Abstract:

A novel and low-cost micro-sensor with a diameter of 12 μm was developed based on Titanium dioxide-Polyaniline/Silk fibroin fiber ($\text{TiO}_2\text{-PANI/SFF}$). $\text{TiO}_2\text{-PANI}$ composites were deposited on surfaces of SFFs by in-situ polymerization. The microfibers were characterized by Scanning electron microscopy (SEM), Energy dispersive spectrometer (EDS), Raman spectrometer, Fourier transform infrared (FTIR) spectroscopy and X-ray diffraction (XRD), and the formation mechanism of them was illustrated in detail. With ammonia (NH_3) as model gas, the $\text{TiO}_2\text{-PANI/SFF}$ micro-sensor showed good sensing performance with response value of 0.82 and response time of 10 s to NH_3 of 100 $\mu\text{g/L}$. When the micro-sensors were applied for pork freshness evaluation, the output response values showed good correlation with the total volatile basic nitrogen (TVB-N) levels in pork ($R^2=0.990$), and the discriminant results of the micro-sensors for pork freshness based on linear discriminant analysis (LDA) showed the prediction accuracy of calibration and prediction set was 90.73% and 86.38%, respectively, which indicated the great potential of $\text{TiO}_2\text{-PANI/SFF}$ micro-sensor for pork freshness evaluation.

Silk fibroin; Titanium dioxide; Polyaniline; pork freshness; microfiber sensor

32

33 1. Introduction

34 Achieving accurate and rapid detection of meat freshness is one of the major
35 challenges for meat industry [1]. Quality of pork decreases rapidly during
36 transportation and storage because of bacterial growth and enzymatic actions [2, 3],
37 which may cause poor food taste or even food poisoning. The traditional methods for
38 evaluating pork freshness include sensory test, chemical analysis and viable bacterial
39 counts [4-6]. Sensory test is a rapid method, but it's not reliable when meat freshness
40 changes slightly. Both chemical analysis and viable bacterial counts are objective
41 methods, but they are time-consuming and couldn't be competent with modern
42 industrialization process. Therefore, development of new fast, low-cost and accurate
43 method for evaluation of pork freshness is of great significance.

44 Gas sensing technology has been playing an increasingly important role due to
45 their promising applications in many fields such as medical diagnosis, monitoring of
46 environmental pollutants and human health and safety [7-9]. Moreover, it could be
47 applied to the evaluation of meat freshness. Volatile amines, including ammonia,
48 histamine, tyramine, tryptamine and putrescine, etc., are produced by protein
49 decomposition of pork because of microbial spoilage and biochemical reactions [10,
50 11]. These volatile amines constitute the total volatile basic nitrogen (TVB-N) which
51 are closely related to meat freshness [6]. It might be possible to relate the freshness of
52 pork with the concentration of volatile amines so as to make prepared sensors as
53 indicators to evaluate pork freshness. There have been several studies attempting to
54 marry meat freshness with the presence or concentration of certain substance emitted
55 by meat [12-14]. For example, Cheuk-Fai Chow et al. [15] successfully applied
56 Re(I)-Pt(II) sensor to detect CH_3SCH_3 in real rotten pork with a linear luminometric
57 response up to $20.0 \text{ mg}\cdot\text{kg}^{-1}$ ($R = 0.997$) and the detection limit as $0.05 \text{ mg}\cdot\text{kg}^{-1}$.
58 Naomi Funazaki et al. [16] presented a semiconductor gas sensor based on
59 $\text{Rh-La}_2\text{O}_3\text{-In}_2\text{O}_3$ showing excellent sensitivity and selectivity to ethyl acetate
60 produced in the initial bacterial putrefaction of meat at 300°C . These studies
61 confirmed the reliability of gas sensors for assessing freshness of meat. However, the
62 prepared sensors based on these studies are often complicated to fabricate, high cost
63 or environmentally harmful as the rare metal was used in their sensors. Therefore, it is
64 highly desirable to develop a micro-size, cost-effective and eco-friendly sensor for the
65 evaluation of meat freshness.

