New insights into biomass combustion ash categorisation: a phylogenetic analysis

20

21 **Abstract:** Combustion of biomass within power stations is a more sustainable way to generate
22 electricity than the use of fossil fuels provided the feedstock is sustainably grown. The physical
23 and chemical properties of biomass combustion ash from different feedstocks was statistically
24 analysed using 168 published database records. Plant taxonomy of the feedstock has a strong
25 influence on the major element composition of the ash, and biomass feedstocks that are burnt
26 commercially can usefully be categorised as hardwood, softwood, grass crop residues, and non-
27 grass crop residues. The most abundant elements in hardwood ashes are calcium > potassium >
28 phosphorous, whereas in the softwood ashes they are calcium > silicon > potassium. The most
29 abundant elements in eudicot straw ashes are potassium > calcium > chlorine > phosphorous, and
30 in grass straw ashes they are calcium > potassium > calcium > chlorine. Differences in major
31 element chemistry between the feedstock categories are visualised using a ternary plot of the
32 normalised calcium oxide, dipotassium oxide, silicon dioxide contents. Other properties depend
33 principally on whether the feedstock is herbaceous or woody. Herbaceous feedstocks produce
34 significantly more ash (typically 5-9%) than woody feedstocks (typically 1-2%) and their ash has
35 a significantly lower initial deformation (melting) temperature than ash from woody feedstocks,
36 and thus has greater potential to form slag and foul the furnace. These findings allow for the impact
37 on ash characteristics to be include in commercial and operational decisions about power station
38 feedstock.

39

40 1. Introduction

41 Anthropogenic CO₂ emissions are a significant cause of climate change, which accounted for
42 three-quarters of the global warming potential of anthropogenic emissions in 2010 [1]. Worldwide,
43 electricity and heat generation are the largest source of anthropogenic CO₂ emissions due to their
44 heavy reliance on fossil fuels, accounting for ~40% of the global total in 2016 [2]. Thus, there is a
45 strong incentive to use alternative energy sources for heating, and particularly for electricity
46 generation that release less CO₂. Despite the criticisms that it may promote deforestation and can
47 displace food production, burning of biomass within power stations is seen as a more sustainable
48 way to generate electricity than fossil fuels, provided the biomass is a waste from another industry
49 or grown sustainably (further crop growth reduces the half-life of the CO₂ in the atmosphere [3]).

50 Ash is an inevitable by-product of biomass combustion. Industrial scale combustion forms ash
51 with one of two characteristic size fractions: bottom ash (or sometimes slag) that is discharged from
52 the grate (median size typically >1mm), and fly ash recovered from the flue gases (median size
53 typically 10–100 µm) [4-8]. Effective reuse of these ashes or, as an absolute minimum, their safe
54 disposal is essential to the environmental sustainability of using biomass fuels. Biomass ashes are
55 mainly composed of the inorganic constituents of the feedstock, together with some unburned
56 organic phases. They have been characterised as a heterogeneous poly-component inorganic-
57 organic mixture with variable compositions, which contain non-crystalline (amorphous) semi-
58 crystalline and crystalline phases [6]. In a review of ash from 120 different sources Vassilev et al.
59 [6] have identified 229 phases or minerals found in biomass ash, with quartz, calcite, sylvite,
60 arcanite, anhydrite, char, glass, lime, periclase and hematite as the common mineral phases.
61 Further, there are usually compositional differences between the fly and bottom ash from the same

62 feedstock, as volatile phases vaporised in the furnace (particularly salts and heavy metals) can
63 condense onto the fly ash [4, 5, 9]. Similarly, different furnace technologies (e.g. grate furnace or
64 fluidised bed) also affect ash composition due to differences in the furnace temperature [9]. Such
65 a detailed view of biomass ash composition is not helpful when attempting to identify different
66 potential reuse strategies for an industrial by-product. It implies that detailed knowledge of the
67 biomass composition and the combustion technology are necessary to reliably predict the
68 characteristics of the ash. Whereas practical and commercial considerations, such as seasonal
69 availability and supply security, may necessitate rapid decisions about feedstock. Thus, there is a
70 pressing need for more general guidance on how ash characteristics vary with type of feedstock.

