Abstract

rGO-Fe₃O₄ nano-sized composites containing various concentrations of rGO (reduced Graphene Oxides) were synthesized by the hydrothermal method. rGO nanosheet provides a solid framework for Fe₃O₄, improving the overall conductivity as well as reducing agglomeration of Fe₃O₄ nanoparticles. rGO-Fe₃O₄ exhibits a specific surface area of 207.2 m² g⁻¹ with a total pore volume of 0.203 cm³ g⁻¹. Fabricated into electrode, rGO-Fe₃O₄ demonstrates a specific capacitance of 182.2 F·g⁻¹ at a current density of 1.25 A·g⁻¹ with a retention rate maintaining at 92.4% after 1000 cycles. Material degradation of the electrode inevitably changes the solid electrolyte interface (SEI) and causes capacitance loss during long-cycle tests. In this regard, advanced surface analysis techniques were applied to better understand the degradation mechanism and reveal possible reactions occurring at the electrode interface after various cycling stages. Strategically, Iron molybdate (FeMoO₄) has been added as an electrolyte additive in the experiment where molybdenum disulfide (MoS₂) formed on the electrode surface and remarkably rejuvenated the capacity with maximum values rising to 186.6 F·g⁻¹, 171.8 F·g⁻¹ and 153.4 F·g⁻¹ at the current densities of 1.25 A·g⁻¹, 2.50 A·g⁻¹ and 3.75 A·g⁻¹ respectively. The notable recovery of capacitance achieved by adding FeMoO₄ provides a practical method in solving the problem of material degradation and rejuvenating rGO-Fe₃O₄ electrode performance in Na₂SO₃-based electrolyte.

Keywords: rGO-Fe₃O₄, degradation mechanism, supercapacitor, interface

Introduction

As high-performance energy storage devices, supercapacitors have both fast charge-discharge characteristics and battery energy storage characteristics. They are a promising chemical power source and belong to the emerging class of power compensation and energy storage devices. Compared with conventional capacitors, the advantages of supercapacitors mainly include high power density, low cost, long cycle life, and high recyclability [1-3]. Supercapacitors have significant advantages in fast electronic transmission, promoting them widely used in electric vehicles, renewable energy power generation systems, rail transportations and aerospace applications.

Transition metal oxide (TMOs) such as NiO, Co₃O₄, and TiO₂ have shown remarkable capability in electrochemical performance and electric capacitance [4-6]. In addition, TMO nano-structured compounds combined with graphene, carbon nanotubes, fullerenes have attracted attention in the field of energy storage [7-9]. Among them, nanosized magnetite (Fe₃O₄) exhibits potentially attractive properties in applications such as high-efficiency energy storage devices and supercapacitors with high specific capacitance. In order to solve the problem of the low conductivity and the agglomeration of Fe₃O₄ nanoparticles strategically, carbon-based materials (such as graphene) are commonly used to improve the electrochemical properties of Fe₃O₄ electrode in an aqueous environment due to the low dynamic viscosity of aqueous electrolytes [10-13]. The rGO-Fe₃O₄ composites prepared by Jianling [14] can reach a high specific capacity of 1065 mAh·g⁻¹ at a current density of 0.1 A·g⁻¹. The prepared rGO-Fe₃O₄ carbon (AC) lithium-ion capacitor has an excellent energy density of 98.8 Wh·kg⁻¹ and a power density of 3.4 kW·kg⁻¹. However, it retained 78.9% after 1000 charge/discharge cycles; the degradation mechanism causing this large performance drop is unclear.

Understanding the degradation mechanism of the electrode and inhibiting material degradation is particularly challenging. Krzysztof [15] described the degradation mechanisms at the interface between the carbon-Li₂SO₄/LiNO₃ electrolytes using Raman spectroscopy. In their system, material degradation was caused by the oxidation of the carbon surface or reduction of the negative ions. Masahiro [16] studied the aging characteristics of carbon electrodes and the results showed that the Faradaic process on the negative electrode is the main cause of the decrease of capacitance. Muhammad [17] demonstrated the successful surface engineering of polyaniline coated iron oxide nanoparticles (Fe₃O₄/PANI-NPs), with PANI coating preventing degradation of the material as well as improving the capacitance stability from 92% to 96.5% at current density of 15 A g⁻¹ after 25,000 charge-discharge cycles. Abbas [18] demonstrated that the MoO₄²⁻ anion improved the total capacitance and inhibited corrosion based on the Faradaic process, and Na₂MoO₄ has been considered as the additive in a 1 mol·L⁻¹ lithium sulfate electrolyte. Chodankar [19] applied redox-active electrolytes to multi-wall Carbon nanotubes/manganese dioxide (MWCNTs/MnO₂) and achieved a significant improvement in electrochemical performance in a redox-induced Na₂SO₄ electrolyte, with a maximum specific capacitance of 1012 F·g⁻¹ at the current density of 2 mA·cm⁻². Mingyuan [20] improved the capacitance of an activated carbon electrode from 147.1 F·g⁻¹ to 229.2 F·g⁻¹ (1A·g⁻¹) by adding 0.1 M K₃Fe(CN)₆ in 2M KOH electrolyte. Although there are many published studies considering the electrochemical performance and application prospects of Fe₃O₄ related composites in supercapacitor, none of them have revealed the fundamental degradation mechanism of Fe₃O₄ electrode. Therefore, it is of great significance to understand the material deterioration occurs on the Fe₃O₄ electrode surface scientifically.

In this work, Fe₃O₄ nanoparticles (Fe₃O₄ NPs) were successfully grown on the graphene nanoplate via a simple hydrothermal route, which created a large specific surface area. However, capacity deterioration was found over long-term charge/discharge processes. Therefore, this work has two goals; firstly, to reveal the material deterioration mechanism of the rGO-Fe₃O₄ composites as a candidate supercapacitor over long-term charge/discharge processes. Secondly, to improve the capacitance by introducing iron (II) molybdate (FeMoO₄) as an additive. This work correlated the electrochemical measurements, specific capacities, and long-term stability with the detailed surface morphology changes. Furthermore, the introduced FeMoO₄ as an additive has rejuvenated the specific capacitance, simultaneously providing a feasible solution to mitigate capacity loss and extend the service life of supercapacitors.