66 Polymer-metal oxide based composites have recently attracted extensive

attention due to their unique properties of catalytic activity [17], photocatalytic activity [18] and gas sensitivity [19]. Polyaniline (PANI), a kind of polymer with conjugated electronic structure, has been widely applied to the development of various devices on account of its good environmental stability and unique properties such as electrochemical, electroluminescence, redox behavior [20-22]. TiO_2 , a typical n-type semiconductor, has also received extensive studies in gas detection because its electrical resistance has a strong dependence on the concentration of surrounding gases [23]. Previous study has reported gas-sensing performance of polymer-metal oxide (n-type) based sensor could be greatly improved owing to the P-N junction presenting in their backbones [24]. Accordingly, the synergetic effect of TiO_2 -PANI may show great gas-sensing property over conventional sensors based on nanometal oxides. Unfortunately, the applications of polyaniline based sensors are restricted for poor mechanical property and low processability of polyaniline [17].

Natural silk provides a way to solve the above problems due to its excellent characteristics. Natural silks produced by silkworm have unique structure as shown in the supplementary information (Fig. S1 (a) and (b)), Silk fibroin fiber and sericin protein are the main components of natural silk [25]. Owing to the water solubility of sericin protein, natural silks have to be degummed before use. As shown in Fig.S1 (c) and (d), silk fibroin fiber contains a large number of amino acid residues providing great potential for surface modification of silk fibroin fiber [26, 27], and the past reports have confirmed that the main components of silk peptides could be endowed with a great number of in situ active sites [28, 29]. In addition, silk fibroin fibers in size of about 10 μm not only ensure the convenience for further processing and assembly, but also meet the needs for miniaturization. Therefore, silk fibroin fiber provides a great potential for the fabrication of low-cost and micro-size gas sensor.

The aim of this study is to develop a cost-effective and eco-friendly microfiber sensor for ammonia detection and pork freshness evaluation. TiO_2 -PANI nanocomposites were firstly deposited on the surfaces of silk fibroin fibers by in-situ polymerization. The obtained composites were characterized in detail and then applied as the gas sensors. The performances of the prepared TiO_2 -PANI/SFF micro-sensors were evaluated by detecting ammonia gas at room temperature. Finally, the prepared sensors were applied to evaluate pork freshness.

99 **2. Experimental**

100 *2.1. Materials*

101 Cocoons of silkworm were supplied by Zhejiang textile Co., Ltd. (China).
102 Sodium carbonate (Na_2CO_3 , 99.8%), P25 titanium dioxide powder (TiO_2 , 95%),
103 sulfuric acid (H_2SO_4 , 98%), ammonium persulfate (APS, 98%), trimethylamine
104 (TMA, 33%) and ammonium hydroxide ($\text{NH}_3\cdot\text{H}_2\text{O}$, 25~28%) were purchased from
105 Sinopharm Chemical Reagent Co., Ltd. (China). Aniline was purchased from Aladdin
106 Chemical Reagent Co., Ltd and distilled under reduced pressure before use. High
107 purity air was purchased from Jiangsu Thorpe Co., Ltd. (China). Fresh pork was
108 bought from Auchan supermarket. (Zhenjiang, China). Double distilled water was
109 used to prepare all solutions.

110 *2.2. Preparation of TiO_2 -PANI/SFF sensor*

111 *2.2.1. Preparation of silk fibroin fibers*

112 Silk fibroin fibers were obtained by degumming method removing the sericin
113 proteins from silkworm cocoons. The degumming process was carried out through
114 boiling the cocoons in 0.05 M Na_2CO_3 solution for half an hour. Then double distilled
115 water was used to wash the degummed SFFs thoroughly. The obtained SFFs were
116 dried in a vacuum at 40°C for 12h and stored in the dark at room temperature.