71 The elemental constituents of an ash must be derived from the elemental constituents of the
72 biomass, and while there is loss of organic matter and phase changes in the furnace, and
73 fractionation of volatile constituents between the ash fractions, the bulk characteristics of the ash
74 are likely to be correlated with the composition of the feedstock. Many different types of biomass
75 are used worldwide to provide heat on a domestic scale, but commercial biomass combustion for
76 electricity generation requires large volumes of consistent feedstock, so primary fuels are forestry
77 or agricultural residues. Their sources can thus be classified as softwood, hardwood, grasses (which
78 includes all cereal crops), and other crop residues. Crops grown and harvested specially for biomass
79 combustion, such as willow (hardwood) and miscanthus (grass) also fall in one of these categories.
80 Thus, primary biomass fuels are all derived from land plants (Embryophyta), but these plants fall
81 into three distinctly different groups from an evolutionary standpoint (Fig. 1). All the extant
82 softwoods are gymnosperms (they have unenclosed seeds) and taxonomically they are grouped in
83 a single division Pinophyta in the order Pinales [10, 11]. The gymnosperm lineage separated from

84 flowering plants (angiosperms) about 270-330 Myr ago [12-15]. Similarly, all grasses are from the
85 family Poaceae within the monocotyledon (monocot) clade of the angiosperms, whereas the
86 majority of hardwoods that are used as a commercial fuel are Rosids (e.g. oak, beech, walnut,
87 willow) within the eudicotyledon (eudicot) clade of the angiosperms (the remainder are Asterids
88 also within the eudicot clade of the angiosperms) [11, 16]. Other crop residues used as biomass
89 fuels (e.g. rapeseed, sunflower, alfalfa) also belong to the eudicots (rapeseed and alfalfa are Rosids
90 and sunflower is an Asterid). The eudicot lineage separated from the monocot (grasses) lineage
91 around about 143-157 Myr ago [17, 18].

92 These evolutionary differences are reflected in the structural differences between softwood,
93 hardwood, herbaceous eudicot and monocot stems (biomass fuels that are burnt commercially are
94 overwhelmingly plant stems, such as straw, stalks, and wood). Between node points (e.g. buds,
95 leaves, and branching points) the stems of gymnosperms and eudicots typically consist of a ring of
96 vascular bundles (for the transport of water and food) between outer and inner regions of ground
97 tissue, whereas the vascular bundles in monocots are arranged in more than one ring or are scattered
98 throughout the cross-section [19]. Wood is formed during the secondary (lateral) growth by most
99 gymnosperms (softwoods) and by woody eudicots (hardwoods). It is composed of secondary xylem
100 tissue produced within the vascular bundles [20], which in hardwood contain vessels for the
101 transport of sap but not in softwood where sap is transported by evolutionarily more primitive
102 tracheid cells [21]. Thus, the distribution organic tissues within the stem of plants is determined by
103 evolution. The inorganic constituents that remain after biomass combustion will reflect the
104 composition of the organic tissues from which they originate, so there are likely to be systematic
105 differences in the composition of the ashes produced by combustion of different feedstocks.

106 The supposition that the taxonomy of the feedstock will influence the composition of biomass
107 ash is supported by systemic differences in the silicon content between taxonomically distinct
108 groups of plants, and variation in the amount of ash produced by different categories of feedstocks
109 (grasses produce far more ash than woody biomass [22]). Deposition of Si in plants mostly occurs
110 in epidermal cells, and is thought to be an evolved defensive response to pathogens and pests [23].
111 Hodson et al. [24] undertook meta-analysis of the data from 735 different species of land plants
112 which showed variations in the shoot Si concentration with taxonomic grouping, with high Si
113 accumulation in the taxonomic families that contain grasses and palms, and to a lesser extent in the
114 families that include common hardwoods (including oak, beech, birch, alder, hazel, hornbeam,
115 walnut, hawthorn, cherry, elm, willow, poplar).

116 This study reviews 168 database records reporting the major element chemical composition of
117 biomass combustion ash from different feedstocks and proposes an evolutionary-based system for
118 categorising biomass derived ash into four categories: hardwood ash, softwood ash, eudicot straw
119 ash and grass straw ash. Systematic differences in the ash properties between these categories are
120 qualitatively and quantitatively determined. Finally, guidance is offered to commercial generators
121 of electricity from biomass to help them make rational decisions about feedstock variation.

122 2. Methodology

123 Biomass ash sample characterization data was recovered from the Energy Research Centre of
124 the Netherlands (ECN) Phyllis2 classification database (<https://phyllis.nl/Browse/Standard/ECN-Phyllis#>). The Phyllis2 databases are designed and maintained by the Netherlands Organization for
125 Applied Scientific Research for the Netherlands Government. Phyllis2 contains around 3000
126 compositional data records from biomass fuels organized based on a mixture of plant physiology
127

128 and practical considerations. Of these data records, 168 contain the major element chemical
129 composition of their corresponding combustion ashes and these were selected for the present study.
130 These records also contain incomplete details of other relevant ash properties such as trace metal
131 composition and ash melting temperatures, which were also compiled and included in the present
132 study. No data on organic contaminant composition of ashes (e.g. PCBs, dioxins) were available in
133 the Phyllis2 database. The ash composition data consisted of data from both hardwood and
134 softwood samples and a wide range of crop straws ashes (Table 1). All the extracted data, along
135 with their corresponding Phyllis2 database ID numbers, is provided in the supplementary
136 information (S.I. Tables S1 - S4).

