Supporting Information

**ABSTRACT:** Polypeptoid-coated surfaces and many surface-grafted hydrophilic polymer brushes have been proven efficient in antifouling—the prevention of nonspecific biomolecular adsorption and cell attachment. Protein adsorption, in particular, is known to mediate subsequent cell-surface interactions. However, the detailed antifouling mechanism of polypeptoid and other polymer brush coatings at the molecular level is not well understood. Moreover, most adsorption studies focus only on measuring a single adsorbed mass value, and few techniques are capable of characterizing the hydrated *in situ* layer structure of either the antifouling coating or adsorbed proteins. In this study, interfacial assembly of polypeptoid brushes with different chain lengths has been investigated *in situ* using neutron reflection (NR). Consistent with past simulation results, NR revealed a common two-step structure for grafted polypeptoids consisting of a dense inner region that included a mussel adhesive-inspired oligopeptide for grafting polypeptoid chains and a highly hydrated upper region with very low polymer density (molecular brush). Protein adsorption was studied with human serum albumin (HSA) and fibrinogen (FIB), two common serum proteins of different sizes but similar isoelectric points (IEPs). In contrast to controls, we observed higher resistance by grafted polypeptoid against adsorption of the larger FIB, especially for longer chain lengths. Changing the pH to close to the IEPs of the proteins, which generally promotes adsorption, also did not significantly affect the antifouling effect against FIB, which was corroborated by atomic force microscopy imaging. Moreover, NR enabled characterization of the *in situ* hydrated layer structures of the polypeptoids together with proteins adsorbed under selected conditions. While adsorption on bare SiO<sub>2</sub> controls resulted in surface-induced protein denaturation, this was not observed on polypeptoids. Our current results therefore highlight the detailed *in situ* view that NR may provide for characterizing protein adsorption on polymer brushes as well as the excellent antifouling behavior of polypeptoids.

### INTRODUCTION

Protein adsorption onto solid substrates is a widespread phenomenon, and its prevention is critical for proper functioning of medical devices and implants, as well as in bioseparation and other applications involving surfaces prone to contamination.<sup>1–6</sup> The adsorption of proteins in these cases is largely of a nonspecific nature, and there is little control over the structure and composition of the adsorbed protein layer. When proteins from blood are adsorbed onto the surfaces of medical implants, the interfacial processes could undermine device integration at an early stage, trigger adverse cellular responses, and compromise the device's performance and fate. In the use of porous media (e.g., porous filtration membranes or packed columns), protein-surface interactions form an important basis for separation and purification and even the tuning of refoldable 3D structures. However, irreversibly adsorbed proteins not only reduce the flux but also pose the risk of cross-contamination. Therefore, techniques or materials that can effectively inhibit nonspecific protein adsorption have a variety of applications.

A number of factors affect the extent of protein adsorption or protein-substrate interactions.<sup>4,6–12</sup> These include protein

size, shape, stability, charge and charge distribution, concentration, pH, and ionic strength. Surface properties of the substrate material such as its chemical nature, hydrophobicity, charge, and charge density also play important roles. Electrostatic and hydrophobic interactions are major driving forces of protein adsorption on hydrophilic and hydrophobic surfaces, respectively.<sup>13</sup> High protein adsorption generally occurs on hydrophobic surfaces. On the other hand, a range of strategies related to surface wetting/hydrophobicity have been explored to minimize adsorption, including air-trapping superhydrophobic surfaces as well as highly hydrated zwitterionic surfaces.<sup>1,6</sup> Once adsorbed, further interactions between protein molecules and the interface, including dissociation and re-association of hydrogen bonding and

**Received:** July 30, 2020

**Revised:** September 24, 2020

**Published:** September 24, 2020

other intermolecular interactions, may result in protein structural deformation and possible unfolding.

Antifouling polymer brushes have been a main approach developed to reduce protein adsorption.<sup>3,5,6,14</sup> Polymers such as poly(vinyl chloride), poly(ethylene oxide), poly(etherurethane), poly(dimethylsiloxane), poly(*N*-isopropylacrylamide), and poly(tetrafluoroethylene) and their copolymers can provide different extents of protein resistance, but their hemo-compatibility is often poor.<sup>3,15</sup> Poly(ethylene glycol) (PEG) and related graft co-polymers have also been widely reported, although in some cases they may encounter chemical or enzymatic degradation.<sup>16</sup> In our previous studies, we have demonstrated that coatings with zwitterionic phosphorylcholine (PC) containing copolymers can substantially reduce protein adsorption.<sup>3,4</sup> We also reported antifouling brushes composed of peptoids, which mimic the polypeptide backbone.<sup>17–19</sup> However, overall, neither the solid-liquid interfacial structure of peptoid and other polymer brushes nor the physical state of residual proteins subsequently adsorbed has been well studied. Furthermore, most studies focus on short-term experiments demonstrating “zero” adsorption of novel systems, but fouling and subsequent protein-mediated interactions, nonetheless, occur in practical settings, not least around defects sites and as antifouling layers degrade over time.<sup>6</sup>

