and *An. stephensi* (blue bars). (B) When rate summation is used to estimate the predicted additional effects of DTR on biting rate and parasite development, the proportional reduction in vectorial capacity increases with mean ambient temperature and temperature variation. No predictions are available for *An. gambiae* at 33°C as vectorial capacity is already zero without additional effects of DTR.

The laboratory colonies of mosquitoes that we used are likely adapted to standard insectary temperatures of 25–27°C, and the parasite strain has also been selected to infect optimally under these conditions. In nature, local adaptation could lead to different temperature optima, and different susceptibilities to temperature fluctuation²¹. Such local adaptation could limit direct extrapolation of our results to field settings. However, there is scant information on the nature and extent of local adaptation in malaria vectors²¹, and mean temperatures of 25–27°C are typical for areas with high endemic transmission²⁸. One of the only studies to explore local thermal adaptation in a mosquito vector (in this case *Culex pipiens*, a vector of certain arboviruses) found that although local populations differed in key life history traits such as development and survival, variation was not correlated with local temperatures and thus did not support the local thermal adaptation hypothesis²⁹.

Regardless of local adaptation, the unimodal, nonlinear relationships between life history traits and temperature are fundamental³⁰. Moreover, upper critical temperatures exhibit limited capacity for response to selection^{31,32}, suggesting that effects of exposure to high temperatures tend to be conserved at the species level. This premise is supported by the fact that our two mosquito species did not exhibit identical responses to high temperatures, even though they have been under similar lab-based selection for many generations. Thus, we expect variation in temperature above the optimum to yield reductions in transmission potential irrespective of local adaptation. The more general caution regarding extrapolation of lab-based results to field settings is important to acknowledge. However, data on the effects of temperature on malaria mosquito and parasite traits are surprisingly scant. For example, the best available data to describe the relationship between vector competence and temperature² derive from a single, poorly replicated study published in 1940 that actually examined *P. vivax* infection in a North American vector species³³. Certain modeling studies ignore temperature dependence of traits such as competence, in part, because of the scant nature of the data^{9,28}. We believe our study provides important new insights into the temperature dependence of malaria transmission that should motivate further field research.

The Intergovernmental Panel on Climate Change 2014⁸ predicts global warming to cause expansions in the current geographical range of malaria and other vector-borne diseases, due to increases in suitable habitat for vectors and increased duration of the transmission season. The current study provides important empirical evidence to counterbalance this recurrent emphasis in the climate change literature. Based on data in the Malaria Atlas Project (<http://www.map.ox.ac.uk/>), we estimate there are >320 million people at risk in the highest transmission areas of Africa (i.e. areas with optimal conditions for endemic transmission leading to annual *P. falciparum* parasite rates in the 2–10 year old age class >40%). In high transmission settings, the epidemiology of malaria is complex, not least because prevalence exhibits a strongly non-linear, saturating relationship with measures of transmission intensity such as vectorial capacity or entomological inoculation rate³⁴. Thus, changes in transmission potential need not lead to obvious changes in prevalence, although the link to incidence is likely more direct. Nonetheless, changes in temperature due to modification of local landscape and housing, or longer-term climate change, could work in concert with control efforts and improvements in public health infrastructure to reduce malaria transmission in these highly endemic settings. Indeed, there is some evidence that this might already be occurring³⁵.

At a more basic level, our data emphasize the importance of local environmental context for understanding temporal and spatial patterns of transmission. We demonstrate multi-fold-differences in malaria transmission potential due to small changes in mean temperature and DTR. Transient shifts of $\pm 3^\circ\text{C}$ or more in mean temperature and DTR are commonplace (SI Fig. S2^{6,10}) and do not require long-term climate change to be relevant, yet few studies consider such effects. We also demonstrate important differences between vector species in thermal sensitivity of life history traits and overall vector competence, cautioning against the use of mixed-species data and extrapolation across vector-parasite pairings, which is a common feature of many studies exploring environmental influences on transmission^{2,7,9,28}.

Methods

We reared *Anopheles gambiae* (Keele strain) and *Anopheles stephensi* (Liston) under standard insectary conditions at $27 \pm 0.5^\circ\text{C}$, 80% humidity, and a 12 h light: 12 h dark photo-period and on a 10% glucose solution diet. Upon emergence, three-day old female adult mosquitoes were randomly distributed into experimental cages ($20 \times 20 \times 20\text{ cm}$; $N = 150$) representing one of 18 treatment groups consisting of three mean temperatures (27°C , 30°C and 33°C), three diurnal temperature ranges (DTR 0°C , $\pm 0^\circ\text{C}$; DTR 6°C , $\pm 3^\circ\text{C}$; and DTR 9°C , $\pm 4.5^\circ\text{C}$), and two infection treatments (bloodfed controls and *P. falciparum* infected) (SI Fig. S3). We have two and three full biological replicates of the *An. gambiae* and *An. stephensi* experiments, respectively. Mosquitoes were deprived of sugar for a 12 hr interval of time, after which they received either an uninfected bloodmeal or a *Plasmodium falciparum* (8% gametocytemia; NF54 isolate, MR4) infectious bloodmeal through a membrane feeder. Both *An. gambiae* and *An. stephensi* received an infectious bloodmeal from the same *P. falciparum* culture to ensure similar parasite dosages and minimize any inter-culture variation. Directly after the bloodfeeds, mosquitoes were then placed into the appropriate temperature treatment and were maintained on 10% glucose solution daily.