Materials and methods

Material preparation

Iron (III) chloride hexahydrate ($\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$) was purchased from VWR Chemicals (USA). Sodium acetate (NaAc), sodium dodecyl sulfate (SDS), polyethylene glycol (PEG) and FeMoO_4 were purchased from Sigma-Aldrich, Ethylene glycol (EG) was purchased from Fisher Scientific (UK). Sodium sulfite was bought from Alfa Aesar and graphene nanoplates were purchased from SUZHOU TANFENG GRAPHENE TECHNOLOGY Co., Ltd. All the chemicals were used as received without further purification.

Synthesis of Fe_3O_4 NPs

Fe_3O_4 NPs were synthesized by the hydrothermal method [21-22]. 2.7g $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ was dissolved in a 100ml ethylene glycol and put on a hotplate with magnetic stirring for 25 minutes. Then 7.2 g NaAc and 2.0 g of SDS were slowly added into the solution for another stirring of 15 minutes. In the next step, the mixture solution was transferred into a Teflon-based autoclave with a nitrogen flow for 30 minutes to remove oxygen and then hydrothermally treated at 190 °C for 8h. After the mixture was cooled to room temperature, Fe_3O_4 NPs were collected by an external magnetic method in order to remove the impurities, and then followed by washing several times with ethanol and deionized water. Finally, the products were dried under vacuum at 100 °C for 12 h.

Synthesis of rGO- Fe_3O_4 composites

To prepare rGO- Fe_3O_4 composites containing various mass ratios of rGO, a rGO suspension was prepared by adding a certain amount of rGO to deionized water (20 mL) and sonicating for 30 minutes to form a suspension (suspension I). Meanwhile, 2.7 g of prepared Fe_3O_4 NPs and 2 g of PEG were dissolved in 60 ml of ethylene glycol with 200 mg sodium dodecylbenzene sulfonate (SDBS) and the mixture solution was stirred at 60°C for an hour (suspension II). Suspension I was then added to suspension II and mixed uniformly, and the homogeneous mixture was transferred to a polytetrafluoroethylene-based autoclave and deoxygenated with nitrogen for an hour followed by heating to the desired temperature of 190 °C for 12 hours. The products were washed with ethanol and deionized water at least three times. They were then extracted by using magnetic separation and dried overnight in a constant temperature oven at 70°C. Final products are labeled as 0.75 $\text{mg} \cdot \text{ml}^{-1}$ -rGO- Fe_3O_4 , 1.5 $\text{mg} \cdot \text{ml}^{-1}$ -rGO- Fe_3O_4 and 3.0 $\text{mg} \cdot \text{ml}^{-1}$ -rGO- Fe_3O_4 respectively, according to the mass of rGO within rGO- Fe_3O_4 composites, which was measured by thermal gravimetric analysis (TGA, Mettler Toledo Star^e System). It can be noted that the small increase in carbon content when rGO concentration doubles may be attributed to the uneven dispersion of rGO in the aqueous environment [23].

The morphology of the products was observed by scanning electron microscopy (SEM, FESEM, Hitachi SU8230), the crystal structure of the composites was obtained using (XRD, Panalytical X'pert Pro) and Raman spectroscopy. The elemental composition of the products was characterized by Electron energy-dispersive x-ray spectroscopy (EDS, Oxford AZtec). N_2 adsorption-desorption was carried out by TriStar 3000 V6.04 to obtain data for pore-size distribution, isothermal desorption and specific surface area (SSA).

Electrochemical characterization of rGO- Fe_3O_4 supercapacitor

Electrochemistry tests were conducted in a standard three-electrode system. The electrolyte is 1 mol/L Na_2SO_3 solution with platinum foil as the counter electrode and a saturated

silver/silver chloride as the reference electrode. cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) tests were performed at room temperature using an ACM Gill 1800 electrochemical workstation. For the rGO-Fe₃O₄ electrode, cyclic voltammetry was performed at a potential range of -1.2 V and 0.15 V versus silver/silver chloride. The AC impedance test frequency ranged from 100 kHz to 10 mHz. The galvanostatic charge/discharge tests (GCD) at various current densities were performed using a LAND CT-2001A battery test system (Wuhan Jinnuo Electronics Co., Ltd.).

The specific capacitance is calculated according to the following equation [24-26]:

$$C = I \frac{\Delta t}{m \Delta V} \quad (1)$$

Where C (F·g⁻¹) is the specific capacitance, I(A) represent the discharge current, m(g), ΔV(V) and Δt (s) represent the mass of the active materials, the potential drop during discharge and the total discharge time, respectively.

Fabrication of a supercapacitor electrode

The prepared active material, acetylene black (carbon black, acetylene 99%, Alfa Aesar) and polyvinylidene fluoride (PVDF, Alfa Aesar) were mixed at a weight ratio of 8:1:1 and thoroughly mixed to a uniform slurry which was spread on an aluminum foil and dried for 12 h at 100 °C in a vacuum oven. After drying, 10 MPa pressure was applied to the electrode, thereby improving the stability and electrochemical performance of the electrode. Afterward, the electrode was cut into a square chip (area=1 cm × 1 cm). Specifically, the loading amounts of rGO-Fe₃O₄ were determined by comparing the weight of aluminum foil.