In this work, we report recent studies of *in situ* neutron reflection (NR) dedicated to improving this part of understanding. Specular NR is capable of quantitative determination of the thickness and uniformity of an interfacial layer with subnanometer sensitivity along the surface normal direction.<sup>7,9,11,20–24</sup> It effectively determines how the volume fraction ( $\phi$ ) of the layer varies with the distance perpendicular to the interface. The technique has been widely used in determining the interfacial layer structure of a variety of soft matters such as surfactants,<sup>25–30</sup> peptides,<sup>21,22,25,26,31,32</sup> proteins,<sup>33–37</sup> antibodies,<sup>2,38–43</sup> DNAs,<sup>44,45</sup> polymers,<sup>44</sup> and lipids.<sup>36,46</sup> As an example system, we employed a set of peptoid peptidomimetic polymers (PMPs) that we have previously demonstrated to prevent protein adsorption and cell attachment above certain chain length-dependent critical grafted chain densities.<sup>16,18,47</sup> PMPs form an excellent model brush system because of their exact chain lengths controlled by solid phase synthesis.<sup>18,48</sup>

From optical matrix analysis of NR reflectivity profiles, we were able to obtain polymer density height-profiles of grafted PMP layers. Focusing on intermediate PMP-grafted densities that allowed some protein adsorption, we likewise obtained adsorbed layer profiles of two model proteins with a similar isoelectric point (IEP)-human serum albumin (HSA, 67 kDa; IEP = 4.8) and the much larger fibrinogen (FIB, 340 kDa; IEP = 4.3). The NR technique enabled *in situ* measurements of proteins interacting with the underlying brush in a hydrated state, simulating native biological environments. We were therefore able to characterize the heterogeneous brush and adsorbed protein layer profiles that depended on both the protein, the experimental pH, as well as on the brush chain length, thus informing the future design of antifouling polymer brushes.

## RESULTS AND DISCUSSION

In this work, NR has been used to investigate protein adsorption on grafted PMPs at the solid-liquid interface, with the substrate being the SiO<sub>2</sub> surface on a silicon crystal block

and the solution being aqueous buffer containing the peptoid or protein (see the Supporting Information for NR chamber configuration). The PMP is a previously reported design containing two parts (Figure 1): a mussel adhesive-inspired

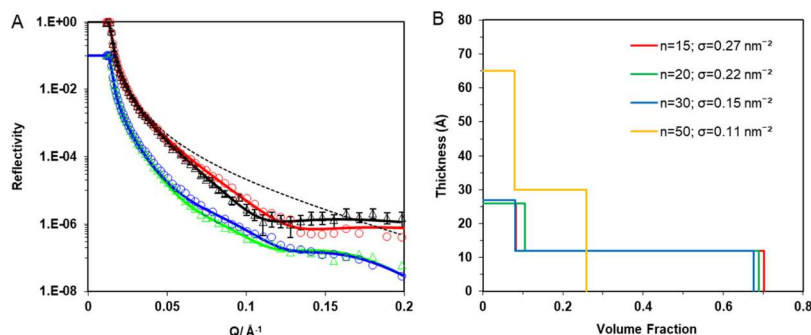

**Figure 1.** Chemical structure of PMPs (PMP<sub>*n*</sub>) where *n* = 15, 20, 30, and 50, with an antifouling polypeptoid segment and DOPA-Lys-DOPA-Lys-DOPA pentapeptide surface adhesion unit.

pentapeptide (DOPA-Lys-DOPA-Lys-DOPA) and a peptoid antifouling chain.<sup>17</sup> The short DOPA pentapeptide provides robust adhesion of the coupled peptoid chain to wet surfaces. DOPA has been used to couple a variety of molecules on diverse substrates without affecting the functionality of the immobilized molecule.<sup>49</sup> Therefore, we believe that DOPA will simply serve to immobilize PMP and not interfere with antifouling properties.

The chosen peptoid homopolymer (“polypeptoid”) has methoxyethyl side chains resembling the repeating unit of PEG.<sup>17,47</sup> We have previously shown that this overall PMP design is able to prevent protein adsorption as well as fibroblast and bacterial cell attachment above certain “critical” surface-grafted chain densities that range from 0.4 to 0.8 chain/nm<sup>2</sup> as the chain length decreases from 50 to 15 repeating units.<sup>16–18,47</sup> In this study, we focus on lower chain densities. This allowed us to observe some limited protein adsorption in order to facilitate investigation of the effects of chain length, protein size, and buffer pH, all of which are major variables controlling protein interactions with a polymer brush. We have previously used such a methodology to study differences in electrostatic interactions of various zwitterionic antifouling peptoid designs.<sup>18</sup> These subcritical densities also mimic situations inevitably encountered in practical applications, such as defect sites and long-term degradation of polymer brush surfaces.<sup>6</sup>

**PMP Grafting Analysis.** Typical NR data for grafting of polypeptoids 15, 20, 30, and 50-mer long are shown in Figure 2. Grafting of polypeptoids was evident from the deviation of reflectivity profiles from the reference measured at the bare SiO<sub>2</sub>/D<sub>2</sub>O interface control (Figure 2A). Reflectivity profiles were analyzed using the widely adopted optical matrix approach.<sup>50</sup> Analysis was pursued by first calculating a reflectivity profile based on an assumed interfacial structure and then comparing it with the measured one. The process was iterated until an acceptable fit was obtained within the experimentally sensitive *Q* range of 0.012–0.25 Å<sup>−1</sup>. The parameters obtained from optical matrix data analysis are listed in Table 1, and the molecular weights and the scattering length densities (SLDs) obtained from NR fitting are summarized in Table S1.