117 *2.2.2. Preparation of TiO_2 -PANI/SFF microfiber*

118 TiO_2 -PANI/SFF microfibers were prepared by in-situ polymerization technique.
119 Specifically, 0.15 g of SFFs were dispersed in 0.5 M H_2SO_4 solution (40 mL)
120 containing different amount of TiO_2 nanoparticles with magnetic stirring for 0.5 h,
121 followed by the addition of 182.4 μL of aniline dissolved in 0.5 M H_2SO_4 (10 mL)
122 with magnetic stirring for 20 min. Then the in-situ polymerization of aniline was
123 initiated by dropwise adding 0.456 g APS dissolved in 0.5 M H_2SO_4 (50mL) into the
124 above solution. The whole synthesis process was carried out in ice/water bath at 0 °C
125 for different hours with magnetic stirring. At last, the prepared composite was washed
126 and filtered for five times with distilled water and then dried for 12 h at 40 °C.

127 *2.3. Characterization*

128 The morphologies of composite microfibers were characterized using a scanning
129 electron microscope (SEM, S-4800, Hitachi, Japan). Energy scattering pattern were
130 obtained using X-max EDS spectrometer (Oxford, UK). Raman spectra were
131 investigated using a microscopic confocal Raman spectrometer with 532 nm laser

excitation (ThermoFisher, USA). The structure changes of prepared materials were studied by a Thermo Scientific Nicolet iS50 FT-IR Spectrometer (ThermoFisher, USA). The XRD patterns were obtained from a Rigaku Miniflex 600 powder diffractometer (Cu K α radiation, 40 kV 15 mA) with a D/Tex Ultra 250 1D CCD detector.

The volume conductivity σ was calculated as follows [30]:

$$\sigma = \frac{4L}{\pi D^2 R} \quad (1)$$

Where σ , R, D and L is the conductivity (S/cm), resistance (Ω), diameter (cm) and length (cm) of prepared fiber samples, respectively. The conductivity was calculated by repeatedly measuring the resistance of samples five times via 2-probe method at room temperature using a digital multimeter (Agilent 34410A, USA). The length (L) of prepared fiber samples was 0.5 mm. The diameter of fibers was about 12 μ m seen from SEM morphologies of prepared materials.

2.4. Fabrication of TiO₂-PANI/SFF micro-sensor

A simple fabrication strategy was used to assemble TiO₂-PANI/SFF micro-sensor. Briefly, conductive silver adhesive was utilized to weld a single composite microfiber onto both ends of positive and negative electrodes of a flexible flat cable (FFC, spacing of 0.5mm) with the help of an optical microscopy. The photo of the FFC cable and the details of the prepared sensor were shown in Fig. 1 (a), respectively.

Fig. 1 (a) the photo of the FFC cable and the details of the prepared micro-sensor; (b) Schematic diagram of sensors' performance testing setup.

2.5. Performance testing of the prepared micro-sensors

Gas-sensing performances of the prepared micro-sensors were studied by a

home-made system at room temperature of 25 °C as shown in Fig. 1 (b). Teflon tubing was used as the connection pipeline. Pure air was employed to vent 30 min at a speed of 2 L/min to purify the whole test device before testing. During the test, a certain amount of liquid volatile ammonia was injected into the gas chamber by using a micro-injector, and then the fan was opened for 2 h to make injected liquid evaporate completely and mix evenly. Mixed gases could enter into the test chamber by controlling switching state of the needle valves. Resistance of a sensor was measured by a multimeter at 2 s intervals.

The concentration of ammonia in gas phase was controlled by controlling the injection amount. The concentration of target gas was calculated by the following formula [31],

$$C = \frac{22.4 * \rho * d * V_1}{M * V_2} \quad (2)$$

where C (ppm) is the target gas concentration, ρ (g/mL) is the density of the liquid, d is the purity of the liquid, V_1 (μ L) is the volume of the liquid, V_2 (L) is the volume of the glass chamber, and M (g/mol) is the molecular weight of the liquid.