Results and discussion

The SEM images of Fe₃O₄ NPs, graphene nanoplates and rGO-Fe₃O₄ composites are provided in Figure 1(a), (b) and (c). The synthesized Fe₃O₄ NPs displayed a similar diameter of 100 nm. The SEM images of the rGO-Fe₃O₄ composites exhibit a two-dimensional sheet morphology with the Fe₃O₄ NPs attached to the wrinkled surface of graphene, this observation was in good agreement with previous works [27-28]. The knitted coupling between the Fe₃O₄ NPs and graphene is derived from thermodynamically stable bending, and high conductivity graphene provided efficient and rapid electron transport for the charge storage. The overall Raman results of graphene, pure Fe₃O₄, and rGO-Fe₃O₄ samples are shown in Figure 1(d). The characteristic peak of Fe₃O₄ appeared at 675 cm⁻¹. The D band around 1343 cm⁻¹ is attributed to the presence of chaotic graphite structures caused by amorphous carbon and defects, which stems from the symmetric A1g model of defective graphite. The G band near 1571 cm⁻¹ is derived from the tangential in-plane tensile vibration of the C-C band, which is attributed to the E_{2g} graphite model [29-31]. In addition, the intensity of the G-band is stronger than the intensity of the D-band, and the intensity ratio of the D-band and G-band (ID/IG) is used to evaluate the degree of modification or defect of the rGO [32]. The Raman results confirmed that the prepared rGO-Fe₃O₄ composites have a lower ID/IG ratio, exhibiting an ordered crystalline structure with the presence of fewer structural defects [33-35]. The overall XRD pattern for the reduced graphene oxide(rGO), pure Fe₃O₄ NPs, and rGO- Fe₃O₄ composites are shown in Figure 1(e). It is clear that the peaks at 2θ of 18.3°, 30.1°, 35.4°, 43.1°, 56.9°, 62.5° and 74.5° corresponded to (2 2 0), (3 1 1), (4 0 0), (5 1 1), (4 4 0) and (5 3 3) were well matched with a typical Fe₃O₄ spinel phase (JCPDS no. 19-0629) [36]. Four distinctive peaks at 26°, 44.5°, 54.3° and 65° were observed for crystalline graphite, confirming the presence of rGO-Fe₃O₄ composites were synthesized successfully via the hydrothermal method [37]. SSA and total pore volume (TP) results obtained

by N₂ adsorption-desorption are provided in Figure 1(f), both of which increase with increasing rGO concentrations and reach a maximum of 207.2 m³ g⁻¹ and 0.203 cm³ g⁻¹. TGA analysis shows the mass fraction (wt.%) of rGO within the samples were 12.2%, 15.7%, and 18.5%, respectively, suggesting that the increase in the rGO concentration can provide high conductivity and sufficient active sites for charge storage and ion diffusion.

Electrochemical properties and capacitance characteristics of rGO-Fe₃O₄ material were investigated by cyclic voltammetry tests in a 1M Na₂SO₃ solution. Figure 2(a) shows that the rGO-Fe₃O₄ composite electrode has a voltage window of -1 V to 0.15 V at various scan rates of 2.5 mV·s⁻¹, 5 mV·s⁻¹, 10 mV·s⁻¹, 20 mV·s⁻¹, 30 mV·s⁻¹, and 50 mV·s⁻¹, respectively. The CV curves exhibit that the characterization of the capacitance is different from an ideal electric double layer capacitance (EDLC). The results also show that the shape remains the same at various scan rates, the areas of CV curves were bigger as the increased in the scan rates, suggesting that rGO-Fe₃O₄ has fast diffusion at the material interface with high capacitive behaviour. The CV curve shows two coupled redox peaks near -1 V and -0.2 V, indicating the presence of Fe₃O₄ NPs provides favorable surface adsorption sites for sulfite anions, which acts as the subsequent catalyst for redox or intercalation reactions. Energy storage of supercapacitors mainly depends on the pore size of the electrode material and their relationship with the solvated ion size of electrolyte [38]. Possible reactions to the sulfur-containing product are listed in Equations 2 and 3 [39]. Similar work was done by Shih-Yu [40], where the main reaction mechanisms for the current system, rGO-Fe₃O₄ composites exposed to the Na₂SO₃ solution is the redox reaction of sulfur from sulfate and sulfite anions or the intercalation of sulfite ions for the redox reaction between Fe²⁺ and Fe³⁺.

The AC impedance spectra of pure Fe₃O₄ NPs and rGO-Fe₃O₄ composites with various rGO concentrations are shown in Figure 2(b). The three impedance spectra of various rGO concentrations have similar features, a semicircle at the high-frequency region and a Warburg impedance represented the diffusion of ions in the bulk electrode. As the rGO concentrations rose from 0.75 mg·ml⁻¹ to 3.0 mg·ml⁻¹, R_{ct} values decreased from 2.08 Ω to 1.62 Ω, suggesting that the enhanced conductivity and high-capacity performance. The straight line obtained in the low-frequency region is attributed to the Warburg impedance and the electrode with an rGO content of 3.0 mg·ml⁻¹ has a small capacitive reactance, which is attributed to the acceleration of electron transport and reduction of resistance by rGO. The pure Fe₃O₄ NPs electrode has the largest semicircle in the high-frequency range, suggesting a higher charge-transfer resistance of the electrode.

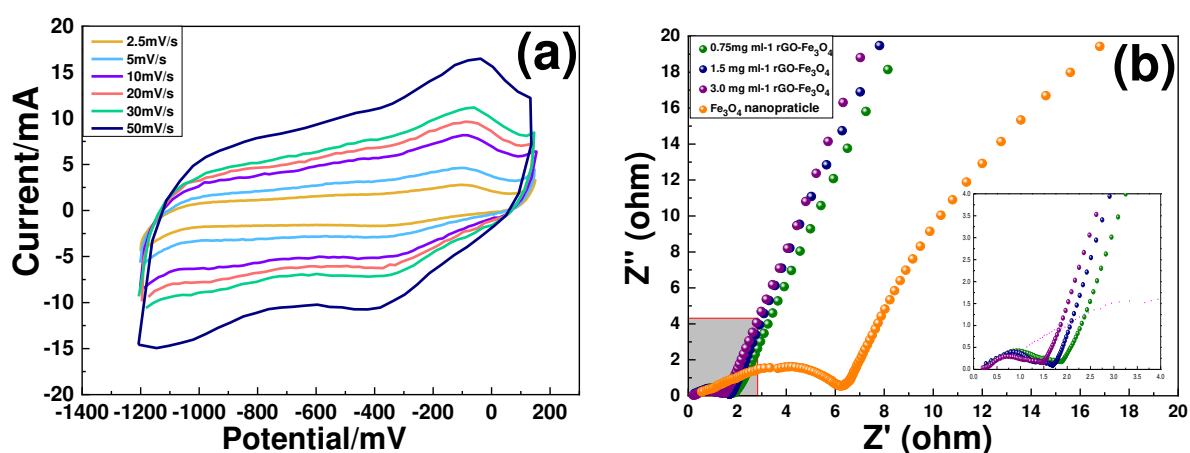

Figure 2(a) Cycling voltammetry of rGO-Fe₃O₄ composite with an rGO concentration of 1.5mg·ml⁻¹ measured by a potential varying from -1.2 V to 0.15 V; (b) Nyquist plots of rGO-Fe₃O₄ composites in a 1 M Na₂SO₃ electrolyte with various rGO concentration compared with pure Fe₃O₄