The fitting to the bare SiO<sub>2</sub>/D<sub>2</sub>O interface led to the native oxide layer thickness of 13 Å and its SLD of 3.4 × 10<sup>−6</sup> Å<sup>−2</sup>. Because the SLD for this layer was the same as commonly accepted values of solid bulk SiO<sub>2</sub>, the result indicated a void-free and smooth SiO<sub>2</sub> substrate surface. Subsequent analysis of polypeptoid grafting was undertaken by assuming that the

**Figure 2.** (A) Representative plots of NR profiles of PMPs at the interface of the SiO<sub>2</sub> surface and D<sub>2</sub>O buffer (20 mM phosphate, pH 7). Data after 1 h immersion of PMP<sub>15</sub> (black and red) and PMP<sub>50</sub> solutions (green and blue), both at 0.1 mM before (Δ) and after buffer wash (○) are shown. The solid lines are the best fits to the measured data. The dashed line is the bare SiO<sub>2</sub>/D<sub>2</sub>O reference. For clarity, PMP<sub>50</sub> data have been shifted down 1 order of magnitude along the vertical axis, and error bars are only shown in one set of data. The thickness of SiO<sub>2</sub> was found to be 13 ± 1 Å. Parameters obtained by the data fitting are shown in Table 1. (B) Two-step polymer volume density plots as a function of height from the SiO<sub>2</sub> surface measured for PMP<sub>n</sub> (*n* = 15, 20, 30, and 50). The corresponding chain densities (*σ*) are shown in the legend.

structure of the SiO<sub>2</sub> layer remained unchanged during the course of the experiments.

Grafting of PMP<sub>n</sub> (*n* = 15, 20, 30, and 50) was undertaken by flowing polypeptoid solutions through the NR sample chamber over the SiO<sub>2</sub> substrate. The attached amount of PMP did not vary much against concentration within the concentration range studied (from 0.03 to 0.3 mM, after 1 h immersion). The results shown in Figure 2 and throughout this report are all based on brushes obtained at 0.1 mM.

Data analysis revealed that the distribution of grafted PMP chains of all chain lengths can be fitted to a common two-step model differing in polymer density (Figure 2B). The inner slice close to the SiO<sub>2</sub> surface had thicknesses ( $\tau$ ) of 16–30 Å with corresponding SLD of 3.4–5.2 × 10<sup>-6</sup> Å<sup>-2</sup>, while the second upper slice had thicknesses of 18–35 Å and SLD of 6 × 10<sup>-6</sup> Å<sup>-2</sup>. The large difference in SLD is indicative of the different amount of polypeptoid chains in each slice (discussed further below). The two-step model is an approximation, limited by the amount of information obtainable from NR, of the smoothly increasing density of polymer chains toward the substrate surface, as anticipated by both theoretical<sup>47</sup> and simulation studies.<sup>51</sup>

The volume fraction ( $\phi$ ) of polypeptoid in each slice, the area per molecule (*A* in Å<sup>2</sup>), and the surface adsorbed amount

( $\Gamma$ , in mg m<sup>-2</sup>) can be calculated from the following equations<sup>9,11,21</sup>

$$\phi_p = \frac{\rho - \rho_w}{\rho_p - \rho_w} \quad (1)$$

where  $\rho$ ,  $\rho_p$ , and  $\rho_w$  are the SLDs for the slice/layer, polypeptoid, and water, respectively. The labile hydrogens in the polypeptoids were assumed to be fully exchangeable with the D<sub>2</sub>O solvent. The equivalent area per molecule of each overall layer can be expressed as

$$A = \frac{V_p}{\tau \phi_p} \quad (2)$$

where  $V_p$  is the volume of the polypeptoid and  $\tau$  is the thickness of the layer. The surface chain density ( $\sigma$ ) is simply the inverse of *A*. The surface adsorbed amount ( $\Gamma$ ) can be obtained from

$$\Gamma = \frac{MW}{6.02A} \quad (3)$$

where MW is the molecular weight of the polypeptoid (Table S1). Note that the total surface adsorbed amount could be obtained from adding the contributions from each slice from

which a nominal area per molecule for the entire layer can be worked out from eq 3.

The nature of the NR experiment suited our goal of obtaining intermediate surface chain densities ( $\sigma$ ). For example, we obtained  $\sigma = 0.27 \text{ nm}^{-2}$  for PMP<sub>15</sub> binding on SiO<sub>2</sub> at room temperature, compared to  $0.68 \text{ nm}^{-2}$  on a TiO<sub>2</sub> surface under near cloud point/lower critical solution temperature conditions (50 °C).<sup>47</sup> Lower grafted densities are generally obtained when grafting longer chains, and we obtained  $\sigma = 0.22$ ,  $0.15$ , and  $0.11 \text{ chain nm}^{-2}$  for PMP<sub>20</sub>, PMP<sub>30</sub>, and PMP<sub>50</sub>, respectively (Figure 2B).