Mean temperatures and diurnal temperature ranges were selected based on microclimate data collected from various housing types throughout the transmission season in Chennai, India¹¹ and Tanzania¹⁵, and we used the Parton-Logan model for diurnal temperature fluctuation (SI Methods) to program our fluctuating reach-in incubators. We dissected midguts and salivary glands on days 7 and 15 post-infection (PI) from each *P. falciparum* exposed treatment group to quantify the effects of variation in mean temperature, diurnal temperature fluctuation, and treatment on measures of vector competence (SI Methods). Throughout the duration of the experiment we counted the number of dead mosquitoes in each cage daily to quantify the effects of mean temperature, diurnal temperature fluctuation, and treatment on daily mosquito mortality.

All statistical analyses for these experiments were run in IBM SPSS Statistics 22.0 (IBM Corporation). We used mixed effects generalized linear models to assess the effects of temperature, diurnal temperature range, and infection treatment on the following response variables: oocyst prevalence, oocyst intensity, sporozoite prevalence, and

daily mosquito survival. Temperature (27°C, 30°C, and 33°C), diurnal temperature range (DTR 0°C, DTR 6°C, and DTR 9°C), and their interaction were included in all models as fixed effects. Infection treatment (bloodfed control and *P. falciparum* infected) and days post-infection were included in all survival models as an additional fixed effect and a covariate, respectively. To control for any variation influencing our response variables across biological replicates, we included replicate as a random factor in all model analyses (SI Methods).

We calculated vectorial capacity (C) with the following equation:

$$C = \frac{ma^2be^{-\mu EIP}}{\mu}, \quad (1)$$

where m represents infectious vector density, a is the daily probability of a human host being fed on by a vector, EIP is the extrinsic incubation period of the parasite, μ is the daily probability of adult mosquito mortality, and b is vector competence. The density of infectious mosquitoes (m) was estimated by taking the average number of mosquitoes alive in each treatment group upon completion of the parasite's extrinsic incubation period at each temperature. Due to significant block effects, we used estimated marginal means from our mixed model analysis to parameterize vector competence (b ; the proportion of infectious mosquitoes), and the daily probability of mortality of potentially infectious adult mosquitoes (μ) for each treatment group. To estimate the parasite extrinsic incubation period (EIP) and mosquito biting rate (a) at a given mean temperature (T), we used Briere's thermal equation:

$$x(t) = cT(T - T_o)\sqrt{T_m - T}, \quad (2)$$

where T_o and T_m are the thermal minimum and maximum for a given trait (x), and c is a constant. The values used for T_o , T_m , and c for the extrinsic incubation period (EIP) and the daily biting rate (a) were taken from Mordecai *et al.*². In order to estimate potential effects of diurnal temperature fluctuation on these parameters, we used rate summation³⁴ defined as

$$x = \int r(T(t))dt, \quad (3)$$

where a given trait (x) is defined as a rate (r) that adjusts instantaneously to temperature (T), which in turn is a function of time (t).

35. Meyrowitsch, D. W. *et al.* Is the current decline in malaria burden in sub-Saharan Africa due to a decrease in vector population? *Malar. J.* **10**, 1475–2875 (2011).

Acknowledgements

We thank members of the Thomas and Read lab groups for discussion, J. Teeple for insectary support, and M. Kennedy for parasite culturing and assistance with dissections. We thank L. von Seidlein *et al.* for providing us with temperature data from Tanzania and the Gambia. This research was funded in part by NIH-NIAID (ICEMR award U19AI089676 and R01AI110793). The content of this paper is solely the responsibility of the authors and does not necessarily represent the official views of the National Institute of General Medical Sciences, the National Institute of Allergy and Infectious Diseases, and the National Institutes of Health. This project was also partly funded under a grant with the Pennsylvania Department of Health using Tobacco Settlement Funds. The Department specifically disclaims responsibility for any analyses, interpretations or conclusions.

Author Contributions

C.C.M. was in charge of the design, execution, and data analysis of the experiments, as well as writing this manuscript. E.D.S. helped with the data analysis of the experiment and provided microclimate data included in the supplementary information file. M.B.T. consulted on the design of the experiment, the data analysis, and the writing of the manuscript.