The capacitance behaviour of rGO-Fe₃O₄ composites containing various rGO was further studied by GCD tests at various current densities and shown in Figure 3. The geometrically symmetrical triangular curves in Figure 3(a) verify the behaviour of an ideal pseudocapacitor and the highly reversible charge-discharge process [41]. At low current density, the passivation zone occurred before the point reached 0.15 V during the charging process, and the results showed that the increase in current densities, resulted in the charge and discharge time being reduced. According to Figure 3(b), specific capacitances of 212.8 F·g⁻¹, 182.5 F·g⁻¹, 151.4 F·g⁻¹, 130.5 F·g⁻¹ and 122.1 F·g⁻¹ were recorded for rGO-Fe₃O₄ composites at the corresponded current densities of 0.75 A·g⁻¹, 1.25 A·g⁻¹, 2.5 A·g⁻¹, 3.75 A·g⁻¹, 5 A·g⁻¹, respectively, indicating that the reduction of the specific capacitance was observed, and suggesting a low current density having better accessibility of ions go into the electrode material. The long-term cycle performance of 1.5 mg·ml⁻¹-rGO-Fe₃O₄ composites at current densities of 0.75 A·g⁻¹ and 5 A·g⁻¹ is provided in Figure 3(c). The results indicate a better retention rate of 92.4% at 0.75 A·g⁻¹ compared with 87.7% at the current density of 5 A·g⁻¹. Moreover, the results also suggest that the specific capacitance of rGO-Fe₃O₄ improves significantly with the increase in the rGO concentrations from 0.75 mg·ml⁻¹ to 1.5 mg·ml⁻¹ as shown in Figure 3(d). Compared to the pure Fe₃O₄ NPs, the enhanced electrochemical performance was partly attributed to the good electronic conductivity of graphene [42]. In Figure 3(d), as the rGO concentration increased from 0.75 mg·ml⁻¹ to 1.5 mg·ml⁻¹, higher rGO concentration provides high conductivity and sufficient active sites for charge storage and ion diffusion, thus enhancing the electrodes' charge-discharge performance and the specific capacitance is significantly improved from 126.2 F·g⁻¹ to 212.8 F·g⁻¹ at the current density of 0.75

$\text{A}\cdot\text{g}^{-1}$. When rGO concentration was further increased from $1.5 \text{ mg}\cdot\text{ml}^{-1}$ to $3.0 \text{ mg}\cdot\text{ml}^{-1}$, however, the excessive rGO was covered the Fe_3O_4 nanoparticles and hinder the interaction with the electrolyte, thereby reducing the capacitance to $188.1 \text{ F}\cdot\text{g}^{-1}$, similar observation has been reported by Yanqun [43].

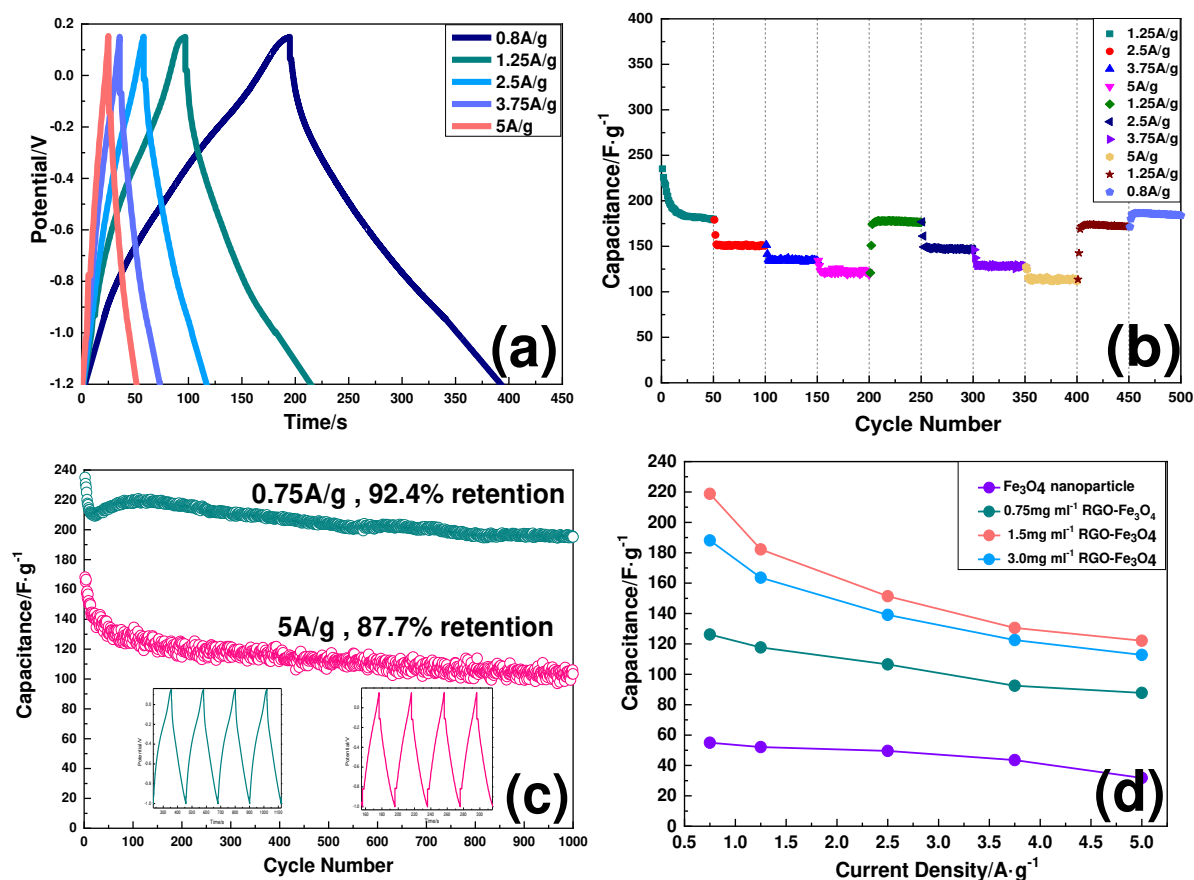

Figure 3(a) GCD curves of rGO-Fe₃O₄ composite with an rGO concentration of $1.5 \text{ mg}\cdot\text{ml}^{-1}$ at various current density (b) Cycling performance (c) Long-term coulombic efficiency and capacity retention at the current densities of $0.75 \text{ A}\cdot\text{g}^{-1}$ and $5 \text{ A}\cdot\text{g}^{-1}$ and (d) Specific capacitance of samples with different rGO concentration at various current densities.