The response value of sensor was defined as:

$$S = \frac{R - R_0}{R_0} \quad (3)$$

Where R is the resistance when the sensor was exposed to testing gases, R_0 is the resistance of the sensor in pure air.

2.6. Evaluation of pork freshness

In order to examine the feasibility of the fabricated TiO₂-PANI/SFF micro-sensors, a piece of fresh pork was cut into pieces of 10 g, and then they were stored separately in test chambers at 4 °C. In the following seven days, two parts of pork samples were prepared to test response values of the sensor and determine the content of TVB-N in pork every day, respectively. TVB-N, as a traditional indicator of pork freshness, could well reflect the degree of protein decomposition in pork [6, 32]. Response values of the prepared micro-sensors were measured by a home-made system as shown in Fig. S2 (a), and the test steps of pork freshness evaluation was illustrated in detail in the document of “Supplementary Material”. TVB-N content in pork was determined by a steam distillation method according to the previous

literature [33]. All results are the average value of five times repetition to same sample. The correlation between the response values and TVB-N contents was fitted through the curve fitting to verify the correlation between them. Linear Discriminant Analysis (LDA), constructing discriminant functions through linear combination of labeled data, is one of the most widely used supervised classification procedure [34]. In this study, LDA was applied to verify the feasibility of the prepared micro-sensor used in the prediction of pork freshness.

3. Results and discussion

3.1. Characterization of TiO_2 -PANI/SFF microfiber

Morphologies of the silk fibroins coated with different nanomaterials including PANI, TiO_2 -PANI were characterized by SEM images. As shown in Fig.2 (a), the uncoated silk fibroins possessed quite smooth surfaces, and the diameters of silk fibroins were about 12 μm . Fig.2 (b) showed the surface morphology of silk fibroin deposited with PANI. It can be observed there existed polyaniline lamellar structure on the surface of silk fibroin. The growth of polyaniline layer may result from the large number of amino acid residues of silk fibroins seizing the aniline monomer or its polymer through hydrogen bonding and ionic bond. Fig.2 (c) and (d) were the SEM images of TiO_2 -PANI/SFFs prepared by controlling the reaction time of 2 h and TiO_2 amount of 0.025 g. The doping of TiO_2 had a significant effect on morphologies and structures of the microfibers. The smaller TiO_2 nanoparticles were agglomerated in the presence of polyaniline, forming larger TiO_2 -PANI composite particle clusters. A large number of polyaniline filaments with diameter of about 20 nm extended from the surface of particle clusters, which could be a boost for binding the particle clusters to the surfaces of silk fibroins. At last these particle clusters were randomly distributed on the surfaces of silk fibroins, forming a layer of TiO_2 -PANI composite with a large specific surface area.

Fig. 2 SEM images of (a) SFF, (b) PANI/SFF, and (c-d) TiO₂-PANI/SFF.

The incorporation of TiO₂ nanoparticles on the polyaniline substrate was verified by energy dispersive spectrum (EDS). As seen in Fig.3 (a), the titanium peak in the spectrum confirmed the successful modification of TiO₂ onto polyaniline substrate. The functional groups vibration of the composites was characterized by laser Raman spectroscopy in Fig.3 (b). The characteristic peaks at 1163 and 1491 cm⁻¹ are attributed to the stretching vibration of C=N double bond of quinoid structure from PANI [35]. The peaks at 419 and 1594 cm⁻¹ exhibited the presence of benzene ring in PANI [36, 37]. However, these peaks were not obvious in the silk fibroins spectra, which confirmed the existence of polyaniline in the prepared composites.

Fig. 3 (a) EDS, (b) Raman spectra, (c) FTIR spectra and (d) XRD patterns of SFF, PANI/SFF and TiO₂-PANI/SFF.