By comparing (Table 1) the amounts of polypeptoid bound to the surface before and after replacing the PMP solution with buffer (i.e., rinsing), we could gauge the strength of the DOPA pentapeptide for grafting polypeptoid chains. For the shortest PMP<sub>15</sub> before buffer rinsing, the total thickness of the two-step layer was 36 Å, and  $A = 284 \text{ Å}^2$  and  $\Gamma_{\text{PMP}} = 1.51 \text{ mg m}^{-2}$ . After rinsing, the total thickness was reduced to 28 Å, and  $A = 377 \text{ Å}^2$  and  $\Gamma_{\text{PMP}} = 1.14 \text{ mg m}^{-2}$  (i.e., ca. 75% retention). For the longer polypeptoids, much higher PMP retentions were observed after rinsing, for example, for PMP<sub>50</sub>,  $\Gamma_{\text{PMP}}$  decreased from 1.32 to  $1.17 \text{ nm}^{-2}$  (i.e., ca. 90% retention), while  $A$  increased slightly from 835 to  $942 \text{ Å}^2$ , and the total layer thickness remained at 65 Å. These results showed that PMP grafting was stronger and predominantly irreversible when each DOPA pentapeptide (together with its polypeptoid) had more space to interact with the SiO<sub>2</sub> surface.

The two-step interfacial structures after rinsing found for PMP<sub>20</sub> and PMP<sub>30</sub> were similar to PMP<sub>15</sub>, with essentially the same polymer density/volume fraction in each slice.  $\phi_{\text{PMP-lower}}$  was consistently around 0.7, and  $\phi_{\text{PMP-upper}}$  was around 0.1 (Figure 2B). While the overall layer thickness remained ca. 26 Å and volume fraction stayed constant, the fact that the chain length was increasing contributed to the decreasing grafted chain density (Table 1). With a further increase in the chain length to PMP<sub>50</sub>, the overall brush layer became thicker, and the lower chain density measured had to be matched by corresponding decreases in  $\phi_p$ , presumably due to the steric effect of the long chain. Overall, these differences demonstrate the extension of PMP chains in a brush, consistent with past ellipsometry measurements and molecular theory.<sup>16,47</sup> On the other hand, the current NR studies provide better depth resolution and can therefore provide more consistent structural details about changes in the shape of the layer distribution along the surface normal and the total adsorbed amount.

For comparison, binding of the DOPA pentapeptide alone as a function of concentration has also been examined, with the results shown in Figure 3 and the best fit parameters listed in Table 2. At the 0.1 mM concentration used for PMP grafting, the surface bound pentapeptide layer could be described as a single uniform slab of 10 Å, with  $\phi_{\text{peptide}} = 0.776$  and  $\Gamma = 1.19 \text{ mg m}^{-2}$ , respectively. These parameters match very well with those of the lower slice of PMPs, especially for PMP<sub>15</sub> to PMP<sub>30</sub> (Figure 2B). This supports the two-step PMP model discussed above for which the high polymer density of the inner slice consisted mostly of the DOPA pentapeptide and the low-density outer slice consisted of polypeptoids extending away from the surface, as would be expected of a surface-grafted brush. The value of  $\phi_{\text{peptide}}$  and the thickness of the anchoring slice are also consistent with our earlier simulation results.<sup>47</sup>

At a high DOPA pentapeptide concentration of 1 mM, the peptide formed a two-step distribution with thicknesses around

**Figure 3.** NR profiles at the SiO<sub>2</sub>/D<sub>2</sub>O buffer interface with DOPA-Lys-DOPA-Lys-DOPA at the concentration of 1 mM ( $\Delta$ , red), 0.1 mM ( $\square$ , black), and 0.01 mM ( $\circ$ , blue) (20 mM phosphate buffer in D<sub>2</sub>O, pH 7). The solid lines are the best fits to the measured data. Error bars are only shown for one set of data for clarity. The NR profile at the bare SiO<sub>2</sub>/D<sub>2</sub>O interface is shown as reference (dashed line) with the oxide layer thickness of  $13 \pm 1 \text{ Å}$ . Parameters obtained from data fitting are shown in Table 2.