The morphology of the electrode surface after GCD at a constant current of $1.25 \text{ A}\cdot\text{g}^{-1}$ in a $1 \text{ M Na}_2\text{SO}_3$ solution was observed by SEM. The development of the corrosion products was observed during the charge and discharge processes as shown in Figure 4(a). It can be seen from Figure 4(b) that the rGO-Fe₃O₄ composites started to form clusters of spherical particles with sizes ranging from 100 nm to 500 nm . After 500 cycles, the corrosion products covered the entire electrode surface as shown in Figure 4(c). By comparing the XRD spectra before and after the cycling tests, peaks appeared at $2\theta = 29.7^\circ, 33.6^\circ, 43.2^\circ$ and 53.2° were detected, which corresponded to (1 1 0), (1 1 2), (1 1 4) and (3 0 0) of FeS (JCPDS no. 65-3356) as shown in Figure 4(d). It should be noticed that the characteristic peaks at $2\theta = 38^\circ, 44^\circ, 65^\circ$ and 78° are derived from the aluminum foil during electrode fabrication. Therefore, it can be concluded that FeS was determined to be the reaction product that may cause the capacitance deterioration.

Figure 4 (a),(b),(c)The formation of FeS on the electrode surface (d) XRD patterns before and after the GCD measurements

The effect of FeMoO₄ as an electrolyte additive on the capacitance performance

The rGO-Fe₃O₄ composites were further surface engineered to improve the capacity performance during the charge and discharge processes at different current densities via introducing FeMoO₄ as an additive to the electrolyte. FeMoO₄ was added to the 1M Na₂SO₃ electrolyte and mixed well to form a homogeneous mixture. Figure 5 shows the change of the capacitance after introducing 500mg FeMoO₄. It is interesting to note that the capacitance started to increase after 200 cycles and the highest peaks were detected at 475 cycles, 492 cycles and 497 cycles with a capacity of 187 F·g⁻¹ 172 F·g⁻¹ and 153 F·g⁻¹ for the current densities of 1.25 A·g⁻¹, 3.75 A·g⁻¹ and 5 A·g⁻¹, respectively. The scattered particles in Figure 5(b) show reaction products grow on the rGO-Fe₃O₄ electrode surface after 200 cycles and suggest that the formation of the products was able to increase the electrical conductivity and effectively improve the capacity performance.

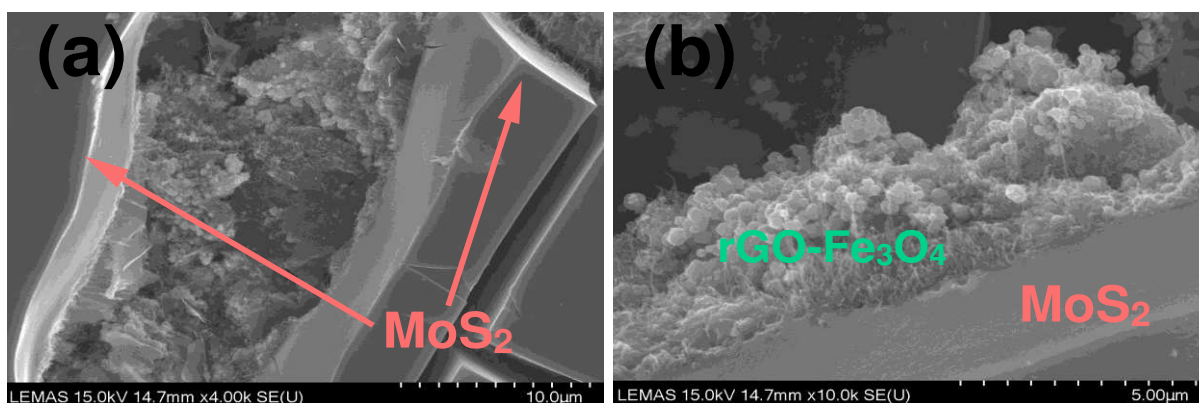

Figure 5(a) Comparison of specific capacitance after adding Iron(II) Molybdate with no additive, (b) morphology of growing MoS₂

In order to investigate the function of the flaky products formed on the surface and their role in renewing the capacitance of the rGO-Fe₃O₄ electrode, both electrochemistry experiments and surface analysis were performed. We observed the growth of flaky products after 500 cycles on the electrode surface via SEM images as shown in Figures 6(a) and 6(b).

EDS analysis, XRD and Raman spectroscopy were used to identify the surface products formed on the electrode surface. The EDS results in Figure 6(c) show a uniform elemental distribution of Mo, S, O, Fe and C within the products. XRD peaks in Figure 6(d) at $2\theta = 14.2^\circ$, 33.1° , 39.2° and 58.9° were assigned to (0 0 2), (1 0 0), (1 0 3) and (1 1 0), corresponding to MoS₂ [44] (JCPDS card no. 37-1492). Figure 6 (b and c) indicates that the presence of MoS₂ was determined and the results suggest that the formation of MoS₂ and rGO-Fe₃O₄ composites were detected on the electrode surface after various charge/discharge cycles. Raman spectroscopy in Figure 6(e) clearly shows the two characteristic peaks at 380.7 cm^{-1} and 407.8 cm^{-1} , which correspond to the E_{2g}^1 and A_{1g} mode of MoS₂ respectively. The separation between the two peaks of 26.3 cm^{-1} is larger than the 19 cm^{-1} reported for exfoliated flakes [45-47]. Combined with the rejuvenating capacitance during the charge and discharge described in Figure 5(a), generated MoS₂ builds a structure of staggered gaps and channels instead of covering the entire surface, which allows electrical interaction between rGO-Fe₃O₄ and the electrolyte and effectively improves the capacitive performance.