The structure changes of prepared materials were studied by FTIR spectroscopy. As Fig.3 (c) shows, the characteristic peaks for pure SFF occurs at 1643 cm⁻¹ (amide I), 1520 cm⁻¹ (amide II), 1331 cm⁻¹ (amide III), 1163 cm⁻¹ (amide IV), indicating the existence of β -sheet structure in SFF [38]. The main characteristic FTIR spectra of PANI/SFF shows the band at 1564 and 1501 cm⁻¹ ascribed to C=C and C=N

(stretching vibrations of benzenoid and quinoid rings) of PANI, while a band at 1297 cm^{-1} is attributed to C—N stretching vibrations of benzenoid unit and that at 1095 cm^{-1} is assigned to C—O stretch [39]. TiO_2 -PANI/SFF exhibits spectral information similar to that of PANI/SFF. Remarkably, the peak for both amide I and amide II in TiO_2 -PANI/SFF move to lower wave number (1564 cm^{-1} and 1501 cm^{-1}), which indicate that polyaniline has some interactions with peptide linkages in SFF macromolecular chains[40].

Fig.3 (d) shows the XRD patterns of three types of fibers (SFF, PANI/SFF, TiO_2 -PANI/SFF). Obviously the characteristic diffraction peak for the degummed fibers occurs at $2\theta = 20.4^\circ$, which are corresponding to the β -sheet structures in silk II fibroin of SFF[41]. Compared with SFF, PANI/SFF and TiO_2 -PANI/SFF show fairly large shifts in position of diffraction peak, confirming that the interaction of polyaniline with the peptide linkages in SFF macromolecular chains[40]. According to the previous work [40, 42, 43], hydrogen-bonding interactions between peptide linkages and hydrogen atom on nitrogen atoms of PANI are considered to be main interactions to anchor the PANI on SFFs while the electrostatic attraction may play a secondary role.

According to the above analysis, the mechanism of TiO_2 -PANI/SFF preparation was shown in Fig. 4. Firstly, the titanium dioxide was distributed uniformly in H_2SO_4 solution. When the aniline monomer and ammonium persulfate were added, the aniline monomers were polymerized to form polyaniline on the surfaces of titanium dioxide nanoparticles and silk fibroins, respectively. Then the titanium dioxide nanoparticles coated with polyaniline were gradually agglomerated forming titanium dioxide-polyaniline composite particles with diameter of about 2 μm . Meanwhile, protonated amino groups of polyaniline backbones were combined with the amino acid residues of silk fibroins, forming sheath structures on surfaces of silk fibroins. After that, a large number of polyaniline filaments attached to silk fibroins were further extended making the combination of TiO_2 -PANI composite particles and silk fibroins more stable.

Fig. 4 The mechanism of TiO₂-PANI/SFF microfiber preparation.

3.2. Gas-sensing performance of TiO₂-PANI /SFF micro-sensor

3.2.1. Optimization of TiO₂-PANI /SFF micro-sensor

In order to obtain good gas-sensing performances of TiO₂-PANI/SFF micro-sensors toward volatile amines produced by pork spoilage, ammonia (NH₃) was selected as the simulation model gas to optimize performances of the prepared sensors. In this study, two variables were considered during the optimization, i.e. TiO₂ concentration and polymerization time.

Typical resistance transients of the TiO₂-PANI/SFF micro-sensor toward NH₃ were shown in Fig. 5 (a). When the sensor was exposed in NH₃ gas, dramatic resistance changes could be observed due to the deprotonation of polyaniline [44] as following : $\text{PANI-H}^+ + \text{NH}_3 \rightleftharpoons \text{PANI} + \text{NH}_4^+$. When NH₃ gas was replaced with air, the resistance gradually returned to its original state. Fig. 5 (b) showed transients and changes of the response values of the TiO₂-PANI/SFF micro-sensors prepared respectively with 0.005 g, 0.015 g, 0.025 g and 0.05 g of TiO₂ toward 100 µg/L of NH₃. Clearly, response values of the sensors increased with TiO₂ amount rising from 0.005 g to 0.025 g, which may be ascribed to the synergies of the n-p junction presenting in the backbones between titanium dioxide and polyaniline. However, response values of the sensors decreased obviously with further increasing TiO₂ amount, which could be explained by the fact that excessive TiO₂ amount obstructed the bonding between the target gas and inner composites of the sensors. A conclusion from the Fig. 5 (b) could be drawn that the optimum amount of TiO₂ is 0.025 g for improving ammonia sensing performances.