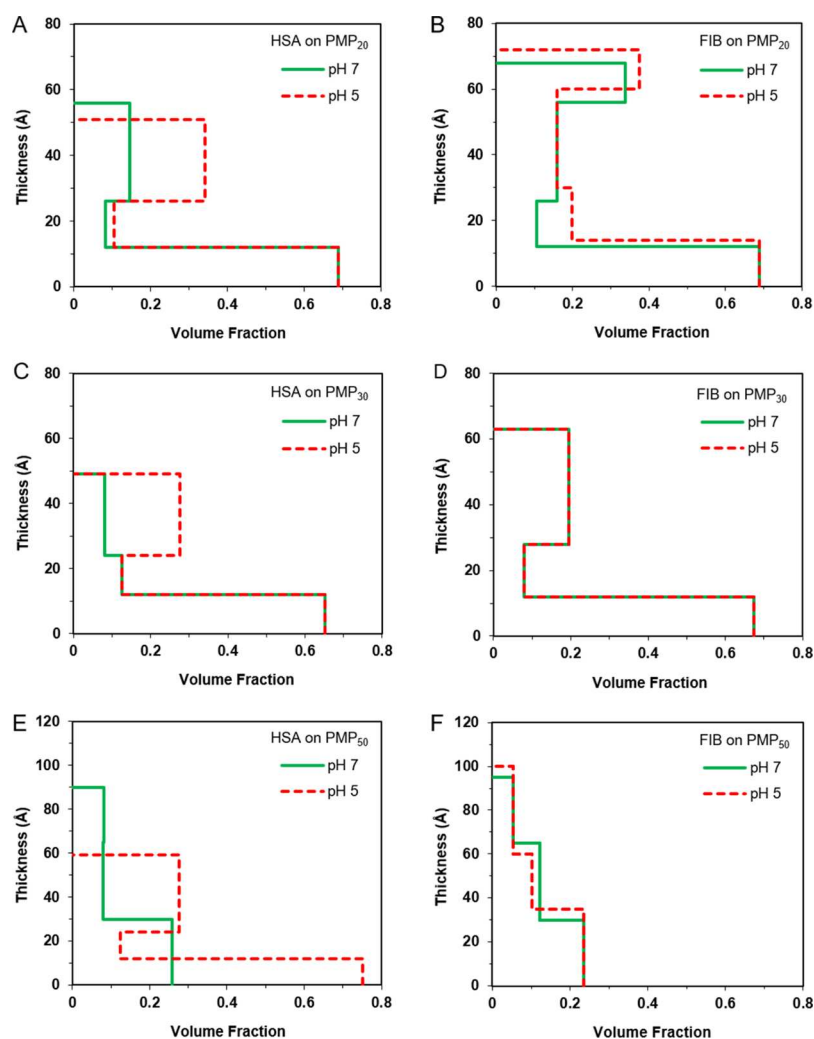

10 Å each and a high total adsorbed amount of  $2.7 \text{ mg m}^{-2}$ . The inner slice was more densely packed ( $\phi_{\text{peptide}} = 0.941$ ) than the single layer obtained from the 0.1 mM solution above. In contrast, the outer slice was about half packed ( $\phi_{\text{peptide}} = 0.446$ ), indicating that some residues were “sticking up” as there was insufficient space to pack the large amount of pentapeptides available. Reduction of the pentapeptide concentration to 0.01 mM resulted in a layer thickness of only 7 Å and  $\Gamma = 0.83 \text{ mg m}^{-2}$ . Interestingly, however,  $\phi_{\text{peptide}}$  remained at 0.776, the same as for binding from 0.1 mM. Overall, given the relatively small three-fold difference in  $\Gamma$  as the concentration changed 100-fold from 1 to 0.01 mM, the propensity for the DOPA pentapeptide binding on SiO<sub>2</sub> was strong.

**Protein Adsorption on Bare SiO<sub>2</sub>.** HSA and FIB were used as model proteins to examine the antifouling effects of the polypeptoid brush surfaces. HSA is widely used in such studies and is a 67 kDa globular protein. Its longest length is around 80 Å, and its shortest length is around 45 Å.<sup>52</sup> Because it comprises several different domains and has large structural flexibility, it tends to deform rather easily upon interfacial adsorption.<sup>20</sup> HSA has an IEP of around 4.8, and its concentration in plasma is about  $50 \text{ g L}^{-1}$ . Human plasma FIB has a concentration of 1.5 to  $4.0 \text{ g L}^{-1}$  in human plasma, and it polymerizes to form fibrin during blood coagulation. It is significantly larger with a molecular weight of about 340 kDa and has dimensions ca.  $470 \times 50 \times 50 \text{ Å}^3$ .<sup>53</sup> Its IEP is around 4.3, close to that of HSA. The similarity in IEP, which specifies the protein’s net charge at a given pH, and hence the long range (ca. >10 nm) of electrostatic intermolecular interactions, is the main reason for choosing HSA and FIB, even though FIB is glycosylated which would also affect its adsorption behavior.

As controls, the adsorption of HSA and FIB at the bare SiO<sub>2</sub>/D<sub>2</sub>O buffer interface has been examined and the data are shown in Figure S1, with the best fit parameters listed in Table S2. The adsorption of HSA at the concentration of  $1 \text{ g L}^{-1}$  and pH 7 resulted in a single-layer structure at the interface. The thickness, volume fraction ( $\phi_{\text{HSA}}$ ), area per molecule ( $A$ ), and surface adsorbed amount ( $\Gamma_{\text{HSA}}$ ) were found to be 30 Å, 0.276,  $9600 \text{ Å}^2$ , and  $1.15 \text{ mg m}^{-2}$ , respectively.

**Table 2.** Best Fit Parameters for DOPA-Lys-DOPA-Lys-DOPA Obtained from Analysis of the Reflectivity Profiles Shown in Figure 3

concentration	$\tau \pm 1$ (Å)	$(\rho \pm 0.05) \times 10^{-6}$ (Å <sup>-2</sup> )	$\phi_p$	A (Å <sup>2</sup> )	$\Gamma$ (mg m <sup>-2</sup> )
1 mM	14	3.5	0.941	53.3	2.70
	10	5.0	0.446		
0.1 mM	10	4.0	0.776	121	1.19
0.01 mM	7	4.0	0.776	173	0.83

**Figure 4.** Layer thicknesses plots against material volume fraction after 1 h incubation in protein solutions at pH 7 (green) and pH 5 (red). Data for PMP<sub>20</sub> (A,B), PMP<sub>30</sub> (C,D) and PMP<sub>50</sub> interfaces (E,F) are sorted by rows. HSA experimental results are shown on the left (A,C,E) and FIB results on the right (B,D,F). The corresponding NR profiles are shown in Figure S2, and the parameters obtained by data analysis are listed in Tables S3 and S4. 1 g L<sup>-1</sup> HSA and 0.15 g L<sup>-1</sup> FIB in 20 mM phosphate buffered D<sub>2</sub>O were used.