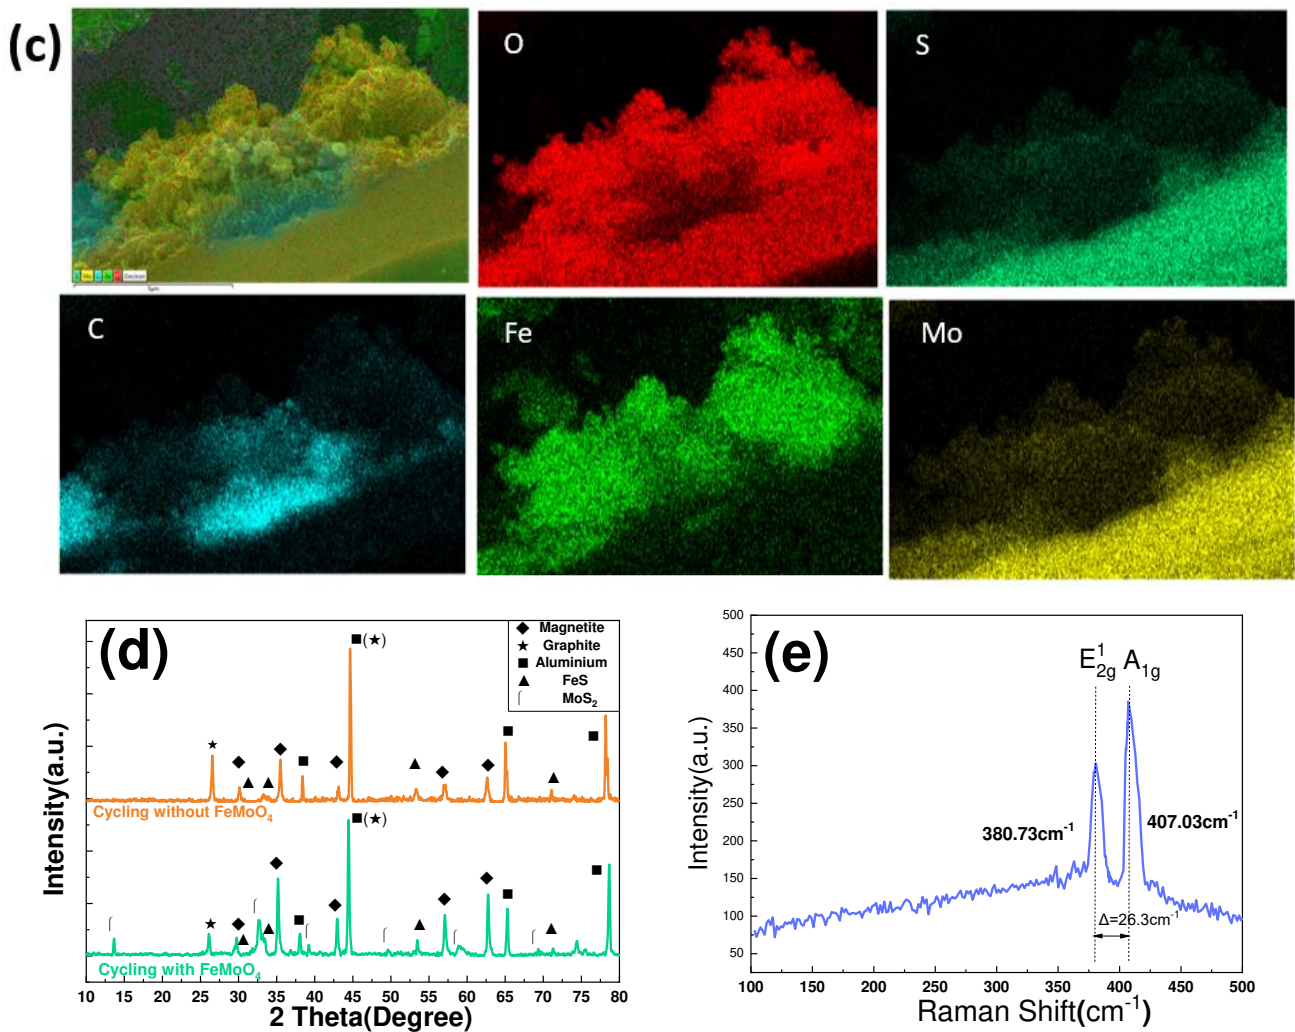

Figure 6(a) SEM images of the flaky MoS₂, (b) MoS₂ with rGO-Fe₃O₄ composites (c) EDS mapping of the MoS₂ with rGO-Fe₃O₄ composites, (d) Compared XRD pattern of the electrode after cycling and (e) Raman spectroscopy of MoS₂

In order to clarify that the observation of the formation of MoS₂ increases the capacity performance through introducing the FeMoO₄ to the electrolyte during the charge and discharge processes, cyclic voltammetry and AC impedance of the electrode in the mixed electrolyte at specific cycles of 100, 300, 500 were tested at a current density of 1.25 A·g⁻¹. Cyclic voltammetry in Figure 7(a) shows that the redox peak near -0.1 V gradually weakens, indicating the deteriorating of the redox reaction of divalent iron ions. An enhanced oxidation peak appeared near -1.0 V, corresponding to the formation of flaky MoS₂ on the electrode surface. Cycling voltammetry was consistent with the XRD and Raman results. The EIS measurements in Figure 7(b) provides the electrochemical behaviour of the material after various cycles in terms of electrolyte resistance and charge transfer resistance. The results showed that the materials after the 100th cycle exhibited a bigger semicircle at the high-frequency region compared to the 500th, indicating that the electron transfer resistance reduced from 1.95 Ω to 1.52 Ω, suggesting the improved conductivity and ion transport for the formation of MoS₂ on the rGO-Fe₃O₄ electrode.