Fig. 5 (a) Typical resistance transients of the TiO₂-PANI/SFF micro-sensor toward NH₃; (b) Transients and inset (1) changes of the response values of the micro-sensors prepared respectively with 0.005g, 0.015g, 0.025g and 0.05g of TiO₂ to 100 μg/L of NH₃; (c) Transients and inset (2) changes of the response values of the micro-sensors prepared respectively with stirring time of 1h, 2h, 4h and 8h to 100 μg/L of NH₃.

The transients and changes of the response values of the TiO₂-PANI/SFF micro-sensors prepared respectively with stirring time of 1 h, 2 h, 4 h and 8 h toward 100 μg/L of NH₃ were shown in Fig. 5 (c). With stirring time extending from 1 h to 8 h, response values of the sensors increased first and then decreased. When stirring time was 2 h, the resultant TiO₂-PANI/SFF sensor exhibited the best sensing properties toward 100 μg/L of NH₃ compared to the others. The most likely reason is that an entire network of PANI is difficult to form on the surfaces of silk fibroins as polymerization time is short. The response values decreased obviously when stirring time was more than 2 h, which could be explained that the conjugated monomers are apt to form conductive particles in the solution instead of attracting unceasingly on the surface of fibers with polymerization time prolonged [40]. The conductivities of obtained materials were measured to support the view. The results measured were: 3.16*10⁻⁶, 7.37*10⁻², 5.83*10⁻⁴ and 9.21*10⁻⁵ S/cm for 1, 2, 4 and 8 h, respectively. It can be seen that the conductivities of the TiO₂-PANI/SFF composites were the best while the polymerization time was two hours, which support the validity of the conjecture.

3.2.2. Ammonia sensing performance

Fig. 6 (a) showed resistance transients of the TiO₂-PANI/SFF micro-sensor versus ammonia in the concentrations of 5-600 µg/L under the optimum conditions at 25 °C. The prepared micro-sensor showed good response-recovery characteristic. When the sensor was exposed to ammonia, the resistance increased rapidly and eventually reached equilibrium, the response time was about 10 s. When exposed in the air, resistance of the sensor gradually returned to baseline, the recovery time was about 280 s. Fig. 6 (b) showed response values of the sensor with ammonia concentration increasing. The regression equation is $y = -0.0000069x^2 + 0.00999x + 0.00105$ ($R^2 = 0.991$). The summary table about performance of reported PANI based sensors and the comparison between them and our work was included in Table 1. Compared to reported works, the prepared sensor has the advantages of faster response, wider detection range and speedy recovery.

Fig. 6 (a) Resistance transients and (b) response values of the TiO₂-PANI/SFF micro-sensor exposed to NH₃ of different concentration at 25 °C; (c) Resistance transients of the micro-sensor to 100 µg/L of NH₃ for five times; (d) Response values of the micro-sensor to several common reducing gases at 25 °C; (e) Response transients of the same sensor to both ammonia and trimethylamine with the same concentration of 100 µg/L.

3.2.3. Repeatability, stability and selectivity of TiO₂-PANI/SFF micro-sensor

For practical application, reliability of a gas sensor depends largely on the repeatability and stability of itself. Fig. 6 (c) showed resistance transients of the prepared sensor toward 100 µg/L of NH₃ for five times. From the resultant figure, each response curve was basically similar, and the resistance could be restored to initial state after each round of testing. The relative standard deviation of response values for five times was 3.14% indicating great repeatability of the prepared sensor. Subsequently, the stability of same sensor toward 100 µg/L of NH₃ was studied for a month. The results showed response value of the sensor was reduced to 88.1% of its initial value after the 30th day indicating relatively long-term stability.