137 Major element data was transformed to nominal oxide format prior to use (e.g. elemental Ca
138 data was converted to CaO wt. %, etc.), and any data reported as below laboratory detection limits
139 were given a value of zero. In addition, when the nominal oxide compositions are reported on
140 ternary diagrams, the oxides being reported were normalized to 100% on a total oxide composition
141 basis.

142 Ash composition data were analysed to test the null hypothesis that there was no significant
143 difference in median elemental composition between the four ash types using a Kruskal-Wallis test.
144 Dunn's post-hoc test was then used to test pairwise differences in the median values between the
145 different ash types where significance was apparent ($p < 0.05$). All analyses were undertaken in
146 IBM SPSS v24.

147 3. Results

148 3.1. Ash content derived from biomass

149 The median ash content produced by each biomass type (Table 2) indicates that eudicot straw
150 (median 8.8%) and grass straw (5.2%) tend to produce more ash upon burning than either hardwood

151 (1.6%) or softwood (1.0%). Kruskal–Wallis analysis of the ash contents indicates that there are two
152 or more separate populations within the overall dataset (Table 2; $p < 0.001$), and while the pairwise
153 comparisons show that there is no significant between the hardwood and softwood ash contents or
154 between the eudicot straw and grass straw ash contents, woody biomass (hardwood or softwood)
155 has significantly lower ash content than straw biomass (eudicot straw and grass straw) ($p < 0.001$).

156 A subset of the biomass ash database records considered in this study also report biomass
157 feedstock data (see S.I. Fig. S5). Hardwoods contain significantly more volatile matter (median
158 84%) than eudicot straw (78%) and grass straw (77%). Softwoods also have higher volatile content
159 than grass straw, but are not significantly different from either hardwoods or eudicot straw.
160 Hardwoods contain less fixed carbon (median 15%) than either softwoods or grass straw (17-18%).
161 Ultimate analysis (the relative time proportions of the major components, carbon, hydrogen,
162 nitrogen, oxygen and sulphur), again indicates only very modest, albeit significant differences
163 between some of the biomass categories. Hardwood, softwood and eudicot straw have slightly
164 higher C content (medians 50-52%) than grass straw (49%), while there is no significant difference
165 in H content across biomass categories. Grass straw has a higher O content (median 44%) than
166 softwood and eudicot straw (40-42%) but is similar to hardwood (43%). Eudicot straw has a
167 significantly higher S content (median 0.22%) than grass straw, hardwood and softwood, with grass
168 straw (0.11%) having a significantly higher S content than hardwood or softwood (0.01-0.05%). N
169 content follows a similar pattern being significantly higher in eudicot straw (median 2%) than any
170 other biomass categories.

171 3.2. Ash chemical compositions

172 Fig. 2(a)-(d) shows the chemical compositions (in the form of common oxide) of four ash
173 categories. The abundant oxide phases in hardwood ashes (median concentration $>5\%$ w/w) are

174 CaO > K₂O > P₂O₅ (Table 2), whereas in the softwood ashes they are CaO > SiO₂ > K₂O. The
175 abundant oxide phases in eudicot straw ashes are K₂O > CaO > Cl₂O > P₂O₅, and in grass straw
176 ashes they are SiO₂ > K₂O > CaO > Cl₂O.