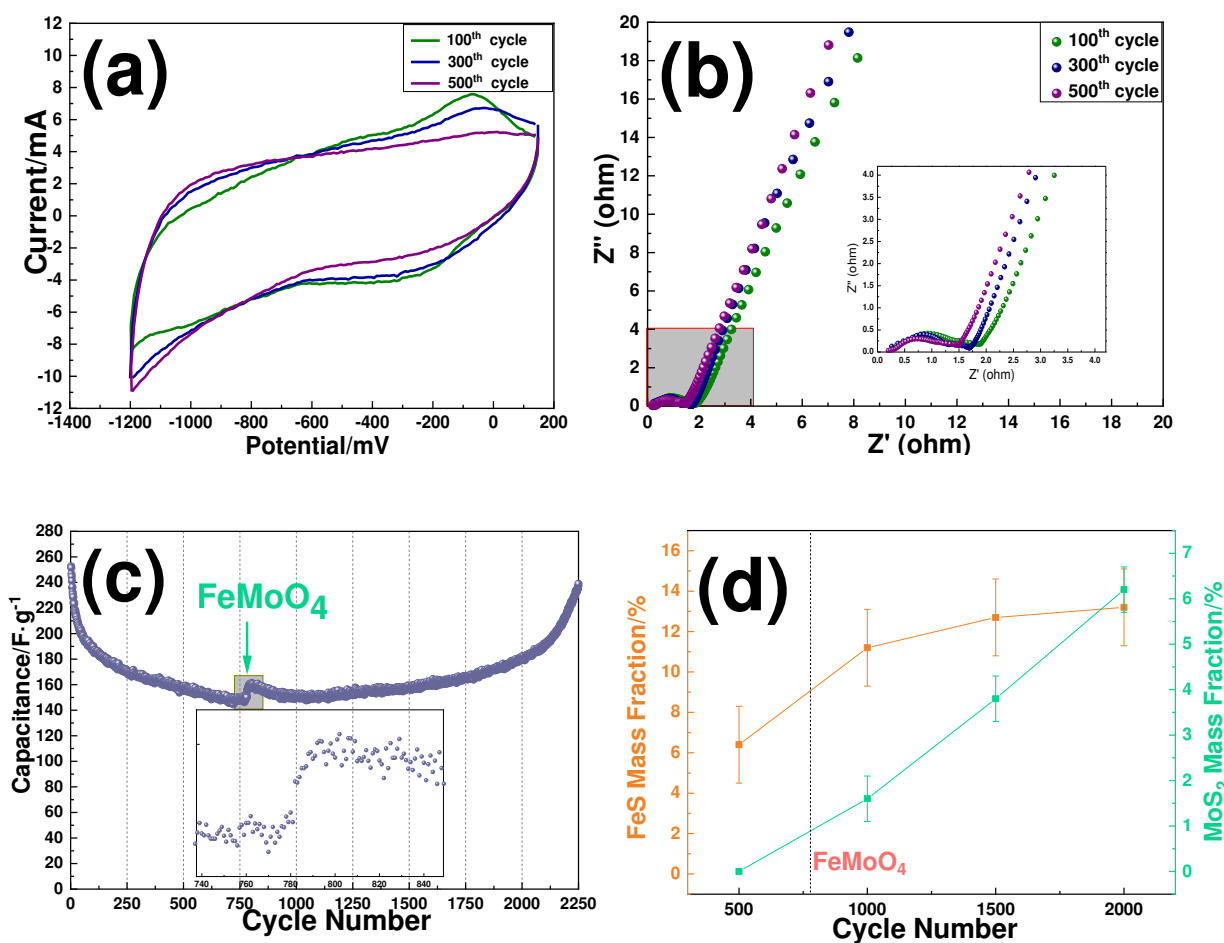

Figure 7(a) CV curves and (b) AC impedance after introducing FeMoO₄ at various cycles (c) long-cycle test with FeMoO₄ and (d) amount of FeS/MoS₂ from profile-fitted peaks at various cycles

Figure 7(c) describes the effect of adding FeMoO₄ on the long-term stability of rGO-Fe₃O₄. The electrode was charged and discharged in 1M a Na₂SO₃ solution at a current density of 1.25 A·g⁻¹ when 500mg FeMoO₄ was added into the electrolyte at the 780th cycle. The result shows a declining trend before adding FeMoO₄ and a reviving capacitance after 1000 cycles, with the capacitance reaching 238.87 F·g⁻¹ by the end of 2250 cycles. The amount of FeS and MoS₂ were calculated by XRD fitting peak quantitative analysis (Figure 7d) at 500th, 1000th, 1500th and 2000th cycles, respectively. The mass fraction of FeS was 6.4%, 11.2%, 12.7% and 13.5% at 500th, 1000th, 1500th and 2000th cycle respectively, while the amount of MoS₂ was 0, 1.6%, 3.8% and 6.2% at corresponding cycle. Results indicate that the addition of FeMoO₄ hindered the growth of FeS, which confirms the inhibitory effect of growing MoS₂ on the formation of FeS and improving the specific capacitance in the long-term stability test.

Fe₃O₄ degradation mechanism

The behavior of the rGO-Fe₃O₄ electrode in sodium sulfite solution was explained by redox reactions on the surface (equations 2 and 3) [48]:

Equation 4 explains the degradation mechanism of Fe₃O₄-rGO composites during charge and discharge in the 1M Na₂SO₃ electrolyte, which is attributed to the growth of the FeS layer. According to the CV results obtained in Figure 3(a), the characteristic peak was caused by the conversion from Fe³⁺ to Fe²⁺. Fe₃O₄ is converted into FeS, which is consistent with the sulfuration of Fe₃O₄ [49-51]. Due to the mutual attraction of the opposite charges, Fe²⁺ in the solution is distributed on the surface of the negatively charged rGO, thus reacting with S²⁻ and forming the FeS layer[52]. A schematic diagram of growing FeS on the electrode surface is shown in Figure 8.

Figure 8 Schematic diagram of the process of FeS covering electrodes (a) after 50 cycles (b) partially covered.