Adsorption generally increases near a protein's IEP since proteins of the same species can pack more closely on a surface as charge repulsion is eliminated.<sup>54</sup> Accordingly, decreasing pH to 5 resulted in an increased amount of adsorbed HSA (IEP = 4.8) that has a mass distribution best fit with a two-step model of 60 Å thickness. Each modeled slice was 30 Å, with the inner surface slice having a higher  $\phi_{\text{HSA-inner}}$  of 0.503 and the outer slice having only  $\phi_{\text{HSA-outer}} = 0.179$ . This height distribution is consistent with HSA molecules spreading on the SiO<sub>2</sub> surface, presumably to increase total protein–surface interactions (i.e., surface-induced denaturation). The surface coverage (equivalent to  $\phi_{\text{HSA-inner}}$ ) is also close to the maximum possible for random adsorption (i.e., “jamming limit” = 0.547 for roughly globular proteins).<sup>55</sup> Correspondingly, the total  $\Gamma_{\text{HSA}}$  increased

from 1.15 mg m<sup>-2</sup> at pH 7 to 2.84 mg m<sup>-2</sup> at pH 5. These structural features are consistent with previous studies.<sup>10,11,20</sup>

In parallel, FIB adsorption from a solution of 0.15 g L<sup>-1</sup> at pH 7 has also been examined. A two-step model indicating protein spreading was already required to fit the data for this larger protein far above its IEP of 4.3. Similar to HSA, the total thickness was found to be 60 Å and each slice was again 30 Å thick, with the inner slice being denser ( $\phi_{\text{FIB-inner}}$  and  $\phi_{\text{FIB-outer}}$  were 0.374 and 0.125, respectively). The total adsorption ( $\Gamma_{\text{FIB}}$ ) was 2.4 mg m<sup>-2</sup>.

**Protein Adsorption on PMPs.** Further experiments were carried out to investigate the antifouling properties of the PMP brush surfaces. The intermediate grafting densities grafted (Table 1) are at roughly half the critical densities<sup>18,47</sup> required

**Figure 5.** AFM images of PMP<sub>30</sub> (0.1 mM and pH 7) grafted on silica substrates (A) and followed by FIB (0.15 g L<sup>-1</sup>, pH 5) adsorption (B).

to essentially eliminate adsorption. This enabled measurable protein adsorption in order to study the effects of chain length, protein size, buffer pH on protein-brush interactions and mimicked practical situation such as defect sites and long-term degradation. Strong chain length-dependent effects were already observed for PMP<sub>20</sub>, PMP<sub>30</sub>, and PMP<sub>50</sub>, and we focus on data from these three chain lengths below.

Figure 4 shows the adsorbed mass density profiles obtained after HSA (1 g L<sup>-1</sup>) and FIB solutions (0.15 g L<sup>-1</sup>) in D<sub>2</sub>O phosphate buffer were incubated over the PMP interface. Measurements were taken after incubation in protein solutions at neutral pH 7 for 1 h and then at pH 5 for another 1 h. The corresponding NR profiles are shown in Figure S2, and the best fit parameters are listed in Tables S3 and S4. The fitting analysis assumes that the underlying two-step distributions of the PMP chains shown in Figure 2B were preserved, but the thickness and density of each slice in the model were allowed to vary. Adsorbed proteins were modeled by either a single layer or two-step model as required for consistency with the NR data.

HSA incubation at pH 7 on PMP<sub>20</sub> (Figure 4A) at the chain density chosen (0.22 nm<sup>-2</sup>) led to the formation of a single overlayer of adsorbed mass with a thickness of 30 Å but a relatively low protein volume fraction ( $\phi_{\text{HSA}}$ ) of only 0.146, giving the adsorbed amount of  $\Gamma_{\text{HSA}} = 0.61 \text{ mg m}^{-2}$  (Table S3). Compared to incubation at the corresponding pH on bare SiO<sub>2</sub>/D<sub>2</sub>O (Table S2), half of the adsorption was prevented. The single-step HSA model, in contrast to the two-step protein layer model required to describe adsorption on the SiO<sub>2</sub> control, also indicated the ability of PMP<sub>20</sub> to limit surface-induced denaturation. Moreover, no changes to the PMP<sub>20</sub> two-step layer structure was required to fit the data after protein adsorption—the HSA appeared to simply be associated with the top of the brush layer and not penetrating it.

As the chain length increased, the antifouling effect increased significantly, as expected from theories of brush behavior.<sup>14,47</sup> At the PMP<sub>30</sub> interface, HSA adsorption at pH 7 reduced to  $\Gamma_{\text{HSA}} = 0.28 \text{ mg m}^{-2}$  and it could be described by a single layer with an effective thickness of 25 Å and an even lower  $\phi_{\text{HSA}}$  of 0.081 (Figure 4C), meaning that adsorption decreased by half compared to the PMP<sub>20</sub> interface. Again, no changes to the PMP two-step layer structure was observed.