177 Kruskal–Wallis analysis of the elemental oxide contents indicates that there are significant
178 differences in sample medians between ash types for each of the oxides reported except Na₂O
179 (Table 2; p < 0.05 for SO₃ and p < 0.001 for other oxides). Pairwise comparisons of the CaO content
180 indicate there is no significant difference between the hardwood ash and softwood ash (the pairwise
181 elemental oxide comparisons are reported using superscript letters in Table 2), but both have a
182 significantly higher CaO content than grass straw ash. Eudicot ash also has significantly higher
183 CaO than grass straw but is not significantly different from hardwood or softwood ash. Similar
184 pairwise comparisons indicate that the eudicot straw ash has a significantly higher K₂O content
185 than the hardwood ash and the grass straw ash, which in-turn have significantly higher K₂O
186 contents than the softwood ash (but there is no significant difference between the hardwood and
187 grass straw ash). Also, the grass straw ash has a significantly higher SiO₂ content than the other
188 three ashes. The SO₃ and Cl₂O contents of the ash are important indicators of the amount of volatile
189 sulphur and chlorine in the feedstock, which can result in acid gas emissions that cause high
190 temperature corrosion and may require additional air-pollution control measures. There are no
191 significant differences in SO₃ content between the ash categories in pairwise comparisons (the
192 overall median value across all ash categories was 3.0%, range: 0.1-14.0%). In comparison, the
193 median Cl₂O contents of the eudicot and grass straw ashes were similar and both were significantly
194 higher than either hardwood or softwood ashes, which had similarly low Cl₂O values. However,
195 the small sample size for softwood and hardwood Cl₂O data must be noted (N = 4 for both). Lastly,

196 the hardwood and eudicot straw ashes have significantly higher P₂O₅ contents than the softwood
197 and grass straw ashes. Statistical analysis of the other main elemental oxides can be found in Table
198 2.

199 3.3. Trace metal concentration in biomass ash

200 Contaminant trace metal concentrations are reported in a subset of the data records considered
201 in this study (Fig. 3). The median Cu concentrations in the biomass ashes are 90, 329, 72, and 42
202 mg/kg for the hardwood, softwood, eudicot straw and grass straw ashes, respectively. The median
203 Pb concentrations in the biomass ashes are 135, 29, 3, and 4 mg/kg for the hardwood, softwood,
204 eudicot straw and grass straw ashes, respectively. The median Cd concentrations in the biomass
205 ashes are 10, 1, 0, and 0.1 mg/kg for the hardwood, softwood, eudicot straw and grass straw ashes,
206 respectively. For comparison, the Finnish limits for ash use as a forest fertiliser are 700, 150 and
207 17.5 mg/kg for Cu, Pb and Cd respectively [5]. The equivalent Swedish limits are 400, 300 and 30
208 mg/kg, respectively [25]. The Cu concentration in softwood ash is significantly higher than in either
209 straw ash (S.I. Table S6), but the difference between the two straw ashes is not significant
210 (contaminant trace metal concentrations were reported for insufficient hardwood ash samples for
211 statistical inference). Similarly, the Pb and Cd concentrations in softwood ash are significantly
212 higher than in eudicot straw ash, although grass straw ash is not significantly different from either
213 softwood ash or eudicot straw ash. Hg concentrations are only reported for three softwood samples,
214 but all three values are non-zero (median value 1.7 mg/kg), so these values are significantly higher
215 than the zero (i.e. below detection limit) values reported for the two straw ashes. Cr concentrations
216 are only reported in three data records so no inference can be drawn from the data.

217 3.4. Ash fusion temperatures

218 Fig. 4 reports initial deformation temperature (IDT), softening temperature (SOT),

219 hemispherical temperature (HT) and fluid temperature (FT) of the four ash types (these
220 temperatures are important in evaluating ash slagging, fouling and corrosion effects on the boiler
221 and thus its conversion efficiency [26-28].

222 Hardwood and softwood ashes have significantly higher IDTs (medians 1363°C and 1196°C,
223 respectively; see S.I. Table S7) than the eudicot straw and grass straw ashes (860°C and 910°C,
224 respectively), but the difference between the wood ashes and the difference between the straw ashes
225 are not significant. Softwood ash has a significantly higher SOT (median 1244°C) than the eudicot
226 straw and grass straw ashes (920°C and 1025°C, respectively), but the difference between the straw
227 ashes is not significant (no data is reported for hardwoods). It is harder to discern the trends in HT
228 and FT data, but both the mean and median HT and FT of grass straw are lower than those of the
229 other ashes (S.I. Table S7).

230 4. Discussion

231 4.1. Biomass categorisation

232 A wide range of factors can affect the chemical composition of potential biomass plants [e.g.
233 plant species, soil characteristics, nutrition and stresses during growth, plant maturity, timing of the
234 harvest, plant component being harvested, etc.; 22, 29-34], but it is impossible to recognise all these
235 factors in any functional system for classifying the ash produced by biomass combustion. This
236 complexity has meant that most published work has tended to use only very broadly defined
237 categories to characterise biomass ash properties, such as “herbaceous and agricultural biomass
238 (HAB)” and “wood and woody biomass (WWB)” [35], which provide the user with very little
239 information except the likely ash content.