It is worth noting that rGO-Fe₃O₄ composites provide a high capacity, however, it decreases as Fe₃O₄ inevitably undergoes irreversible redox reaction with sulfide ions in the solution (Equation 4) and finally forms FeS on the electrode surface through dissolution and recrystallization reactions during the charge and discharge cycles[53]. Despite that FeS derived from Fe₃O₄ has a relatively high theoretical capacity, significant changes in volume during the insertion/extraction of sodium ions lead to rapid loss of capacity. Hence, the formation of FeS on the electrode surface impedes the contact between Fe₃O₄ and the electrolyte[54-55]. As a result, A solid electrolyte interface(SEI) that inhibits redox reactions is formed on the electrode, thus preventing the Fe₃O₄ from exerting the pseudocapacitance effect and reducing the specific capacitance. On one hand, rGO contributes to stabilizing the electrode surface and improves cycling stability[56]. The oxygen-containing functional groups(like -OH) carried on rGO can increase surface wettability and provide additional pseudocapacitance[57]. On the other hand, the consumption of the electrolyte and the oxidation of the graphite also account for the capacitance loss over long-term charge and discharge process in which the oxygen content was increased in rGO. The possible redox reaction of rGO oxidation happened on electrode is presented [58-60]:

Equation 5 explains the process by which the hydroxyl groups on the rGO surface interact with water to form anions and produce hydronium ions. In long-term charge/discharge cycles, the functional groups may react with the electrolyte or decompose, and the increase in the oxygen content of rGO may reduce the conductivity of the carbon electrode, resulting in low specific capacitance and poor rate performance[61-62]. The influence of rGO on the electrochemical performance of rGO-Fe₃O₄ and its degradation mechanism deserves more effort in the future study.

The increase in capacity performance by introducing the FeMoO₄ as an additive.

The chemical equilibrium in the solution when adding FeMoO₄ can be summarised as [63]:

Fe(II) and Mo(VI) within the electrolyte are considered as soluble ions. Pseudocapacitor reactions of rGO-Fe₃O₄ involve the redox reaction of sulfur from sulfate and sulfite anions or the intercalation of sulfite ions for the redox reaction between Fe²⁺ and Fe³⁺. The presence of the Mo element contributes to the formation of flaky MoS₂ through [64-65]:

The intermediate hydrogen sulfide reacts with molybdate ions under an aqueous environment to form the flaky MoS₂. The flaky MoS₂ covered electrode is electrically conductive, improving the electrical contact active area [66]. On the other hand, the consumption of sulfur ions (S²⁻) inhibited the growth of FeS on the electrode surface and increased the capacity performance over long-term cycles.

The formation of flaky MoS₂ on the rGO-Fe₃O₄ composites in sodium sulfite solution can be generally classified into two stages, which is shown in Figure 9. The improvements in capacity performance by introducing FeMoO₄ can be attributed to two aspects. Unlike FeS, the formation of the porous MoS₂ layer with a gully morphology allows additional redox reactions, it is suggested that the formation of flaky MoS₂ with Fe₃O₄ was able to increase the electrical conductivity compared to that of pure Fe₃O₄ NPs. On the other hand, conductive MoS₂ provides an easy ion-diffusion path at electrode/electrolyte interface, which contributes to taking advantage of the electrochemical performance of rGO-Fe₃O₄ to the maximum extent. As a result, MoS₂ nanosheet generated on the electrode surface possessing a large surface area that provides abundant active Faraday redox reaction sites as well as facilitates electron transfer between electrode and electrolyte[67-69]. Meanwhile, the presence of MoS₂ effectively stabilizes the electrode/electrolyte interface and reinforces electrical conductivity[60]. These benefits could help to inhibit material degradation and slow down capacitance deterioration. Therefore, introducing FeMoO₄ can be concluded as an effective way to solve material degradation on rGO-Fe₃O₄ electrode surface in Na₂SO₃ environment under the test conditions. However, further work should be done on the investigation of the growth of MoS₂ and enhancement of the capacitance recovery within shorter periods.

Figure 9. Schematic diagram of growing MoS₂ with rGO-Fe₃O₄ composites (a) partially covered and (b) fully covered

Conclusions

In summary, rGO-Fe₃O₄ composites were successfully synthesized by a hydrothermal method. Topographic and crystal characterization of XRD, SEM, Raman and TGA were used to confirm the formation of rGO-Fe₃O₄. As-prepared rGO-Fe₃O₄ composites show better electrochemical performance than pure Fe₃O₄, which proves the synergetic effect between Fe₃O₄ nanoparticles and rGO nanosheet. Capacitive properties of rGO-Fe₃O₄ were measured with cyclic voltammetry, GCD and impedance spectroscopy for electrodes with different rGO mass ratios. Enlarged specific surface area, high conductivity and low internal resistance facilitate electron transport effectively, thus improving the specific capacitance in Na₂SO₃ electrolyte. The sample with 1.5 mg·ml⁻¹ rGO content exhibits the highest specific capacitance of 182.2 F·g⁻¹ at a current density of 1.25 A·g⁻¹ among prepared electrodes, with a retention rate of 92.4% after 1000 cycles. The degradation mechanism of rGO-Fe₃O₄ is based on the decrease in capacitance over long-term cyclic stability caused by the formation of FeS on the electrode surface and the oxidation of the carbon over long-term charge/discharge processes. Intentionally, FeMoO₄ was added as an additive to the electrolyte to inhibit capacitance decline. After adding FeMoO₄, MoS₂ was found on the electrode surface, thus providing additional sites for redox reaction, and assisting electron transfer. The maximum value of the specific capacitance was revived to 186.6 F·g⁻¹, 171.8 F·g⁻¹ and 153.4 F·g⁻¹ at the current density of 1.25 A·g⁻¹, 2.5 A·g⁻¹, and 3.75 A·g⁻¹ after 500 cycles, respectively. Further, MoS₂ is found effectively in paving an easy and fast way for electron transfer and weakening the influence of FeS on deteriorating capacitance within a boundary condition of 2250 cycles. This work provides a new insight into improving the capacitive performance of rGO-Fe₃O₄ composites as well as preventing material degradation on the surface of the electrode.

Supporting Information

Supplementary material is attached in this section to further support research findings. These include a EDX mapping of FeS/MoS₂ products from the electrode surface, a SEM image of rGO-Fe₃O₄ composite and its corresponding EDX mapping.(pdf)