Reducing pH to 5 near HSA's IEP (4.8) increased adsorption, as expected. On PMP<sub>20</sub>,  $\Gamma_{\text{HSA}}$  was 1.18 mg m<sup>-2</sup> (Figure 4A). The amount adsorbed was now similar to that on the SiO<sub>2</sub> control, but a single step protein layer was sufficient to describe the data (i.e., no apparent protein spreading). The increased  $\Gamma_{\text{HSA}}$  meant that a denser HSA layer was formed ( $\phi_{\text{HSA}} = 0.341$ ), and it was also slightly thinner than the one at pH 7. Some protein structural deformation is implied by a fitted protein layer thickness (25 Å) that is much only around

half of the shortest side of HSA (ca. 45 Å). On the other hand, still no changes to the two-step PMP<sub>20</sub> layer structure was required to describe the data.

With the slightly longer PMP<sub>30</sub>, no compression of the protein layer was observed with a decrease to pH 5, although the amount of adsorption ( $\Gamma = 0.96 \text{ mg m}^{-2}$  and  $\phi_{\text{HSA}} = 0.276$ ) was still higher than that at pH 7 (Figure 4C). However, with further increase in the chain length to PMP<sub>50</sub> (accompanied by the lowest grafting density), an increased adsorption at pH 5 ( $\Gamma_{\text{HSA}} = 1.34 \text{ mg m}^{-2}$ ; thickness = 35 Å) caused a significant compression of the brush layer (Figure 4E). Our fitting still produced a single-step protein layer, but the PMP<sub>50</sub> model showed a decreased inner slice height from 30 to 12 Å and an increased  $\phi_{\text{PMP-inner}}$  from 0.258 to 0.751, while the upper “brush” slice also decreased in height from 35 to 12 Å and  $\phi_{\text{PMP-outer}}$  increased from 0.079 to 0.123. This indicated a large redistribution of PMP<sub>50</sub> chains down to the surface.

Analogous experiments were carried out using the much larger protein FIB (ca. 50 × 50 × 470 Å<sup>3</sup>). As with HSA, lower adsorption was observed on PMPs than on the bare SiO<sub>2</sub> control, and the amount adsorbed at pH 7 decreased with increasing brush length (Figure 4B,D,F). For example, the highest adsorption at pH 7 on the shortest PMP<sub>20</sub> chain length was  $\Gamma_{\text{FIB}} = 1.27 \text{ mg m}^{-2}$  (Table S4), significantly lower than that on SiO<sub>2</sub> (2.4 mg m<sup>-2</sup>; Table S2). Moreover, the two-step PMP layer structures were also preserved for all chain lengths after adsorption.

In contrast to the HSA results, only minor increases in FIB adsorption accompanied a reduction in the pH from 7 to 5 (closer to FIB's IEP = 4.3). For example, the adsorbed amount on PMP<sub>20</sub> at pH 5 was  $\Gamma_{\text{FIB}} = 1.33 \text{ mg m}^{-2}$  (Table S3), a 5% increase from pH 7. Moreover, a “reversed” two-step protein layer model with a less dense lower slice adjacent to the top of the polypeptoid was required to describe the FIBs adsorbed at pH 7 (Figure 4B and Table S4)— $\phi_{\text{FIB-lower}} = 0.16$  in the lower 30 Å thick slice and  $\phi_{\text{FIB-upper}} = 0.338$  in the thinner but denser 12 Å upper slice. Obviously, NR layer profiles are approximate descriptions of surface bound layers. Nonetheless, unlike FIB adsorbed on bare SiO<sub>2</sub> (Table S2), the fact that the center of mass of adsorbed FIB was oriented away from the surface indicated that FIB did not spread on the PMP<sub>20</sub> brush. The total protein layer thickness of 42 Å was similar to the short axis of FIB, indicating that FIB adsorbed sideways, consistent with atomic force microscopy (AFM) imaging.<sup>47</sup>

FIB adsorption became much reduced as the chain length increased, and a single-step model was sufficient to describe the protein adsorption. At the PMP<sub>30</sub> interface (Figure 4D), an identical single-step 35 Å thick FIB layer ( $\phi_{\text{FIB}} = 0.196$  and  $\Gamma_{\text{FIB}} = 0.98 \text{ mg m}^{-2}$ ) could describe the adsorption at both pH 5 and 7 (Table S4). For PMP<sub>50</sub>, single-step FIB layers of  $\phi_{\text{FIB}} =$

0.053 and 30 to 40 Å thickness were observed (Figure 4F, Table S4).

AFM was also used to corroborate the (lack of) morphological changes with FIB adsorption on polypeptoid-coated Si/SiO<sub>2</sub> wafers. Examples of PMP<sub>30</sub> (0.1 mM and pH 7) adsorbed onto an SiO<sub>2</sub> substrate (bare Si wafer) before and after FIB adsorption are shown in Figure 5. The surface of our wafers is extremely smooth with root mean square roughness under 0.5 nm. Grafting of PMP<sub>30</sub> preserved the overall flat surface, illustrating also the uniformity of the coating. Upon FIB incubation, the roughness increased by only a small amount and no clear features of assembled/aggregated structures were apparent, consistent with the relatively small amount of FIB adsorption measured by NR (Figure 4D) and the significant antifouling effect of the PMP<sub>30</sub> coating.