240 The hypothesis underlying the statistical analyses presented in this paper is that the biomass
241 feedstock will be a major factor in determining the inorganic elements within a biomass ash, and

242 that feedstocks will exhibit systematic differences due evolutionary divergence. The statistical
243 analyses of database records clearly support this hypothesis. The four biomass categories proposed
244 consistently divided into two or more statistically significant groups based on their content of each
245 abundant elemental oxide, and their ash content. Specifically, the biomass ash categories
246 considered in this paper divide into those that have a comparatively high or low CaO content, those
247 which have a comparatively high or low SiO₂ content, those that have a comparatively high or low
248 P₂O₅ content, those that have a comparatively high, intermediate or low K₂O content, and those
249 that have a comparatively high or low ash content. The four biomass ash categories can be clearly
250 differentiated by considering even a subset of these measures in combination. Hardwood ashes
251 have relatively high CaO and P₂O₅, intermediate K₂O and relatively low SiO₂ and ash contents.
252 Softwood ashes have relatively high CaO, but relatively low SiO₂, K₂O, P₂O₅ and ash contents.
253 Eudicot straw ashes have relatively high K₂O, CaO, P₂O₅ and ash, but relatively low SiO₂ contents.
254 Grass straw ashes have relatively high SiO₂ and ash, intermediate K₂O, but relatively low CaO and
255 P₂O₅ contents.

256 4.2. Chemical composition classification

257 Vassilev et al. proposed a chemical classification system for biomass based on its inorganic
258 composition [36]. They identified that the ash-forming elements are either authigenic or detrital in
259 origin (either elements required for plant growth, or fine mineral grains that become associated
260 with plant matter), and grouped the inorganic elements into three major elemental associations;

- 261 • Ca-Mg-Mn - Elements probably derived from plant matter that form oxalates and carbonates
- 262 • K-S-P-Cl - Elements probably derived from plant matter that form phosphates, sulphates,
263 chlorides and nitrates
- 264 • Si-Al-Fe-Na-Ti - Elements that are potentially derived from detrital material associated with

265 the biomass

266 While the rationale behind these elemental groups needs further confirmation (e.g. Si deposition
267 by plants can be a defensive response to pathogens, pests and grazers; [23], and Al uptake and
268 localised sequestration can be a plant adaptation to Al-toxicity [37]), representing their relative
269 proportions on a ternary diagram has been shown to differentiate between ashes from markedly
270 different fuels (e.g. HAB and WWB) [6, 7, 22, 36]. Presenting the data collated in this study on a
271 “Vassilev” style ternary diagram (Fig. 5(a)) confirms its utility and, despite some scatter, supports
272 the biomass ash categorisation proposed in this study (each ash category plots in a distinct region
273 of the diagram). Most of the 90 grass straw ashes plot in the low CaO+MgO+MnO areas of the
274 diagram, the 28 softwood samples plot in the low K₂O+P₂O₅+SO₃+Cl₂O areas of the diagram,
275 whereas the 24 hardwood and 26 Eudicot straw ashes plot in the low SiO₂+Al₂O₃+ Na₂O+TiO₂
276 areas of the diagram.

277 Review of the data in Table 2 suggests that “Vassilev” style ternary diagram shown in Fig. 5(a)
278 could be simplified by plotting only the most abundant constituent in each of the three groups: CaO,
279 SiO₂ and K₂O (see Figure 5(b)). On the revised ternary diagram, data from three categories of ash
280 exhibit closer grouping than in Fig. 5(a), with very little difference in the grouping of the fourth.

281 Although P₂O₅ and Cl₂O were each either the third or fourth most abundant nominal oxide in
282 two ash categories, the decision was made to omit them from the simplified ternary diagram (Fig.
283 5b). This is because the Kruskal–Wallis analysis clearly indicates that the biomass categories group
284 differently on the basis of their K₂O, P₂O₅ and Cl₂O contents (hardwood ash groups with grass
285 straw ash for K₂O content, with eudicot straw ash for P₂O₅ content, and with softwood ash for Cl₂O
286 content) so it is not appropriate to sum them on a classification diagram. Therefore, K₂O alone was

287 selected from this group of elemental oxides as it is more abundant than the other two in all four
288 categories of ash.

289 All the hardwoods included in the data analysis are Rosids (part of the eudicot clade of
290 angiosperms; see Fig. 1), as are alfalfa and rapeseed (the remaining eudicot grass is an Asterid).
291 However, the herbaceous eudicots ashes form a single group that is distinct from the woody eudicot
292 ashes (see Fig. 5). The principal difference between woody and herbaceous eudicots is that there is
293 far more secondary growth in the stems of the former (i.e. wood) and this is composed of secondary
294 xylem tissue [20]. The xylem is a critical part of the Ca^{2+} delivery system in plants [38], and this
295 probably accounts for the higher CaO in woody eudicot ash than in herbaceous eudicot ash.