Excellent selectivity in detection of a target gas with presence of multiple gases is another critical parameter. Several common reducing gases, including ammonia, ethanol, acetone and methanol, were employed for testing response values of the

prepared micro-sensor at room temperature as shown in Fig. 6 (d). The concentration of each tested gas was kept at 100 µg/L. Clearly, the response value to ammonia was 0.82 while the sensor has little response to the other gases indicating high selectivity of the prepared sensor toward ammonia gas.

It is reported that some toxic small molecular components will be produced during storage of pork meat, such as ammonia, hydrogen sulfide, trimethylamine, etc.[53]. Therefore, Trimethylamine, as a contrast to ammonia, was chosen to test performance of the prepared sensor. Fig.6 (e) shows the response transients of the same sensor to both ammonia and trimethylamine with the same concentration of 100 µg/L. Seen from Fig.6 (e), the prepared sensor has response of 0.29 to trimethylamine while the response to ammonia is more than 0.8, indicating that the sensor has a certain response to amines, but is more sensitive to ammonia.

3.3. Application of TiO₂-PANI/SFF micro-sensor in pork freshness evaluation

Fig. 7 (a) showed the changes of TVB-N contents and response values of the prepared micro-sensor to pork samples with prolonged storage time. Seen from the graph, the sensor response values and TVB-N content had no obvious changes in the first three days, and then both of them increased exponentially with further prolonging storage time of pork. The nonlinear fitting equations were $y=0.178*\exp(x/3.823)-0.260$ ($R^2=0.966$) and $y=11.240*\exp(x/3.559)-12.0$ ($R^2=0.967$), respectively. According to Chinese standard GB/T 5009.44, 2003 [33], TVB-N content less than 15 mg/100g was regarded as fresh meat, content in 15-25 mg/100g as the second and more than 25 mg/100g as spoiled meat. Obviously, pork of the first three days was judged as fresh meat, its quality was on the decline in the fourth day, and the meat had been spoiled on the fifth day, which was consistent with response values of the sensor. Furthermore, Dependence of TVB-N for pork samples on the corresponding response values was shown in Fig. 7 (b), it can be found a good linear relationship between them, the regression equation is $y=74.215x+4.696$ ($R^2=0.990$).

Fig. 7 (a) the changes of TVB-N contents and response values of the micro-sensor to the samples with prolonged storage time. (b) Dependence of TVB-N contents for pork samples on the corresponding sensor response values.

Linear discriminant analysis (LDA) was employed to verify the feasibility of the prepared micro-sensor used in the prediction of pork freshness. All the samples data were randomly divided into calibration and prediction dataset in the ratio of 2:1 used for building the discriminant models. The results obtained showed that the prediction accuracy of calibration and prediction set was 90.73% and 86.38%, respectively, which indicated the prepared micro-sensor had potential for pork freshness evaluation.

4. Conclusions

A novel TiO₂-PANI/SFF micro-sensor was proposed for pork freshness evaluation with the characteristics of easy fabrication, low cost, environment friendly and miniaturization. With ammonia as the model gas, the micro-sensor showed good sensing performance with response value of 0.82 and response time as short as 10 s to NH₃ of 100 µg/L. When the micro-sensor was applied to pork freshness evaluation, a well linear relationship ($R^2=0.990$) was found between output response values and TVB-N levels in pork, and the discriminant results of the micro-sensor for pork freshness based on linear discriminant analysis (LDA) showed the prediction accuracy of calibration and prediction set was 90.73% and 86.38%, respectively. The excellent performance of TiO₂-PANI/SFF sensor benefited from the porous and ultra-thin hairy structure. In conclusion, the proposed TiO₂-PANI/SFF micro-sensor holds great promise in the application of pork freshness evaluation.