Figure 6 summarizes the effects of the polypeptoids with different chain lengths. FIB adsorption at both pH 7 and 5

**Figure 6.** Summary of the antifouling effect of the PMP<sub>n</sub> series of polypeptoids. Surface adsorbed amount of HSA and FIB on the silica surface (HSA/SiO<sub>2</sub> and FIB/SiO<sub>2</sub>) as controls and on the preadsorbed polypeptoids surface at pH 7 and 5.

decreased with the chain length.  $\Gamma_{\text{FIB}}$  on PMP<sub>50</sub> was roughly 3- and 4-folds lower than that on PMP<sub>30</sub> and PMP<sub>20</sub>, respectively. Moreover, FIB adsorption on bare SiO<sub>2</sub>, at 2.4 mg m<sup>-2</sup> at pH 7 (Figure 6 and Table S2) and >4 mg m<sup>-2</sup> at pH 5,<sup>56</sup> was considerably higher than that on all PMP surfaces. Thus, PMP interfaces were able to suppress FIB adsorption by 10–20 folds over the control even when the grafting densities were only around half of the “critical” values for preventing protein adsorption.

On the other hand, for HSA,  $\Gamma_{\text{HSA}}$  on PMP<sub>50</sub> was reduced only by half at pH 7 when compared to the shortest PMP<sub>20</sub>, and adsorption actually increased slightly at pH 5. In comparison, HSA adsorption on the bare SiO<sub>2</sub> control was 1.15 mg m<sup>-2</sup> at pH 7 and 2.84 mg m<sup>-2</sup> at pH 5 (Figure 6 and Table S2), which means that the current grafting densities only reduced adsorption of the smaller HSA by 3–4 folds.

The present results therefore emphasize that the superior antifouling performance of a longer brush (e.g. PMP<sub>50</sub> vs PMP<sub>20</sub>) is maintained for a protein that can be considered to be large relative to the spacing between grafted chains (at least in one dimension), even when the brush density is reduced. The large size of FIB also apparently rendered adsorption relatively insensitive to the effect of pH (i.e., electrostatic interactions). In contrast, resistance against adsorption of a smaller protein (e.g. HSA) was more readily compromised, especially for longer brushes which are more difficult to graft at higher surface densities. In particular, brush compression due to HSA adsorption was obvious on the least densely grafted

PMP<sub>50</sub> when the driving force for adsorption was high(er) (at pH 5-Figure 4E). Incidentally, the effectiveness of the present subcritical PMP<sub>50</sub> surfaces is comparable to some PC polymer-coated surfaces.

## CONCLUSIONS

NR has enabled direct, *in situ* measurements of PMP polypeptoid layers, showing that they consisted of an inner dense region comprising adhesive DOPA pentapeptide and a sparse, highly hydrated, upper polymer brush region with a low volume fraction for all chain lengths and grafting densities studied. Buffer rinsing led to little removal of the bound polypeptoid, demonstrating a strong irreversibility in the surface interaction of the DOPA pentapeptide anchor on SiO<sub>2</sub>, especially when the pentapeptide segment had sufficient space at lower grafting densities to spread on the surface.

NR also characterized in detail the PMP layer distributions and antifouling performances of the grafted PMPs. While our previous studies have already shown that PMP brushes could essentially eliminate protein adsorption at sufficiently high surface grafting densities,<sup>47</sup> we focused on lower PMP densities in the present experiments. This helped differentiate the effects of chain length, protein size, and environmental pH on adsorption and simulated practical antifouling challenges such as surface defects and brush degradation.

We found that polypeptoid surfaces were in fact more effective at reducing the adsorption of larger elongated FIB versus the smaller globular HSA, especially for longer chain lengths. This is similar to observations on zwitterionic PC-incorporated surfaces but different from classic model surfaces like flat SiO<sub>2</sub> and self-assembled monolayers such as octyldecyltrimethoxysilane (OTS) that obey the Vroman effect (higher affinity for larger proteins).<sup>57,58</sup> We also found that at a pH close to the protein's IEP, the resistance against adsorption of HSA decreased but it had little effect on adsorption of the larger FIB. Moreover, there was no indication of surface-induced denaturation on PMPs, which stands in contrast to the spreading and redistribution of protein mass toward the surface that we measured on the bare SiO<sub>2</sub> control (as well as generally observed on hydrophobic surfaces like OTS).

The contrast in antifouling behavior for PMPs compared to classic model surfaces indicates their strong repellent surface effect similar to observation on zwitterionic PC. However, our PMP is uncharged. AFM also revealed no structural feature characteristic of protein aggregation on PMPs, consistent with NR measurements. Although we show results for PMP only on SiO<sub>2</sub> (and previously on TiO<sub>2</sub>),<sup>17,47,59</sup> excellent antifouling properties on various substrates have been demonstrated for polysarcosine,<sup>60–62</sup> a closely related antifouling peptoid, that we first reported with almost identical antifouling properties as PMP.<sup>63</sup> Therefore, peptoid coatings like PMP are very promising in applications such as preventing fouling on biomedical implants. In fact, our NR results also provide direct evidence of the extent to which a protein layer with relatively high adsorbed volume fraction (up to 0.3–0.7) can be supported on top of an underlying brush barrier layer with a much lower polymer fraction (<0.1) composed of mostly water. Even at the current subcritical brush densities, it appears that the adsorbed proteins were mostly interacting with the top of the PMP brushes, which suggests an opportunity to further improve antifouling if attractive protein–polymer interactions could be further reduced.