296 4.3. Contaminant trace metal associations

297 All the eudicot straw ashes were below the Finnish and Swedish limits on Cu, Pb and Cd content
298 for use as a forest fertiliser (data was available for 48 samples). Similarly, almost all of the monocot
299 grass straw ashes were below these same limits (1 of 66 samples failed to meet the more stringent
300 Finnish limit for Pb content). Whereas a noteworthy proportion of the softwood ashes exceeded
301 both the Finnish and Swedish limits on for either Cu content, Pb content, or both (contaminant
302 trace metal concentrations are reported for insufficient hardwood samples for further comment).
303 Part of the reason why softwood ashes tend to contain more contaminant trace metals than either
304 eudicot straw or grass straw ash may be associated with the lower ash content of woody biomass,
305 as the estimated mean Cu content of the original biomass is similar for three biomass types (Table
306 3), and as are the estimated mean Pb and Cd contents of the original softwood and grass straw
307 [interestingly, the estimated trace metal contents of unburnt biomass are similar to those reported
308 elsewhere in the literature; 39, 40, 41]. However other explanations, such as differences in metal
309 uptake mechanism by different plant types or more stringent limits on the soil metal contents for

310 agriculture than forestry cannot be discounted.

311 Uptake of metals not required by, and potentially harmful to plants is likely to be an artefact of
312 nutrient uptake [i.e. uptake of a divalent contaminant metal might be via the Ca^{2+} uptake pathway;
313 42, 43, 44]. The correlation of Cu, Pb and Cd with CaO content was analysed by treating all the
314 ash samples as a single dataset (S.I. Fig. S1 and Table S8). There is considerable scatter in the data,
315 which is to be expected as contaminant metal uptake must be affected by soil concentrations, but
316 there are modest but significant positive correlations between Cu and Ca (Spearman's Rank $r_s =$
317 0.59, $p < 0.001$), Cd and Ca ($r_s = 0.30$, $p = 0.046$) and Pb and Ca ($r_s = 0.35$, $p = 0.016$).

318 4.4. Organic contaminants in biomass ash

319 When organic matter is incinerated polychlorinated dibenzodioxins/dibenzofurans (PCDD/Fs)
320 may form in the furnace from Cl present in the feedstock. Formation occurs as the combustion
321 gases cool and is thus sensitive to the rate of flue gas cooling [45-48]. The rate of production of
322 PCDD/F precursors increases slowly with Cl concentration at the Cl levels of typical feedstocks
323 [49], but transition-metal species associated with the ash particles, especially copper compounds,
324 can promote PCDD/Fs formation [45, 46, 50, 51]. However, production of PCDD/Fs is usually
325 more dependent of the combustion technology used than on the feedstock [47]. This makes
326 systematic collection of PCDD/F data difficult as current databases are organised by feedstock.
327 With a standard domestic furnace typical PCDD/Fs concentrations are about 5 ng/kg I-TEQs in
328 softwood ash and 8-24 ng/kg I-TEQs in grass straw ash [47] (PCDD/F concentrations are report in
329 international toxic equivalents, I-TEQs, per unit dry mass). These concentrations are more than two
330 orders of magnitude lower than the provisional requirements for low persistent organic pollutant
331 content limit in wastes stated in the Basel Convention general technical guidelines [52], and more
332 than an order of magnitude lower than the maximum stated in Japan's environmental quality

333 standard for soil [53], but close to the UK limit for poultry litter ash to be used as fertiliser of 20
334 ng/kg I-TEQs [54]. Thus, disposal of ash from biomass combustion is unlikely to present a problem,
335 but close management of the furnace and feedstock may be required for feedstock with higher Cl
336 contents (such as eudicot straw and grass straw) if the ash is to be applied to agricultural soils.

337 4.5. Associations of ash fusion behaviour and ash chemical composition

338 While this paper is focussed on the chemical composition of biomass ash (which determines
339 whether the ash can be put to beneficial use and/or the issues associated with disposal), commercial
340 operators of biomass power stations need to balance multiple constraints when making decisions
341 about feedstock composition [55]. In addition to concerns with availability, cost and calorific value,
342 operators need to consider the ash fusion characteristics of different feedstocks, as fusing of ash
343 particles can result in slagging, fouling and corrosion within the furnace, and thus thermal
344 conversion efficiency and maintenance requirements for a biomass power station [26, 56, 57].

345 The temperature at four defined points (IDT, SOT, HT and FT) are used to characterise the ash
346 melting process and thus the likelihood that ash particles will fuse together [26, 58], but there still
347 debate about which best correlates with the ash fusion characteristics of biomass [59-61]. The
348 softening temperature (SOT) is generally used as the index of coal ash fusion behavior, but initial
349 work on biomass ash suggests that the initial deformation temperature (IDT) may be the better
350 index for biomass [27]. IDT is also the most widely reported of these indices in the Phyllis2 data
351 records considered in this study (it is reported in 80/168 records), and as IDT is the temperature at
352 which melting is first recorded, it is the lowest of the four defined temperature points.

353 The obvious pattern is that wood ashes have a significantly higher IDT than straw ashes,
354 however four of the elemental oxide contents also show a statistically significant correlation with
355 two or more of the defined temperature points (IDT correlates with all four of these nominal

356 oxides). IDT, SOT, HT and FT are all positively correlated with the CaO content (confidence 99%;
357 see S.I. Table S9), and 36% of the variance in IDT can be explained by the CaO content. IDT and
358 SOT are both negatively correlated with both the K₂O and Cl₂O contents (conf. 99%); 18% of the
359 variance in IDT can be explained separately by the K₂O and Cl₂O contents. IDT, HT and FT also
360 exhibit a weak negative correlation with the SiO₂ content (conf. 95%, 95% and 99%, respectively),
361 but SiO₂ can only explain 4% of the variance in IDT. Thus, IDT increases as CaO content increases,
362 but decreases as K₂O, Cl₂O, and to a lesser extent SiO₂ increase.

363 5. Conclusions

364 Statistical analysis of the chemical composition of 168 biomass combustion ashes from different
365 feedstocks shows that the plant taxonomy of the feedstock has a strong influence on the major
366 element chemical composition of the ash produced. The biomass feedstocks that are burnt
367 commercially for electricity generation can usefully be categorised as hardwood, softwood, grass
368 crop residues (e.g. straw from cereal production), and non-grass crop residues. The abundant
369 nominal oxide phases in hardwood ashes are CaO > K₂O > P₂O₅, whereas in the softwood ashes
370 they are CaO > SiO₂ > K₂O. The abundant nominal oxide phases in eudicot straw ashes are K₂O >
371 CaO > Cl₂O > P₂O₅, and in grass straw ashes they are SiO₂ > K₂O > CaO > Cl₂O. SO₃ and Cl₂O
372 composition are important for high temperature corrosion effects in furnaces and environmental
373 emission control. Cl₂O content was significantly higher in eudicot and grass straw ash than
374 softwood and hardwood ash, while SO₃ content was variable but not significantly different between
375 ash classes.

376 Other properties depend principally on whether the feedstock is herbaceous (eudicot straw and
377 grass straw) or woody (hardwoods and softwoods). Herbaceous feedstocks produce significantly

378 more ash (typically 5-9%) than woody feedstocks (typically 1-2%) but, possibly as a result, the
379 ashes generally contain lower concentrations of contaminant trace metals. Also the initial
380 deformation temperature (IDT) of ash from herbaceous feedstocks (typically 860-910°C) is
381 significantly lower than that of woody feedstocks (typically 1196-1363°C), which is an indicator
382 that such ash has a higher potential to form slag and foul the biomass furnace).

383 Operational decisions about the specific choice feedstock for use in a commercial biomass
384 combustion power station depend on a range of practical and business-related considerations. For
385 example, seasonal availability and supply security may necessitate occasional, and sometimes rapid,
386 feedstock changes. However, the ash reuse or disposal strategy will always be an important
387 consideration when managing such change. The data in this paper indicate how the ash
388 characteristics are likely vary with the type of feedstock, and thus can facilitate dynamic decision-
389 making. An alternative fuel within the same feedstock category is likely to cause only a modest
390 change in the ash's physical and chemical characteristics, whereas a change between categories
391 (e.g. from cereal crop residues to wood-pellets from coniferous forestry) is likely to have a more
392 substantial impact of ash's physical and chemical characteristics.

393 Finally, it is noted that incomplete data on contaminant trace metals and organics hinder the
394 beneficial reuse of biomass ash as in the absence of data regulators often make conservative
395 decisions regarding approval of new ash reuse proposals.

547

548

549 Table 3. Calculated trace metal concentration in the different biomass feedstocks estimated from
 550 the concentrations in the ash samples and the ash content (μg trace metal per g dry weight biomass).

Item	Mean trace metal concentration in biomass ($\mu\text{g/g}$)				Literature values ($\mu\text{g/g}$)
	Hardwood ^a	Softwood	Eudicot straw	Grass straw	
Cu	1.7	11	7.4	4.9	5-20 ^b
Pb	2.6	1.5	0.40	2.1	0.01-3.85 ^{b, c}
Cd	0.19	0.05	0.005	0.02	<1 ^{b, d}

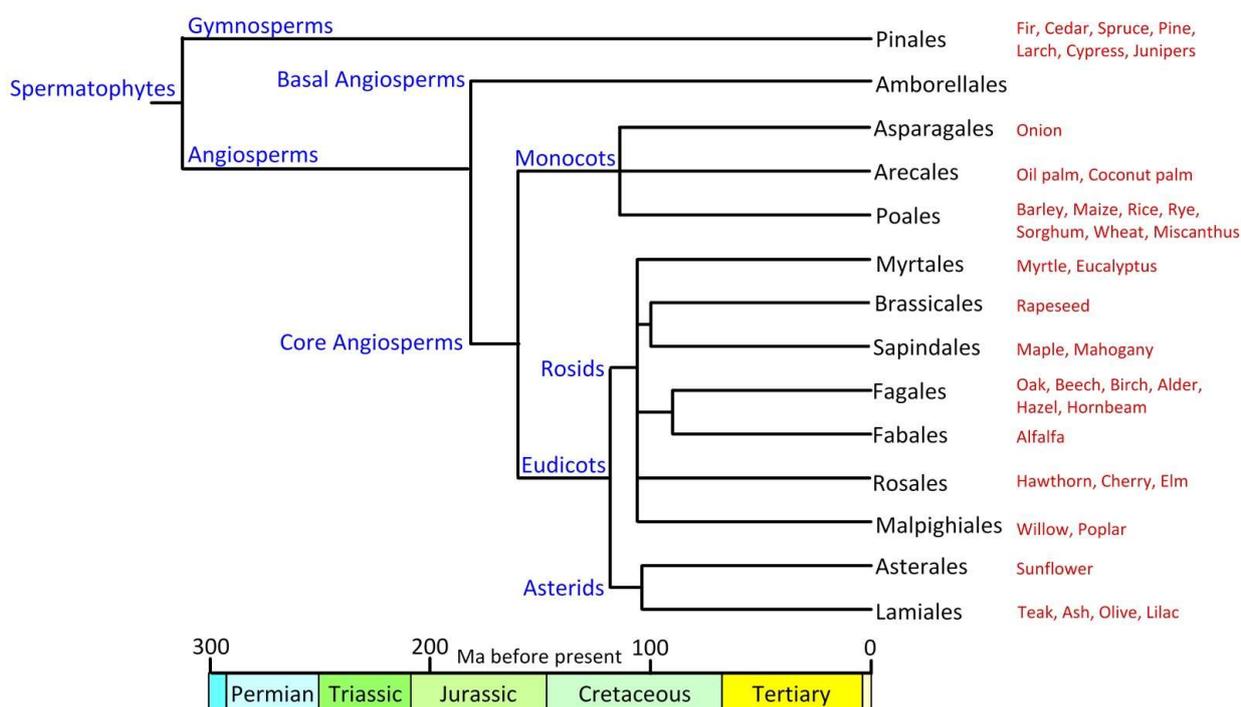

551 ^a Note: Trace metal concentrations are only reported for 2 hardwood ash samples within the dataset.

 561 Fig. 1. Approximate phylogeny of spermatophytes (seed plants) determined using TimeTree[14,
 562 62]. TimeTree estimates phylogenetic relationships and species divergence times from the synthesis
 563 of all available molecular clock analyses [63]. Potential biomass fuels are shown next to the order
 564 to which they belong.

593 Fig. 5. Ternary diagrams for the classification of biomass ash based on inorganic constituents: (a)
 594 Using $(\text{CaO}+\text{MgO}+\text{MnO})$, $(\text{K}_2\text{O}+\text{P}_2\text{O}_5+\text{SO}_3+\text{Cl}_2\text{O})$ and $(\text{SiO}_2+\text{Al}_2\text{O}_3+\text{Fe}_2\text{O}_3+\text{Na}_2\text{O}+\text{TiO}_2)$
 595 as the end members [36] and (b) using CaO , K_2O and SiO_2 as the end members. Note: The Mn
 596 concentration is rarely reported in the Phyllis2 database, so is assumed to be negligible when
 597 plotting (a). The main ternary diagrams plot the chemical composition of all the ash samples, while
 598 the smaller graphs contain interpolated heat maps showing the percentage of samples for each ash
 599 category within each compositional bin.
